- The cationic surfactant and the alkaloidal salts (which also behave as cationic surfactants) on the right side of Table 20-3 constitute the second exception to the Schulze-Hardy rule. Surface-active compounds contain both hydrophilic and hydrophobic moieties within the same molecule. The dual nature of these compounds causes them to accumulate at interfaces. Dodecylammonium and alkaloidal cations are able to displace inorganic monovalent cations from the Stern layer of a negatively charged silver iodide particle. This occurs because they are not only attracted to the particle by electrostatic forces but also by van der Waals forces between their hydrocarbon moieties (i.e., dodecyl chains in the case of the dodecylammonium ions) and the solid particle. Because they are strongly adsorbed from solution onto the particle surface and do not tend to dissociate from it, surface-active cations are very effective in reducing the negative  $\zeta$ -potential of silver iodide particles. Therefore, they have lower *ccv*'s than purely inorganic cations with the same valence.
- Anionic surfactants, like those containing lauryl sulfate ions, also have a tendency to adsorb at solid-liquid interfaces. However, electrostatic repulsion between the negatively charged surface of the silver iodide particles, whose surface layer contains an excess of iodide ions,

**Table 20-3. Coagulation Values for Negative Silver Iodide Sol**

*ccv*, Coagulation value.

(Data from Kruyt HR. *Colloid Science*, vols I and II. Houston: Elsevier, 1949 and 1952 and unpublished data.)

and the surface-active anions usually prevents adsorption from occurring below the CMC. If adsorption does occur, it increases the density of the negative charges in the particle surface, and therefore, raises the *ccv* of the anionic surfactant above the value corresponding to its valence.

The addition of water-miscible solvents such as alcohol, glycerin, propylene glycol, or PEGs to aqueous dispersions lowers the dielectric constant of the medium. This reduces the thickness of the double layer and therefore reduces the range over which electrostatic repulsion is effective, and lowers the size of the potential energy barrier. As a result, the addition of sufficient amounts of such solvents tends to coagulate aqueous dispersions. At lower concentrations, these solvents do not induce coagulation themselves but make the dispersions more sensitive to coagulation by added electrolytes (i.e., they lower the *ccv*).

Progressive addition of salts having counterions of high valence gradually reduces the  $\zeta$  potential of colloidal particles to zero. Eventually, the sign of the  $\zeta$ -potential may be inverted, and its magnitude may then increase in the opposite direction. The  $\psi_0$  and  $\zeta$ -potentials of aqueous sulfamerazine suspensions are negative above their isoelectric points, and those of bismuth subnitrate are positive. However, the addition of  $\text{Al}^{3+}$  to the former and of  $\text{PO}_4^{3-}$  to the latter in large enough amounts inverts the sign of their  $\zeta$ -potentials, while their  $\psi_0$  potentials remain unchanged. Surface-active ions of opposite charge may also produce such charge inversions.

The superposition of the van der Waals attractive energy, with its long-range effectiveness, and the electrostatic repulsive energy with its intermediate-range effectiveness, frequently produces a shallow minimum (designated *S* in Figure 20-7) in the resultant energy-distance curve at interparticle distances *dS*. If this minimum in potential energy is small compared to *kT*, brownian motion prevents aggregation. For large particles, such as those of many pharmaceutical suspensions, and for particles

that are large in one or two dimensions (e.g., rods and plates), this *secondary minimum* may be deep enough to trap them at distances  $dS$  from each other. This requires a depth of several  $kT$  units. Such fairly long-range and weak energies of attraction produce loose aggregates or flocs that can be redispersed by agitation or by reducing the concentration of flocculating electrolytes.<sup>1,2,12,13</sup> This reversible aggregation process involving the secondary minimum is called *flocculation*. By contrast, aggregation in the deep primary minimum  $P$  is called *coagulation* and is irreversible.

### Electrokinetic Phenomena

When a dc electric field is applied to a dispersion, the particles move toward the electrode having a charge opposite to that on their surface. The counterions located inside their hydration shell are dragged along while the counterions in the diffuse double layer outside the plane of slip, in the free or mobile solvent, move toward the other electrode. This phenomenon is called *electrophoresis*. If the charged surface is immobile, as is the case with a packed bed of particles or a tube filled with water, application of an electric field causes the counterions in the free water to move toward the opposite electrode, dragging solvent with them. This flow of liquid is called *electro-osmosis*, and the pressure produced by it is called *electro-osmotic pressure*. Conversely, if the liquid is made to flow past charged surfaces by applying hydrostatic pressure, displacement of the counterions in the free water produces a potential difference between the two ends of the tube or bed called *streaming potential*. These three phenomena depend upon the relative motion of the charged surface and the diffuse double layer outside the plane of slip surrounding the surface. Actually, most of the diffuse double layer lies within the free solvent and can therefore move along the surface.<sup>1,2,14</sup> All three electrokinetic phenomena measure the same zeta potential, which is the potential at the plane of slip.

### MICROELECTROPHORESIS—MEASURING ZETA POTENTIAL

The particles of pharmaceutical suspensions and emulsions, bacteria, erythrocytes and other isolated cells, latex particles, and many contaminant particles in pharmaceutical solutions are visible in a microscope. Therefore, their zeta potentials can be measured by *microelectrophoresis*. A potential difference,  $E$ , applied between two electrodes that are dipped into a dispersion and separated by a distance,  $d$ , produces the potential gradient or field strength,  $E/d$ , expressed as V/cm. The average velocity,  $v$ , of the particles in response to the applied potential difference is determined using the eyepiece micrometer of a microscope and a stopwatch, and used to calculate the zeta potential by the Smoluchowski equation:

$$\zeta = \left( \frac{4\pi\eta}{D} \right) \left( \frac{v}{E/d} \right) = \left( \frac{4\pi\eta}{D} \right) \mu \quad (8)$$

The electrophoretic mobility,  $\mu$ , is equal to  $v/(E/d)$  and is the velocity caused by a potential gradient of 1 V/cm. According to the Smoluchowski equation, particle size and shape do not affect the zeta potential. However, if the particle radius is smaller than or comparable to  $\delta$  (in which case the particles cannot be detected in a microscope), a factor of 6 replaces the 4. The viscosity,  $\eta$ , and the dielectric constant,  $D$ , refer to the aqueous medium within the double layer and cannot be measured directly.<sup>15</sup> By using the values for water at 25°C, expressing the velocity in micrometers/s and the electrophoretic mobility in (micrometers/s)/(volts/cm), and converting into the appropriate units, the Smoluchowski equation is reduced to  $\zeta = 12.9 \mu$  with zeta potential given in millivolts (mV). Whilst the above method can be used, zeta potential is normally measured using systems based on laser scattering methods to measure the electrophoretic mobility of particles and a range of systems are available. When using these techniques it is important to

remember that zeta potential is a function of the particle surface and the dispersant. Given that the zeta potential of a particle depends largely on the ionic nature, ionic strength and pH of the suspending medium, any dilution of samples should take this into consideration and dilutions should be made with solutions of identical composition to the continuous phase of the sample, rather than water.

### CAPILLARY ELECTROPHORESIS

Capillary electrophoresis (CE) is a widely used separation technique best suited for charged, water-soluble molecules having molecular weights ranging from those of amino acids and peptides to nucleic acids. CE has the following advantages: it provides fast and efficient separations, requires only minute amounts of sample, is applicable to a wide range of analytes, and (in contrast to high-pressure liquid chromatography, HPLC) employs aqueous media rather than organic solvents.

Electrophoresis is carried out in horizontal capillaries of fused silica (which is transparent to ultraviolet) with a bore of 20 to 100 micrometers and length of 20 to 100 cm. Both capillary ends are bent downward. Each end is immersed in a vial filled with a buffer solution that contains an electrode assembly. The electrodes are connected to an adjustable high-voltage dc power supply. As the dissolved analytes migrate past a detection window in the capillary, their concentrations are measured by ultraviolet absorption or by (often laser-induced) fluorescence. The silica capillaries are often coated externally with a very thin layer of polyimide to reduce their fragility. This plastic coating is burned off in the window area.

The capillary is filled with buffer solution, the sample is injected at one end, and a constant high potential difference  $E$  is applied, which produces a potential gradient or field strength in the range of 300 to 400 V/cm. If  $E = 20,000$  V and the total capillary length  $d_r = 57$  cm, then  $E/d_r = 350$  V/cm. The velocity of migration,  $v$ , is the capillary length to the detector,  $dL$ , divided by the migration time,  $t$ , of the analyte from the capillary injection end to the detection window. If  $dL = 50$  cm and  $t = 10$  minutes = 600 seconds, then  $v = 50/600 = 0.083$  cm/s. The electrophoretic mobility [ $v/(E/d)$ ] is  $(0.083 \text{ cm/s})/(350 \text{ V/cm}) = 2.4 \times 10^{-4} \text{ cm}^2/\text{V s}$ .

In addition to electrophoresis, electro-osmosis may play an important role in CE. The isoelectric point of hydrated silica is approximately 1.8. The weakly acidic silanol groups become increasingly ionized with increasing pH. Conditioning the capillary with a NaOH solution and then with the buffer ensures that its wall is charged uniformly with partially ionized silanol groups. These negatively charged sites attract cationic counterions from the buffer to form an electric double layer. When an electric potential is applied, the cations in the diffuse part of the double layer beyond the plane of shear (Figure 20-6) migrate toward the negative electrode, entraining water of hydration. Because of the small bore of the capillaries compared to the diffuse double-layer thickness, the electro-osmotic flow (EOF) can be substantial. The EOF moves in a plug profile rather than in the customary parabolic profile of laminar flow. At high pH the EOF is strong, because the silanol groups are extensively ionized. Amphoteric peptides are negatively charged and try to migrate toward the positive electrode or anode. This motion is often overwhelmed by a strong and opposite EOF, which drags them toward the negative electrode or cathode. These analytes move from the injection point in the anode compartment toward the cathode. The order of arrival at the detection window is: cationic analytes (whose electrophoretic migration toward the cathode is superimposed and accelerated by the EOF), non-ionic analytes (which migrate exclusively by EOF), and anionic analytes (whose net migration velocity is that of the EOF minus their electrophoretic migration velocity toward the anode).

At low pH the EOF is small, and the peptides are positively charged. Their migration toward the cathode is then superimposed and accelerated by the EOF in the same direction. The direction of the EOF can be reversed by adding to the buffer a

cationic surfactant, such as cetyltrimethylammonium bromide. It will react and neutralize the silanol groups, and excess surfactant adsorbed on the silica will confer a positive charge to it. The Br<sup>-</sup> counterions cause an EOF toward the anode. The EOF can be suppressed by coating the silica capillaries with a polymer or by using Teflon capillaries.

Unless the heat generated by the electric resistance of the buffer solution (Joule heating) is dissipated, it causes the temperature to increase with time and promotes temperature gradients across the capillary. This interferes with reproducibility and sharpness of the CE separations. The amount of heat generated is directly proportional to the square of the field strength (which is large) and to the conductivity of the buffer solution. While decreasing the voltage, using longer or smaller bore capillaries and/or more dilute buffer solution would reduce the rate of heat generation; it would also increase the separation times.

Short separation times reduce the band broadening due to analyte diffusion, improving the resolution. Therefore, the capillary is cooled with a thermostatted liquid.

A variation of CE is micellar electrokinetic (capillary) chromatography (MEKC). The analytes are solubilized in micelles of an ionic surfactant, such as sodium dodecyl sulfate (SDS), which is added to the buffer solution at a concentration well above its CMC of  $8 \times 10^{-3}$  M. MEKC is suited particularly to separate neutral analytes of limited water solubility, which are extensively partitioned into the micelles, but is also applicable to ionic analytes. Anionic analytes, being well soluble in water, either do not partition into the micelles or form mixed micelles with the anionic surfactant. Cationic analytes often form precipitates with anionic surfactants. Therefore, their separation by MEKC is best carried out with cationic surfactants.

The combination of a nonionic and an ionic surfactant produces mixed micelles. These have lower surface charge densities and larger sizes than the micelles of ionic surfactants, and hence they have lower electrophoretic mobilities. Thus, addition of a nonionic to an ionic surfactant narrows the migration time window, which is the difference between the migration times of the bulk solution in EOF and of the micelles, and often shortens the analysis time.

Analytes with molecular weights of 5000 or higher are not solubilized by micelles. Therefore, while they can be analyzed by CE, they cannot be analyzed by MEKC. Although anionic micelles tend to migrate toward the anode, a strong EOF in neutral or alkaline media will drag them toward the cathode, but with a velocity retarded by their own migration velocity. If a neutral analyte is partly solubilized in micelles and partly dissolved molecularly in the buffer solution, the latter portion has a shorter migration time, because its velocity is that of the EOF.

Capillary gel electrophoresis<sup>16</sup> employs capillaries filled with a gel of cross-linked polyacrylamide, which suppresses EOF. Isotachopheresis and isoelectric focusing, described in previous editions of this text, are other modalities of CE.

## LYOPHILIC DISPERSIONS

Lyophilic dispersions consist either of polymers dissolved in a solvent or of insoluble but extensively solvated particles dispersed in a liquid medium that has a high affinity or attraction for them. The free energy of dissolution or dispersion is  $\Delta G_s = \Delta H_s - T\Delta S_s$ , where  $\Delta H_s$  and  $\Delta S_s$  are the heat or enthalpy change, and the entropy change of dissolution or dispersion, respectively. For dissolution of polymers and dispersion of particulate solids to occur spontaneously,  $\Delta G_s$  must be negative. Because both of these processes are exothermic (i.e., occur with the evolution of heat), their  $\Delta H_s$  is negative. Because the number of available conformations of the polymer chains increases considerably upon dissolution, and the number of positions and orientations of the solid particles increases considerably upon their dispersion in the liquid, their  $\Delta S_s$  is positive (i.e., there is an increase in randomness). The negative enthalpy change and the positive entropy change of dissolution/dispersion both

contribute to making  $\Delta G_s$  negative. Therefore, both types of colloidal systems are formed spontaneously when powders of solid polymers and particulate solids are brought into contact with the liquid dispersion medium. They are thermodynamically stable and reversible (i.e., they are easily reconstituted after the dispersion medium has been removed). The van der Waals energies of attraction between dissolved macromolecules or between dispersed lyophilic solid particles are smaller than  $\Delta G_s$  and are therefore insufficient to cause flocculation or coagulation of the dispersed phase. Furthermore, the solvation layers surrounding dissolved macromolecules and dispersed lyophilic particles form a physical barrier preventing their close approach.

Most liquid dispersed systems of pharmaceutical interest are aqueous. Therefore, most of the lyophilic colloidal systems discussed below consist of hydrophilic solids dissolved or dispersed in water. Most of the products mentioned below are official in the US Pharmacopeial Convention (USP) or National Formulary (NF), where more detailed descriptions can be found; they are also discussed in detail elsewhere in this text. Hydrophilic colloids can be divided into two classes (i.e., soluble and particulate materials). Solutions of water-soluble polymers molecularly dissolved in water can be classified as colloidal dispersions, because the individual molecules are in the colloidal particle size range: the diameter of a randomly coiled polymer chain commonly exceeds 10 nm. Particulate or corpuscular hydrophilic colloidal dispersions are formed by solids that swell and are peptized in water but whose primary particles do not dissolve or break down into individual molecules or ions.

## WATER-SOLUBLE POLYMERS

Most of the hydrophilic colloidal systems used to prepare pharmaceutical dosage forms are molecular solutions of water-soluble, high-molecular-weight polymers. These polymers are either linear or slightly branched but not cross-linked. Water-soluble polymers can be divided into three classes according to their origin:

*Natural polymers* include polysaccharides (acacia, agar, heparin sodium, pectin, sodium alginate, tragacanth, xanthan gum) and polypeptides (casein, gelatin, protamine sulfate). Of these, agar and gelatin are soluble only in hot water.

*Cellulose derivatives* are produced by chemically modifying cellulose obtained from wood pulp or cotton to produce soluble polymers. Cellulose is an insoluble, linear polymer of glucose units in the ring or pyranose form joined by -1,4 glucosidic linkages. Each glucose unit (except for the two at the terminal chain ends) contains a primary hydroxyl group on C6 (the carbon atom at position 6) and two secondary hydroxyls on C2 and C3. Chemical modification of cellulose involves substitutions at these hydroxyl groups, with the primary hydroxyl group being the most reactive. The extent of such reactions is expressed as *degree of substitution* (DS), the number of substituted hydroxyl groups per glucose residue. The highest value for DS is 3. Fractional values are most common, because the DS is averaged over a multitude of glucose residues. A DS value of 0.6 indicates that some glucose repeat units are not substituted while others substituted once or even twice.

Some soluble cellulose derivatives are listed below. Their DS values correspond to their respective pharmaceutical grades; the groups shown replace the hydrogen atoms of the cellulosic hydroxyls. Official derivatives include *methylcellulose* (DS = 1.65–1.93); (-O-CH<sub>3</sub>) and *sodium carboxymethylcellulose* (DS = 0.60–1.00); (-O-CH<sub>2</sub>COO-Na<sup>+</sup>). *Hydroxyethylcellulose* (DS ≈ 1.0); (-O-(CH<sub>2</sub>CH<sub>2</sub>O)<sub>n</sub>H) and *hydroxypropylcellulose* (DS ≈ 2.5);

are manufactured by adding ethylene oxide and propylene oxide, respectively, to alkali-treated cellulose. The value of *n* is about 2.0 for hydroxyethylcellulose and not much greater than

1.0 for hydroxypropylcellulose. *Hydroxypropylmethylcellulose* is prepared by reacting alkali-treated cellulose first with methyl chloride to introduce methoxy groups (DS = 1.1–1.8) and then with propylene oxide to introduce propylene glycol ether groups (DS = 0.1–0.3). In general, the introduction of hydroxypropyl groups into cellulose slightly reduces its water solubility while promoting its solubility in polar organic solvents such as short-chain alcohols, glycols, and some ethers.

The molecular weight of native cellulose is so high that soluble derivatives of approximately the same degree of polymerization would dissolve too slowly and their solutions would be excessively viscous even at concentrations of  $\leq 1$  percent. To overcome these difficulties, controlled degradation is used to break the cellulose chains into shorter segments. Commercial-grade cellulose derivatives, such as sodium carboxymethylcellulose, come in various molecular weights or viscosity grades as well as with various degrees of substitution.

Official cellulose derivatives that are insoluble in water but soluble in some organic solvents include *ethylcellulose* (DS = 2.2–2.7); ( $-\text{OC}_2\text{H}_5$ ); *cellulose acetate phthalate* (DS = 1.70 for acetyl and 0.77 for phthalyl); *hydroxypropylmethylcellulose phthalate*; and *polyvinyl acetate phthalate*. *Collodion*, a 4.0 percent (w/v) solution of pyroxylin (cellulose dinitrate) in a mixture of 75 percent (v/v) ether and 25 percent (v/v) ethyl alcohol, is also a cellulose-based, lyophilic colloidal system.

*Water-soluble synthetic polymers* consist mostly of high-molecular-weight PEGs, or *polyethylene oxides*, and vinyl derivatives such as *polyvinyl alcohol*, *povidone* or polyvinylpyrrolidone, and *carbomer* (Carbopol; Lubrizol Corp.), a copolymer of acrylic acid.

A second classification of hydrophilic polymers is based upon their charge. *Nonionic* or uncharged polymers include methylcellulose, hydroxyethyl and hydroxypropyl cellulose, ethylcellulose, pyroxylin, polyethylene oxide, polyvinyl alcohol, and povidone. *Anionic* or negatively charged *polyelectrolytes* include carboxylated polymers (e.g., acacia, alginate, pectin, tragacanth, xanthan gum, and carbomer) at pH values that result in the ionization of their carboxyl groups. Sodium alginate, sodium carboxymethylcellulose, and polypeptides (e.g., sodium caseinate) at pH values above their isoelectric points are also anionic. Sulfuric acid is a stronger acidic group that exists as a monoester in agar and heparin and as a monoamide in heparin. *Cationic* or positively charged *polyelectrolytes* are rare. Examples include chitin, a polysaccharide found in the shells of beetles and crustaceans, and polypeptides at pH values below their isoelectric points. Protamines such as protamine sulfate are strongly basic due to their high arginine content and have isoelectric points around pH 12.

### PARTICULATE HYDROPHILIC DISPERSIONS

The dispersed phase of these sols consists of solids that swell in water and spontaneously break up into particles having colloidal dimensions. The dispersed particles have high specific surface areas and are extensively hydrated. *Bentonite NF* is a hydrated aluminum silicate that crystallizes in a layer structure with individual lamellas 0.94 nm thick. Their top and bottom surfaces consist of sheets of oxygen ions from silica and an occasional sodium ion neutralizing a silicate ion-exchange site. The clay particles contain stacks of these lamellae. Water penetrates between these lamellae to hydrate the oxygen ions and causes extensive swelling. The bentonite particles in bentonite magma consist of single lamellae or packets of a few lamellae with intercalated water. Their specific surface area amounts to several hundred square meters per gram. *Kaolin USP* is also a hydrated aluminum silicate having a layer structure. In kaolin, hydrated alumina lattice layers alternate with silica layers. Therefore, one of the two external surfaces of a kaolin plate consists of a sheet of oxygen ions from silica, whereas the other is a sheet of hydroxide ions from hydrated alumina. Both surfaces are well hydrated, but water cannot penetrate into the individual lattice layers. Therefore, the particles do not swell in

water or exfoliate into thin plates. As a result, kaolin plates dispersed in water are much thicker than those of bentonite, about 0.04 to 0.2 micrometers. *Magnesium Aluminum Silicate NF*, also known as Veegum® (R.T. Vanderbilt Co.), is a clay similar to bentonite but contains magnesium; it is white, whereas bentonite is gray. *Colloidal Activated Attapulgite USP* also consists of magnesium aluminum silicate. However, instead of having a lamellar habit like the other three clays, it crystallizes in the form of long needles approximately 20 nm wide.

The following additional hydrophilic particles can also produce colloidal dispersions in water. *Titanium dioxide* is a white pigment with excellent covering power. *Colloidal silicon dioxide* consists of roughly spherical particles that are covered with siloxane and silanol groups. *Microcrystalline cellulose* is hydrophilic because of the hydroxyl and ether groups on the surface of the cellulose crystals. Gelatinous precipitates of hydrophilic compounds such as *aluminum hydroxide gel*, *aluminum phosphate gel*, and *magnesium hydroxide* consist of coarse flocs produced by agglomeration of the colloidal particles formed in the initial stages of precipitation.

### LYOPHOBIC DISPERSIONS

Lyophobic dispersions are intrinsically unstable and irreversible because of the lack of attraction between the dispersed and continuous phases. Unlike lyophilic dispersions, their large surface free energy is not lowered by solvation, their dispersion process does not take place spontaneously, and they are not easily reconstituted. For lyophobic dispersions,  $\Delta G_s$  is positive because of a positive (endothermic)  $\Delta H_s$  term, which makes the reverse process (agglomeration) the spontaneous one. Aqueous dispersions of hydrophobic solids or liquids can be prepared by physical means that supply an appropriate amount of energy to the system. However, they are unstable. The van der Waals attractive forces between the particles are stronger than the solvation forces that promote particle dispersal, and therefore, the particles tend to aggregate. Most of the discussion of lyophobic dispersions deals with hydrosols consisting of hydrophobic solids or liquids dispersed in an aqueous medium, because water is the most widely used vehicle. Such hydrosols consist of aqueous dispersions of insoluble organic and inorganic compounds, which usually have low degrees of hydration. Organic compounds that are preponderantly hydrocarbon in nature and possess few hydrophilic or polar groups are hydrophobic, and therefore, insoluble in water. Like all lyophobic dispersions, hydrophobic dispersions are intrinsically unstable. In their most thermodynamically stable state, the dispersed phase has coalesced into large crystals or drops, so that the specific surface area and surface free energy are minimized. Therefore, mechanical, chemical, or electrical energy must be supplied to break up the dispersed phase into smaller particles and overcome the resulting increase in surface free energy that occurs from the parallel increase in specific surface area.

Hydrophobic dispersions can be prepared by either dispersion methods (the reduction of coarse particles to colloidal dimensions through comminution or peptization) or condensation methods (the aggregation of small molecules or ions into particles having colloidal dimensions). Dispersion methods tend to produce sols that have wide particle size distributions. Conversely, condensation methods may produce essentially monodisperse sols provided specialized techniques are employed.

### PREPARATION BY DISPERSION METHODS

The first method, *mechanical disintegration* of solids and liquids into smaller particles before or during dispersion within a fluid vehicle, is frequently carried out by the input of mechanical energy via shear or attrition. Equipment such as colloid and ball mills, micronizers and (for emulsions) homogenizers is described in Chapter 23 ("Powders"). Dry grinding with inert, water-soluble diluting agents also produces colloidal dispersions. For example, sulfur hydrosols may be prepared by

tritulating the powder with urea or lactose followed by shaking with water. Ultrasonic generators provide exceptionally high concentrations of energy. However, the successful dispersion of solids by means of ultrasonic waves can only be achieved with comparatively soft materials such as many organic compounds, sulfur, talcum, and graphite. In cases where fine emulsions are mandatory, such as soybean oil-in-water (O/W) emulsions for intravenous feeding, emulsification by ultrasound waves is the method of choice.

*Peptization* is a second dispersion method used to prepare colloidal dispersions. The term is defined as the breaking up of aggregates (or secondary particles) into smaller aggregates (or primary particles) that are within the colloidal size range. Primary particles are those particles that are not formed from smaller ones. Peptization is synonymous with *deflocculation*. It can be brought about by the removal of flocculating agents, usually electrolytes, or by the addition of deflocculating or peptizing agents, usually surfactants, water-soluble polymers, or ions that adsorb onto the particle surface.<sup>2</sup> When powdered activated charcoal is added to water with stirring, the aggregated grains cannot be completely broken up and the resulting suspension is gray and translucent. The addition of  $\leq 0.1$  percent sodium lauryl sulfate or octoxynol 9 deflocculates the grains into finely dispersed particles and results in a deep-black and opaque dispersion. Ferric or aluminum hydroxide that has been freshly precipitated with ammonia can be peptized with small amounts of acids that reduce the pH below the isoelectric points of the hydroxides. Even washing the gelatinous precipitate of  $\text{Al}(\text{OH})_3$  with water tends to peptize it. Therefore, in quantitative analyses, the precipitate is instead washed with dilute solutions of ammonium salts that act as flocculating agents.

## PREPARATION BY CONDENSATION METHODS

Sulfur is insoluble in water but somewhat soluble in alcohol. When an alcoholic solution of sulfur is mixed with water, a bluish white colloidal dispersion results. In the absence of added stabilizing agents, the particles tend to agglomerate and precipitate upon standing. This technique of first dissolving a material in a water-miscible solvent such as alcohol or acetone and then producing a hydrosol by precipitation with water is applicable to many organic compounds. It has been used to prepare hydrosols of stearic acid, natural resins like mastic, and the so-called pseudolatexes. Another less common physical condensation method is to introduce a current of sulfur vapor into water, which produces colloidal particles. Alternatively, the very fine powder produced by condensing sulfur vapor onto cold solid surfaces (sublimed sulfur or flowers of sulfur) can be dispersed in water by the addition of a suitable surfactant to produce a hydrosol.

Organic compounds that are weak bases, such as the alkaloids, are usually much more soluble at lower pH values, where they are ionized, than at higher pH values, where they exist as the free base. Therefore, increasing the pH of their aqueous solutions above their  $pK_a$  may cause precipitation of the free base. Conversely, organic compounds that are weak acids, such as the barbiturates, are usually much more soluble at higher pH values, where they are ionized, than at lower pH values, where they exist as the free acid form. Therefore, lowering the pH of their aqueous solutions well below their  $pK_a$  usually causes precipitation of the free acid. Depending upon the supersaturation (defined below) of the nonionized bases or acids and the presence of stabilizing agents, the resultant dispersions may be within the colloidal range.

Chemical condensation methods include the reaction between hydrogen sulfide and sulfur dioxide (e.g., by bubbling  $\text{H}_2\text{S}$  into an aqueous  $\text{SO}_2$  solution):

The same reaction occurs when aqueous solutions containing sodium sulfide and sulfite are acidified with an excess of sulfuric or hydrochloric acid. Another reaction is the decomposition of

sodium thiosulfate by sulfuric acid, using either very dilute or very concentrated solutions to obtain colloidally dispersed sulfur:

Both reactions also produce pentathionic acid ( $\text{H}_2\text{S}_5\text{O}_6$ ) as a by-product. The preferential adsorption of the pentathionate anion onto the surface of the sulfur particles confers a negative electric charge to the particles, thereby stabilizing the sol.<sup>2,5</sup> When powdered sulfur is boiled with a slurry of lime, it dissolves with the formation of calcium pentasulfide and thiosulfate. Subsequent acidification produces the colloidal "milk of sulfur," which upon washing and drying yields Precipitated Sulfur USP.

Sols of ferric, aluminum, chromic, stannic, and titanium hydroxides or hydrous oxides are produced by the hydrolysis of the corresponding chlorides or nitrates:

Hydrolysis is promoted by boiling the solution and/or adding a base to neutralize the formed acid.

Double decompositions that produce insoluble salts can also lead to colloidal dispersions. An example is silver chloride:

In addition, the reduction of gold, silver, copper, mercury, platinum, rhodium, and palladium salts with formaldehyde, hydrazine, hydroxylamine, hydroquinone, or stannous chloride forms hydrosols of the metals, which are strongly colored (e.g., red or blue).<sup>2</sup>

## Kinetics of Particle Formation

When the solubility of a compound in water is exceeded, its solution becomes supersaturated and the compound may precipitate or crystallize. The rate of precipitation, the resulting particle size (whether colloidal or coarse), and the particle size distribution (which can be narrow for mono- or homodispersed particles or broad for poly- or heterodispersed particles) depends upon two successive and largely independent processes. These are *nucleation* and *crystallization* (i.e., growth of nuclei). When a solution of a salt or sucrose is supercooled or when a chemical reaction produces a salt in a concentration exceeding its solubility product, the separation of excess solid from the supersaturated solution is far from instantaneous. Clusters of ions or molecules called nuclei must exceed a critical size before they become stable and capable of growing into colloidal-size crystals. These embryonic particles have much more surface for a given weight of material than larger and more stable crystals. Therefore, they have a higher surface free energy and greater solubility.

The occurrence of *nucleation* depends upon the *relative supersaturation*. If  $C$  is the actual concentration of the solute before crystallization and  $C_s$  is its solubility limit, then  $C - C_s$  is the supersaturation and  $(C - C_s)/C_s$  is the relative supersaturation. Russian chemist Peter von Weymarn recognized early in the twentieth century that the rate or velocity of nucleation (number of nuclei formed per liter per second) is proportional to the relative supersaturation. Nucleation seldom occurs at relative supersaturations below 3. However, this statement refers to homogeneous nucleation, where the nuclei have the same chemical composition as the crystallizing phase. If the solution contains solid impurities, such as dust particles in suspension, these may act as nuclei or centers of crystallization (heterogeneous nucleation).

Once nuclei have formed, *crystallization* begins. Nuclei grow by the aggregation of ions or molecules from solution. Crystallization continues until the supersaturation is relieved (i.e., until  $C = C_s$ ) and may result in the formation of either colloidal or coarse particles. The rate of crystallization or growth of nuclei is proportional to the supersaturation:

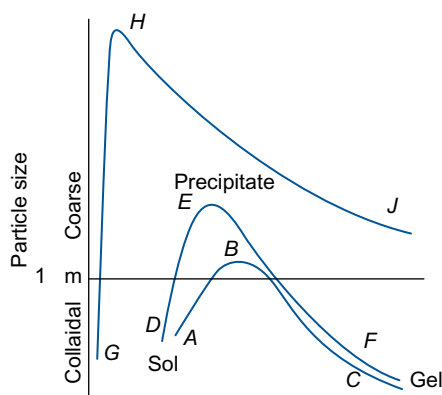

$$\frac{dm}{dt} = \frac{A_{sp}D}{\delta}(C - C_s) \quad (9)$$

This equation is similar to the Noyes-Whitney equation that governs particle dissolution, except that  $C < C_s$  for the latter process, making  $dm/dt$  negative. In both equations,  $m$  is the mass of material crystallizing out in time  $t$ ,  $D$  is the diffusion coefficient of the solute molecules or ions,  $\delta$  is the length of the diffusion path or the thickness of the liquid layer adhering to the growing particles, and  $A_{sp}$  is their specific surface area. The presence of dissolved impurities may affect the rate of crystallization and even change the crystal habit, provided that these impurities are surface-active and become adsorbed onto the nuclei or growing crystals. For instance, 0.005 percent polysorbate 80 or octoxynol 9 significantly retards the growth of methylprednisolone crystals in aqueous media.

Von Weimarn found that the particle size of the crystals depends strongly upon the concentration of the precipitating substance. At very low concentrations and slight relative supersaturation, diffusion is quite slow because the concentration gradient that drives the process is very small. Sufficient nuclei will usually form to relieve the slight supersaturation. However, crystal growth is limited by the small amount of excess dissolved material available to each particle and, therefore, the particles cannot grow beyond colloidal dimensions. This condition is represented by points A, D, and G of the schematic plot of von Weimarn (Figure 20-8)<sup>17</sup>. At intermediate concentrations the extent of nucleation is somewhat greater and much more material is available for crystal growth. Therefore, coarse crystals form rather than colloidal particles. This condition is represented by points B, E, and H in Figure 20-8. At high concentrations, nuclei appear so quickly and in such large numbers that supersaturation is relieved before any appreciable diffusion can occur. The high viscosity of the medium also slows down the diffusion of excess dissolved ions or molecules, retarding crystal growth without substantially affecting the rate of nucleation. Therefore, a large number of very small particles results that, because of their proximity, tend to link and produce a translucent gel. This condition is represented by points C and F in Figure 20-8. Upon subsequent dilution with water, such gels usually yield colloidal dispersions. Thus, colloidal systems are usually produced at very low and high supersaturations.

Low solubility is a necessary condition for producing colloidal dispersions. If the solubility of the precipitate is increased, for instance by heating the dispersion, a new family of curves will result similar in shape to those shown in Figure 20-7 but displaced to the right (toward higher concentrations) and

**Figure 20-8.** Effect of aging and concentration of the precipitating material upon particle size. Curves ABC, DEF, and GHI correspond to increasing aging. Both axes are on a logarithmic scale. (Data from von Weimarn PP. In: Alexander J, ed. *Colloid Chemistry*, vol I. New York: Chemical Catalog Co. (Reinhold), 1926.

upward (toward larger particle sizes).<sup>1,5,18,19</sup> An additional phenomenon illustrated in Figure 20-7 is that aging increases particle size. Curves ABC, DEF, and GHI correspond to increasing time periods after mixing the reagents, namely, 10–30 minutes, several hours, and weeks to years, respectively. This gradual increase in the particle size of crystals in their mother liquor is a recrystallization process called *Ostwald ripening*. Very small particles have a higher solubility than large particles of the same substance due to their greater specific surface area and higher surface free energy. In a saturated solution containing precipitated particles with a wide range of particle sizes, the very smallest particles dissolve spontaneously and deposit onto the larger particles. The growth of the larger crystals at the expense of the very small ones occurs because this process lowers the free energy of the dispersion. Adding small amounts of surface-active compounds that adsorb at the particle surface slows down the process.

Increasing the solubility of the precipitate accelerates the spontaneous coarsening of colloidal dispersions upon aging. For instance, barium sulfate precipitated by mixing concentrated solutions of sodium sulfate and barium chloride is largely in the colloidal size range and passes through filter paper. The colloidal particles gradually grow in size by Ostwald ripening, forming large crystals that can be removed quantitatively by filtration. Heating the aqueous dispersion speeds recrystallization by increasing the solubility of barium sulfate in water.

Conversely, the addition of ethyl alcohol lowers the solubility of barium sulfate and slows Ostwald ripening, which allows the dispersion to remain in the colloidal state for years.

The relationship between particle size and solubility is given by the Ostwald-Freundlich or Kelvin equation, which, for non-ionic solutes, is<sup>2,5</sup>:

$$\ln \frac{S}{S_\infty} = \frac{2\gamma M}{rdRT} \quad (10)$$

where  $S$  and  $S_\infty$  are the solubility of colloidal particles having a radius  $r$  and the solubility of large, flat particles ( $r = \infty$ ), respectively. For electrolytes, the mean ionic activity is included. The solid-solvent interfacial free energy,  $\gamma$ , can only be determined indirectly (e.g., by means of this equation). The ratio of the molecular weight of the solute to its density ( $M/d$ ) equals its molar volume. Assuming  $M = 500$  g/mol,  $d = 1.00$  g/mL, and  $\gamma = 30$  erg/cm<sup>2</sup>, and using the values of  $8.314 \times 10^7$  erg/mol-K for the gas constant  $R$  and 298 K for the absolute temperature  $T$ , dispersed particles having radii of  $1 \times 10^{-6}$  cm (10 nm),  $1 \times 10^{-5}$  cm (0.1 micrometer),  $1 \times 10^{-4}$  cm (1 micrometer), and  $1 \times 10^{-3}$  cm (10 micrometers) correspond to  $S/S_\infty$  ratios of 3.36, 1.13, 1.012, and 1.0012, respectively. Therefore, while particles having sizes at the lower end of the colloidal range are appreciably more soluble than coarser particles of the same compound, the solubility of finely ground drug or excipient powders (particle radii typically in the range of 1 to 10 micrometers) is only increased by 1 percent or less.

Condensation methods generally produce polydisperse sols, because nucleation continues while established nuclei grow. However, monodispersed colloidal sols can be prepared by precipitation using a technique that involves the formation of all nuclei in a single, brief burst. A sufficiently brief period of homogeneous nucleation relieves the supersaturation to such an extent that no new nuclei can subsequently form. Therefore, the nuclei created during the initial burst grow uniformly as the remaining excess of precipitating material diffuses and deposits onto them. The supersaturation never again reaches sufficiently high values for forming new nuclei, because it is relieved by the continuous growth of the existing nuclei.<sup>2,5,18,19</sup>

The controlled hydrolysis of salts of divalent and trivalent cations in aqueous solutions at elevated temperatures has been used to produce colloidal dispersions of metal (hydrous) oxides having uniform sizes in a variety of well-defined shapes (e.g., spheres or laths or cubes or disks). Complexation of the

cations, concentration, and temperature control the rate of hydrolysis, and therefore, the chemical composition, crystallinity, shape, and size of the dispersed phase.<sup>18,20</sup>

### STABILIZATION OF COLLOIDAL SYSTEMS

It should be reiterated that hydrosols of hydrophobic substances are intrinsically unstable. While mechanical disintegration may break up the dispersed phase into colloidal particles, flocculation or coagulation causes the dispersed particles to become progressively coarser and fewer, ultimately resulting in the complete separation of a macroscopic phase. The reduction in surface area and in surface free energy accompanying flocculation or coagulation is small, because irregular solid particles are rigid and only touch at a few points upon aggregation. However, these loose initial contacts may grow with time by sintering or recrystallization. Sintering is the “fusion” of primary particles into larger primary particles, which propagates from the initial small areas of contact. This recrystallization process is spontaneous, because it decreases the specific surface area of the dispersed solid and the surface free energy of the dispersion. Sintering is analogous to Ostwald ripening, the recrystallization process that transfers solids from colloidal to coarse particles. Low solubility and the presence of adsorbed surface-active substances retard both processes.

If aqueous dispersions of hydrophobic solids are to resist re-aggregation (i.e., flocculation and coagulation), they must be stabilized during or shortly after the dispersion process. Stabilizing factors include the presence of electrical charges at the particle surface and the presence of adsorbed macromolecules or nonionic surfactants. The presence of positive or negative charges may result from the dissociation of the solid's ionogenic groups or the adsorption of ions such as ionic surfactants. These stabilizing factors do not alter the intrinsic thermodynamic instability of lyophobic dispersions, and therefore,  $\Delta G_s$  remains positive and phase separation or aggregation is still energetically favored over dispersal. However, they establish kinetic barriers that delay the aggregation processes almost indefinitely; the dispersed particles cannot come together close enough for van der Waals attractive forces to produce coagulation.<sup>2</sup>

Stabilization can be provided by adsorbed surfactants. In a flocculated dispersion, groups of several particles are agglomerated into flocs. Frequently, the particles of a floc are in physical contact. When a surfactant is added to a flocculated sol, the dissolved surfactant molecules adsorb onto the surface of the particles. Surfactant molecules also tend to pry apart the flocs by wedging themselves in between the particle contact points. This action frees additional surface area for surfactant adsorption. The breaking up of flocs or secondary particles is defined as deflocculation or peptization. Ophthalmic suspensions should be deflocculated, because the large particle size of flocs causes irritation to the eye. Parenteral suspensions should also be deflocculated to prevent the larger particles from clogging hypodermic syringes, causing tissue irritation, or blocking capillary blood vessels. However, deflocculated suspensions tend to cake (i.e., the sediment formed by gravitational settling is compact and may be hard to redisperse upon shaking). Caking in oral suspensions is prevented by controlled flocculation.

Surfactants tend to accumulate at interfaces because of their amphiphilic nature. This process is an *oriented physical adsorption*. Surfactant molecules arrange themselves at the interface between water and an organic solid or liquid of low polarity in such a way that the hydrocarbon chain is in contact with the surface of the solid particle or sticks inside the oil droplet while the polar head group is oriented toward the water phase. This orientation leaves the polar head group in contact with the water so that it can be hydrated, and removes the surfactant's hydrophobic hydrocarbon chain from the bulk of the water, where it is unwelcome because it interferes with the hydrogen bonding between water molecules. Figure 20-9 shows that at a low surfactant concentration and at low surface coverage, the hydrocarbon chains of the adsorbed surfactant molecules lie

**Figure 20-9.** Schematic representation of the physical adsorption of surfactant molecules at a hydrophobic solid (S)–water (W) interface. Cylindrical portions and spheres represent the hydrocarbon chains and polar head groups of the surfactant molecules, respectively. (A) Low surfactant concentration, low surface coverage. (B) Near critical micelle concentration, surface coverage near saturation.

flat against the solid surface. At higher surfactant concentrations, the surfactant molecules are adsorbed in an upright position to allow for the greatest number of molecules per unit surface area. In this position, the terminal methyl groups of the hydrocarbon tails are in contact with the hydrophobic particle surface and the hydrocarbon tails are in lateral contact with each other. London dispersion forces promote the attraction between both types of adjoining groups.

The adsorption of ionic surfactants increases the charge density and the zeta potential of the dispersed particles. These two parameters are low for water-insoluble organic substances. The increase in electrostatic repulsion between nonpolar particles due to the adsorption of surface-active ions stabilizes the dispersion against coagulation. This “charge stabilization” is described by the DLVO theory.

Most water-soluble nonionic surfactants are polyoxyethylated. Each molecule consists of a hydrophobic hydrocarbon chain combined with a hydrophilic PEG chain – for example,  $\text{CH}_3(\text{CH}_2)_{15}(\text{OCH}_2\text{CH}_2)_{10}\text{OH}$ . Hydration of the ether groups and the terminal hydroxyl group renders the surfactant molecule water-soluble. It adsorbs at the interface between a hydrophobic solid and water, with the hydrocarbon moiety adhering to the solid surface and the PEG moiety protruding into the water, where it is hydrated. Therefore, the particle surface is surrounded by a thin layer of hydrated PEG chains. This hydrophilic shell forms a steric barrier that prevents close contact between particles and inhibits coagulation (“steric stabilization”). Nonionic surfactants also reduce the sensitivity of hydrophobic dispersions toward coagulation by salts (i.e., they increase the coagulation values).<sup>21</sup>

The adsorption of water-soluble polymers provides a second mechanism for the stabilization of hydrophobic dispersions. Water-soluble polymers that have some hydrophobic groups can be surface-active and adsorb at the interface between water and a hydrophobic organic solid, because their hydrophobic groups limit their water solubility and render them amphiphilic. Such polymers also tend to accumulate at the air-water interface and, therefore, lower the surface tension of the aqueous phase. Conversely, polyelectrolytes that have a high concentration of ionic groups are excessively water-soluble, which reduces or eliminates their surface activity and tendency to adsorb

at interfaces (e.g., sodium carboxymethylcellulose). Polyvinyl alcohol is another polymer that does not adsorb extensively at interfaces because of its high concentration of hydroxyl groups, which makes it very water-soluble. Polyvinyl alcohol is manufactured by the hydrolysis of polyvinyl acetate, which is water-insoluble. Hydrolysis of about 85 percent of the acetyl groups produces a copolymer that is both water-soluble and surface-active. Other surface-active polymers include methylcellulose, hydroxypropyl cellulose, high-molecular-weight polyethylene glycols or PEGs (polyethylene oxides), and proteins. The surface activity of proteins is due to the presence of hydrophobic groups at concentrations too low to cause insolubility in water. Proteins are denatured upon adsorption at air-water and solid-water interfaces.

As shown in Figure 20-10A, polymer molecules adsorb onto solid surfaces in the form of loops projecting into the aqueous phase rather than lying flat against the solid substrate. Only a small portion of an adsorbed polymer is in direct contact with the solid surface. However, because of its great chain length, there are enough of these contact points to anchor the adsorbed macromolecule firmly onto the surface. At sufficiently high concentrations, adsorbed polymers may form a layer surrounding the entire dispersed particles. This layer consists of the polymer chains as well as the water of hydration associated with them and any water mechanically trapped inside the chain loops. This sheath becomes an integral part of the particle surface and may prevent coagulation. The mechanisms by which adsorbed nonionic macromolecules prevent the coagulation of hydrophobic sols are the same ones operative in the stabilization of sols by nonionic surfactants. The hydrophilic PEG moieties of the adsorbed surfactant molecules that protrude into the aqueous phase resemble the chain ends of the adsorbed macromolecules rather than their looped segments.

The following protective mechanisms are operative:

1. The layer of adsorbed polymer and enmeshed water surrounding the particles forms a *mechanical or steric barrier* ("steric stabilization") that prevents the particles from approaching each other closely enough for the interparticle attraction of London dispersion forces to produce coagulation. These forces are only effective over interparticle distances smaller than twice the thickness of the adsorbed polymer layer. These layers are somewhat elastic; they may be dented by a collision between two particles but tend to return to their original shape.
2. When two particles approach so closely that their adsorbed polymer layers overlap, the chain loops of the

opposing layers compress and mix with or interpenetrate each other. The freedom of motion of the chain segments in the overlapped region becomes restricted, which produces a negative entropy change. Therefore, any reduction in interparticle distance, which is required for coagulation, results in a positive change in free energy.

As a result, the reverse process of particle separation occurs spontaneously, because disentangling the two opposing adsorbed polymer layers is more energetically favorable. The particles are thus prevented from coagulating by *entropic repulsion* through the mechanism of *entropic stabilization* of the sol. This mechanism predominates when the concentration of polymer in the adsorbed layer is low.

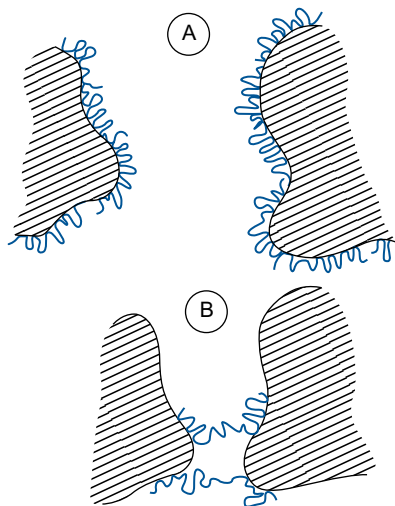

3. As the adsorbed polymer layers on two approaching particles overlap, the polymer concentration in the overlap region causes a local increase in osmotic pressure, which is relieved by an influx of water. This influx of water to dilute the polymer loops pushes the two particles apart, preventing coagulation.
4. If the adsorbed polymer has some ionic groups, stabilization by electrostatic repulsion or charge stabilization, as previously described, is an additional factor that prevents a close interparticle approach and coagulation.
5. The adsorption of water-soluble polymers changes the nature of the surface of hydrophobic particles to hydrophilic, resulting in an increased resistance to coagulation by salts.<sup>22</sup>

The water-soluble polymers whose adsorption stabilizes hydrophobic sols and protects them against coagulation are called *protective colloids*. *Gelatin* and *serum albumin* are the preferred protective colloids for stabilizing parenteral suspensions because of their biocompatibility. These two polymers, as well as casein (milk protein), dextrin (partially hydrolyzed starch), and vegetable gums like acacia and tragacanth, are metabolized in the human body. Cellulose derivatives and most synthetic protective colloids such as *povidone* are not biotransformed. Because of this and their large molecular size, these polymers are not absorbed but excreted intact when administered in an oral dosage form.

## SENSITIZATION

Sensitization is the opposite of protective action (i.e., a decrease in the stability of the hydrophobic sols). At concentrations well below those at which it exerts a protective action, a protective colloid may flocculate a sol in the absence of added salts and/or lower the coagulation values of the sol. In the case of nonionic polymers and of polyelectrolytes having charges of the same sign as the sol particles, flocculation results from the bridging mechanism illustrated in Figure 20-10B. At very low polymer concentrations there are not nearly enough polymer molecules present to completely cover each sol particle. Because the particle surfaces are largely bare, a single macromolecule may be adsorbed onto two particles, thereby bridging the gap between them and pulling them close together. Flocs are formed when several particles become connected through polymer molecules that are adsorbed jointly onto two or possibly even three particles. Such flocculation usually occurs over a narrow range and at very low polymer concentrations. At higher concentrations bridging is unlikely to occur, because there is enough polymer to completely cover all of the particles and the adsorbed polymer stabilizes or peptizes the sol.<sup>5,22</sup>

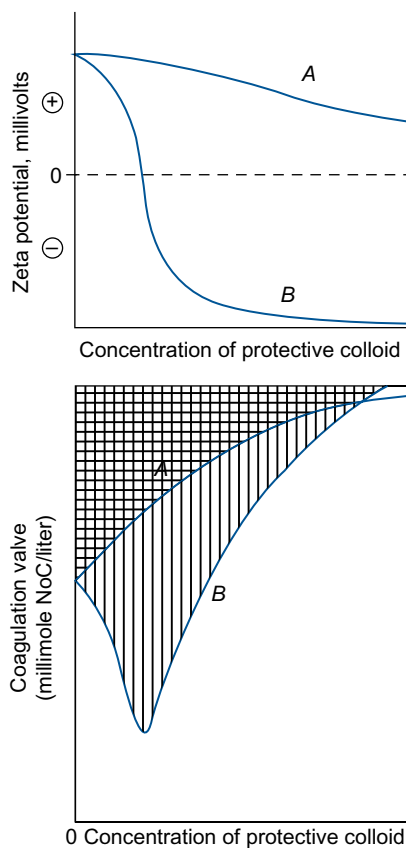

If the polymer contains ionic groups of charge opposite to that of the sol particles, a limited amount of polymer adsorption neutralizes the charge of the particles and reduces their zeta potential to nearly zero. This eliminates stabilization by electrostatic repulsion. In addition, steric stabilization is ineffective because of the low surface coverage of the adsorbed polymer. Therefore, the sol either coagulates by itself or may be coagulated with a very small amount of sodium chloride. At higher

**Figure 20-10.** Protective action (A) and sensitization (B) of adsorbed polymer chains upon sols containing hydrophobic particles.

polymer concentrations, where adsorption is more extensive, the charge on the particles is converted to the sign of the polyelectrolyte, which reactivates charge stabilization and adds steric stabilization. As a result, the coagulation value of the sol increases well above the original value. For example, partly hydrolyzed polyacrylamide containing about 20 percent of ammonium acrylate repeat units is an anionic polyelectrolyte. Addition of this polyacrylamide to aluminum hydroxide sols at a polymer concentration of 1:1,000,000 and a pH of 6–7, where the sols are positively charged and the polyelectrolyte is fully ionized, results in flocculation. At a polymer concentration of 1:10,000 the sols become negatively charged because extensive polymer adsorption introduces an excess of  $\text{-COO}^-$  groups over the  $\text{=Al}^+$  ions on the particle surface. This creation of negatively charged particles introduces electrostatic and steric stabilization, which makes the sols more stable against flocculation by salts than they were before the addition of the polyacrylamide.

Polymer B in Figure 20-11 illustrates this example. The curve in the lower plot indicates sensitization, with the coagulation value for sodium chloride lowered by as much as 60 percent. Zeta potential measurements can be used to distinguish between sensitization by bridging and sensitization by charge neutralization. The charge reversal caused by the adsorption of polymer B is illustrated in the upper plot and indicates that charge neutralization is the cause of sensitization. If polymer B had a zeta potential–polymer concentration plot similar to polymer A, sensitization would be ascribed to bridging. The nonionic polymer A in Figure 20-11 stabilizes the sol at all concentrations. Sensitization is not observed either by bridging or

**Figure 20-11.** Protective action and sensitization. Polymer A exerts protective action at all concentrations, while polymer B sensitizes at low concentrations and stabilizes at high concentrations. Horizontal and vertical hatching indicates region of flocculation for a sol treated with various concentrations of polymers A and B, respectively. Clear region underneath indicates sol is deflocculated. (From Schott H, Martin AN. In Dittert LW, ed., *American Pharmacy*, 7th ed. Philadelphia: JB Lippincott, 1974.)

by charge neutralization. The reason that polymer A slightly lowers the positive zeta potential of the sol is that the increasing amounts of adsorbed polymer chains gradually shift the plane of shear outward and away from the positively charged surface. If polymer A were a cationic polyelectrolyte, the zeta potential–polymer concentration plot would gradually rise with an increase in polymer adsorption rather than drop.

Even water-soluble polymers that are too thoroughly hydrophilic to be adsorbed by hydrophobic sol particles can stabilize such sols. Their thickening action increases the viscosity of the sols. This slows brownian motion and sedimentation, giving the particles less opportunity to come in contact with each other and, therefore, decreasing flocculation.

## ASSOCIATION COLLOIDS

Association colloids are formed by self-assembling enough small molecules to produce aggregates in the colloidal size range. This group of colloids includes surfactant micelles, microemulsions, and liposomes.

### FORMATION OF SURFACTANT MICELLES

The dual or amphiphilic nature of surfactants or surface-active agents was discussed previously. Water attracts their polar head groups but repels their hydrocarbon tails. Consequently, surfactants tend to concentrate and adsorb at air-water, oil-water, and solid-water interfaces. The surface tension of aqueous surfactant solutions decreases with increasing surfactant concentration up to a point, beyond which it remains nearly constant (Figure 20-12). Curves A and B in Figure 20-12 illustrate the surface tension (against air) and the interfacial tension (against oil) of an aqueous surfactant solution as a function of surfactant concentration. Surface-active impurities may cause a minimum in the surface tension (shown as a dotted curve) rather than a mere leveling off. Abrupt changes occur not only to the surface and interfacial properties but also to the surfactant solution's bulk properties such as equivalent conductivity (curve D),

**Figure 20-12.** Effect of surfactant concentration and micelle formation on various properties of the aqueous solution of an ionic surfactant. Curve A, Surface tension; curve B, interfacial tension; curve C, osmotic pressure; curve D, equivalent conductivity; curve E, solubility of a compound with very low solubility in pure water. (From Schott H, Martin AN. In Dittert LW, ed. *American Pharmacy*, 7th edn. Philadelphia: JB Lippincott, 1974.)

co-ion and counterion activities in the case of ionic surfactants, colligative properties like osmotic pressure (curve *C*), turbidity (but the increase is far too weak to be visible to the naked eye), refractive index, ultraviolet and nuclear magnetic resonance (NMR) spectra, partial molar volume, relative viscosity, and the diffusion coefficients and solubility of water-insoluble, oil-soluble compounds (curve *E*). All of these changes occur over a very narrow concentration range, which is shown as a crosshatched band and is referred to as the *critical micelle concentration* (CMC).

As the surfactant concentration in a liquid is increased, the amount of the surfactant adsorbed at the liquid-air and liquid-container interfaces increases and these interfaces become increasingly crowded. When the concentration is increased further, the surfactant molecules will continue to adsorb at these interfaces until tightly packed monolayers are formed and there is no longer any room for further surfactant adsorption. At this point, the surface and interfacial tensions reach their constant values,<sup>23</sup> and it would seem that the bulk solubility limit of the surfactant has been reached. However, if more surfactant is added to the solution, the excess surfactant molecules will begin to associate into small aggregates called *micelles* (at the CMC), while the concentration of nonassociated surfactant molecules remains nearly constant. Diluting the surfactant solution to below the CMC causes the micelles to disperse or break up into single or nonassociated surfactant molecules.

Micelles are not static aggregates; they dissociate, regroup, and reassociate rapidly. The half-life of ionic surfactant micelles in the absence of additives is a small fraction of a second. Furthermore, there is a dynamic equilibrium (i.e., an incessant exchange) between single surfactant molecules in solution, surfactant molecules adsorbed in monolayers at the interfaces, and surfactant molecules associated as micelles.

The shape of micelles in dilute aqueous surfactant solutions is approximately spherical (Figure 20-13A). The polar head groups of the surfactant molecules are arranged in an outer spherical shell, while their hydrocarbon chains are oriented toward the center where they form a spherical core. These hydrocarbon chains are randomly coiled and entangled. The micellar interior has a nonpolar, liquid-like character resembling a liquid normal paraffin such as dodecane. In nonionic surfactant micelles, the polyoxyethylene moieties are oriented outward and permeated by water, while the hydrocarbon moieties form an "oil droplet" core similar to ionic micelles (Figure 20-13B): this arrangement is energetically favorable. The hydrophilic head groups, located externally, are in contact with water and remain extensively hydrated. The hydrocarbon moieties are removed from the aqueous medium and partly shielded from contact with water by the polar head groups. Therefore, they no longer interfere with hydrogen bonding among the water molecules. This interference is the reason why surfactant molecules are pushed out of aqueous media toward interfaces. The hydrocarbon tails of the surfactant molecules, located in the micellar interior, attract one another by weak dispersion forces.<sup>21,24-26</sup>

Representative CMC values and aggregation numbers (number of surfactant molecules per micelle) are listed in Table 20-4.<sup>26,27</sup> Ionic surfactants have higher CMC values than nonionic surfactants, because electrostatic repulsion of the charged head groups makes micellization more difficult. The addition of simple salts reduces these repulsive forces and therefore lowers the CMC values of ionic surfactants. Within any homologous surfactant series, the CMC decreases regularly with increasing hydrocarbon chain length and therefore with increasing surface activity of the surfactant. As is seen in Table 20-4, each additional methylene group decreases the CMC by approximately one-half. This is a consequence of Traube's rule, which states that, 'in dilute aqueous solutions of surfactants belonging to an one homologous series, the molar concentrations required to produce equal lowering of the surface tension of water decreases threefold for each additional CH<sub>2</sub> group in the hydrocarbon chain of the solute'.

With nonionic surfactants, the polyoxyethylene content of the surfactant also influences their CMC (Table 20-4). As the percentage of polyoxyethylene increases, the CMC of the nonionic surfactant increases. Simply, this can be remembered by considering that the surfactant becomes more soluble with increasing polyoxyethylene content. Therefore there is less drive for the surfactants to form micelles and thus micelles form at a higher concentration (a higher CMC). Temperature can also influence the CMC of nonionic surfactants, with the CMC increasing as the temperature decreases. However the changes in CMC are quite small (compare Polyoxyl 12 dodecyl ether at 20°C vs 55°C; Table 20-4).

The micelles of the surfactants listed in Table 20-4 are either spherical or ellipsoidal. They are rather small, because their sizes were determined in relatively dilute solutions (containing only a few percent of surfactant) and mostly in pure water at room temperature. Their diameters are between 2 and 8 nm, which places them at the lower end of the colloidal size range. For this reason, surfactants are sometimes called *association colloids*. Adding salts increases the size of ionic micelles. Raising the temperature increases the size of nonionic micelles, especially if the temperatures are within 20°C of their respective cloud points. These factors reduce the water solubility of ionic and nonionic surfactants, thereby rendering them more surface-active.

As micelles become larger, they also become more asymmetric. Their shape changes from spherical or ellipsoidal to cylindrical and eventually to lamellar. In cylindrical micelles, the polar head groups form the periphery and the hydrocarbon tails fill the interior of the cylinders (Figure 20-13C). In lamellar micelles the surfactant molecules are arranged in parallel bimolecular sheets with a tail-to-tail orientation (i.e., the hydrocarbon tails form the inner layer). Water is stratified between the sheets, thereby hydrating the external polar head groups (Figure 20-13D). In both types of micelles the hydrocarbon tails are randomly coiled and in a liquid-like state.<sup>4</sup> In concentrated aqueous solutions containing 20% or more of surfactant, cylindrical micelles often line up parallel to each other and arrange themselves in hexagonal arrays. Likewise, lamellar micelles are often packed parallel and equidistant from each other with the intervening water layers having a uniform thickness. These ordered solutions are liquid crystals or mesophases; they are birefringent and very viscous. Even though they are liquids, they have some of the properties of crystalline solids.<sup>2,21,25,26</sup>

Oil-soluble surfactants (e.g., heavy-metal soaps, docusate sodium, and nonionic surfactants with hydrophilic-lipophilic balance values <7) form aggregates when dissolved in organic liquids having low polarity such as hydrocarbons and chlorinated hydrocarbons. These micelles are inverted or turned inside out; their hydrocarbon tails are oriented outward into the oil phase, while their polar head groups are in the center of the micelle, where water can be solubilized (Figure 20-13E). Because the bulky head groups are in the center, the aggregation numbers for *reverse micelles* are small, usually between 3 and 20.<sup>25,28</sup>

## MICROEMULSIONS

Microemulsions are liquid dispersions of water and oil that are made homogeneous, transparent, and stable by the addition of relatively large amounts of a surfactant and a co-surfactant. *Oil* is defined as any liquid having low polarity and low miscibility with water (e.g., toluene, cyclohexane, and mineral or vegetable oils). Microemulsions have intermediate properties between micelles containing solubilized oils and emulsions. Emulsions are lyophobic, unstable, and their preparation requires the input of considerable amounts of mechanical energy, which may be supplied by colloid mills, homogenizers, or ultrasonic generators. Conversely, microemulsions are on the borderline between lyophobic and lyophilic colloids. As microemulsions are thermodynamically stable, they generally form spontaneously when oil, water, surfactants, and co-surfactants are mixed together.

**Figure 20-13.** Different types of micelles. (A) Spherical micelle of an anionic surfactant; (B) spherical micelle of a nonionic surfactant; (C) cylindrical micelle of an ionic surfactant; (D) lamellar micelle of an ionic surfactant; (E) reverse micelle of an anionic surfactant in oil. (From Shinoda K, Nakagawa T, Tamamushi B-I, Isemura T. *Colloidal Surfactants*. New York: Academic Press, 1963.)

Both emulsions and microemulsions may contain high volume fractions of the internal phase. For instance, some O/W systems contain 75 percent (v/v) of oil dispersed in 25 percent water, although lower volume fractions of the internal phase are more common.

Microemulsion droplets have a mean diameter range of approximately 6 to 100 nm and a narrow droplet size distribution. Because the droplet diameters are less than one-fourth of the wavelength of light (420 nm for violet and 660 nm for red light), microemulsions scatter little light. Therefore, they are transparent or at least translucent. By contrast, emulsions have broad droplet size distributions and are generally opaque, because most of their droplets have diameters greater than the wavelength of light and most oils have higher refractive indices than water.

Emulsions contain three components, namely, oil, water, and surfactant; in comparison, microemulsions generally require a fourth component, a *co-surfactant*. Commonly used co-surfactants include linear alcohols of medium chain length that are sparingly miscible with water. The combination of surfactant and co-surfactant promotes the generation of extensive interfaces through the spontaneous dispersion of oil in water, or vice versa. The large interfacial area between the oil and water consists of a mixed interfacial film containing both surfactant and co-surfactant molecules. This film is called the *interphase*, because it is thicker than the typical surfactant monolayers formed at the oil-water interfaces in emulsions. The interfacial tension at the oil-water interface in microemulsions approaches zero, which also contributes to their spontaneous formation. According to

another viewpoint, microemulsions are regarded as micelles extensively swollen by large amounts of solubilized oil.

Micellar solutions, microemulsions, and emulsions can be of the O/W or W/O type. As mentioned previously, aqueous micellar solutions can solubilize oils in the hydrocarbon cores of the micelles. Conversely, oil-soluble surfactants like sorbitan monooleate and docusate sodium form reverse micelles in oils (Figure 20-13E) that are capable of solubilizing water in their polar centers. The solubilized oil in the former micelles and the solubilized water in the latter may in turn enhance the micellar solubilization of oil-soluble and water-soluble drugs, respectively.

Typical formulations for an O/W and a W/O microemulsion are shown in Table 20-5. The ratio of grams of surfactant to grams of solubilized or emulsified oil or water ranges from 2 to 20 for micellar solutions and 0.01 to 0.1 for emulsions. Microemulsions have intermediate values. For example, the ratios for the formulations in Table 20-5 are near unity. In industrial formulations, the ratios are closer to 0.1 to reduce costs. Microemulsions are used for a variety of applications including floor polishes, agricultural pesticides, tertiary petroleum recovery, and pharmaceutical delivery systems.

## LIPOSOMES AND BILAYER CONSTRUCTS

Liposomes are synthetic spherical vesicles consisting of an aqueous core surrounded by one or more concentrically arranged bilayer membranes (Fig 20-14). These membranes are commonly composed of phospholipids, but can be prepared

**Table 20-4. Critical Micelle Concentrations and Micellar Aggregation Numbers of Various Surfactants in Water at Room Temperature**

Structure	Name	CMC (mmol/dm <sup>3</sup> )	No. of Surfactant Molecules per Micelle
n-C <sub>11</sub> H <sub>23</sub> COOK	Potassium laurate	24	50
n-C <sub>8</sub> H <sub>17</sub> SO <sub>3</sub> Na	Sodium octane sulfonate	150	28
n-C <sub>10</sub> H <sub>21</sub> SO <sub>3</sub> Na	Sodium decane sulfonate	40	40

<sup>b</sup> At 55°C instead of 20°C.

**Table 20-5. Table .5. Microemulsion Formulations**

Compound	Function	Content in Microemulsions (%)	
		O/W	W/O
Sodium lauryl sulfate	Surfactant	13	10
1-Pentanol	Co-surfactant	8	25
Xylene	Oil	8	50
Water	Lipid	71	15

O/W, oil-in-water microemulsion; W/O, water-in-oil microemulsion.

from a range of lipids and/or surfactants. When lipid molecules are dispersed in an aqueous system, the resultant self-assembled structure is dependent (e.g. micelles versus liposomes) on the structure of the lipid, the lipid mixture, lipid concentration and temperature. In particular the molecular shape of the lipid has a strong driving force in determining the specific colloidal construct formed. The shape of the lipid molecule can be expressed as its critical packing parameter (which considers the ratio of the hydrophilic and hydrophobic volumes of the molecule). For example, single-chain lipids with large head-groups (e.g. sodium dodecyl sulphate) will form micelles, whereas double-chain lipids with large head-groups (e.g. phosphatidylcholine) will form bilayer vesicles.

Due to their bilayer structure (Fig 20-14) liposomes are able to accommodate water- and lipid-soluble molecules, with water

soluble drugs being incorporated into the aqueous regions of the liposomes, whilst lipophilic drugs can be solubilised within the bilayer of the liposomes, in a similar manner to drug solubilisation within micelles. In addition, molecules can be conjugated or electrostatically bound to the surface of the vesicles. By such means a large range of drugs, nucleic acid systems and protein-based therapies can be incorporated within the liposomes thereby offering protection to the drug, and improved delivery and targeting. Indeed, there is a number of clinically approved liposome products already commercially available (see Clinical applications of liposomes in the below Pharmaceutical Application section).

Whilst phosphatidylcholine is generally the most commonly used lipid, there are a range of lipids available with a choice of head-groups (including cationic, anionic and non-ionic surfactants) and also lipids with a variety of lipid acyl tails; the former can be used to manipulate the surface charge of the vesicles, and the latter influences the permeability of the liposomal bilayer. Both the lipid tail carbon chain length and its degree of saturation influence the phase transition temperature of the lipid. The phase transition temperature is defined as the temperature required to change the physical state of a lipid from an ordered gel phase, where the lipids hydrocarbon tails are fully extended and closely packed, to a disordered 'fluid' liquid crystalline state, where the lipid hydrocarbon tails are disordered. When choosing lipids, generally as the hydrocarbon tail length increases, the phase transition temperature increases (due to the increased van der Waals interactions between the tail region). Similarly, unsaturated cis bonds, prohibit effective van der Waals interactions and reduce the phase transition temperature

**Figure 20-14.** Schematic representation of a liposomes with drug entrapped in the aqueous phase, the bilayer or adsorbed to the surface.

of the lipid. These factors will impact on the bilayer permeability, and drug retention of liposomes, with liposomes in their fluid state having more permeable 'leaky' bilayers compared with high-transition temperature lipid bilayers. Therefore at biological temperature, liposomes formulated using a high transition temperature lipid, such as distearoyl phosphatidylcholine (with a transition temperature of 55°C and thus in the ordered state gel state at biological temperature) will show less drug leakage than liposomes prepared from dilauroyl phosphatidyl choline (which has a transition temperature of -1°C and in the disordered fluid state).

A second consideration in the choice of bilayer composition of liposomes is the inclusion of cholesterol. Whilst not able to form bilayers in its own right, due to its amphipathic nature, cholesterol can insert into bilayers and improve the packaging of the lipids within the bilayer, thereby reducing bilayer permeability and drug leakage.

Liposomes are generally classified by their size and number of bilayers: small unilamellar vesicles (SUV) have a single bilayer and are ~ 25 to 100 nm in size, large unilamellar vesicles (LUV) have a single bilayer but are > 100 nm in size and Large multilamellar vesicles (MLV) have several bilayers and are 100 nm to several micrometers in size. Liposomes can be produced by a range of methods, all of which basically involve the dispersion and hydration of the lipid in an aqueous solvent. The size of vesicles formed is generally dictated by the method used to produce the vesicles.

## PHARMACEUTICAL APPLICATIONS OF COLLOIDAL SYSTEMS

Colloidal materials are used for a variety of pharmaceutical applications including therapeutic and diagnostic agents, drug delivery systems, and pharmaceutical excipients. With the recent advances in biotechnology and protein engineering, many new drug substances are colloids including recombinant human insulin, interferons, interleukins, and monoclonal antibodies. Drug substances may also be prepared as colloid-sized particles to improve bioavailability or therapeutic activity (e.g., colloidal sulfur).

### RADIOACTIVE COLLOIDS

Colloidal dispersions containing radioactive isotopes are being used as diagnostic and therapeutic agents in nuclear medicine. *Colloid gold Au 198* is made by reducing a solution of gold ( $^{198}\text{Au}$ ) chloride either by treatment with ascorbic acid or by heating with an alkaline glucose solution. Gelatin is added as a protective colloid. The particle size ranges from 5 to 50 nm with a mean of 30 nm, and the color of the sol is cherry-red in transmitted light. Violet or blue sols have excessively large particle sizes and should be discarded. Colloidal gold is used as a diagnostic and therapeutic aid. The half-life of  $^{198}\text{Au}$  is 2.7 days. *Technetium 99m sulfur colloid* is prepared by reducing sodium pertechnetate  $^{99m}\text{Tc}$  with sodium thiosulfate. The product, a mixture of technetium sulfide and sulfur in the colloidal particle size range, is stabilized with gelatin. It is primarily used in liver, spleen, and bone scanning, and has a half-life of 6.0 hours.

### CROSSLINKED POLYMERS

When linear, water-soluble polymers are crosslinked, they swell in water but no longer dissolve. The crosslinks tie the macromolecular chains together by primary covalent bonds, transforming each particle into a single, giant molecule. The water-swollen grains of crosslinked polymers are permeable to low-molecular-weight solutes. Examples of crosslinked polyelectrolytes include the cation-exchange resin sodium polystyrene sulfonate copolymerized with divinylbenzene (used to reduce hyperkalemia by exchanging some of its  $\text{Na}^+$  with  $\text{K}^+$ ) and the anion-exchange resins cholestyramine and colestipol hydrochloride (which reduce hypercholesterolemia by binding bile salt anions). Polycarbophil, a lightly crosslinked polymer of acrylic acid, only ionizes and swells in the nearly neutral small intestine, where it absorbs water and reduces the fluidity of diarrheal stool.

### COLLOIDAL DELIVERY SYSTEMS

Colloidal delivery systems include micelles, microemulsions, liposomes, parenteral emulsions, microspheres, nanoparticles, and drug-polymer conjugates.

#### Micelles and Solubilization

Micelles have been used to solubilize poorly water-soluble compounds. For example, *AquaMEPHYTON Injection* (Merck & Co.) contains phytonadione (vitamin  $\text{K}_1$ ) dissolved in the core of micelles of a polyoxyethylated fatty acid derivative. *Fugizone®* (Squibb) is a mixed micellar formulation which is used to solubilise Amphotericin B, an anti-fungal agent used to treat invasive fungal infections such as systemic candidiasis and histoplasmosis. As illustrated in Figure 20-15, the interior of surfactant micelles formed in an aqueous media consists of hydrocarbon tails in a liquid-like, disordered state. Therefore, the micelles resemble miniscule pools of liquid hydrocarbon surrounded by shells of polar head groups. Compounds that are poorly soluble in water but soluble in hydrocarbon solvents can be dissolved inside these micelles, and thereby brought homogeneously into the overall aqueous medium.

Being oleophilic, the solubilized molecules are primarily located in the hydrocarbon core of the micelles (Figure 20-15A).

**Figure 20-15.** The locations of solubilizates in spherical micelles. (A) Ionic surfactant (solubilized molecule has no hydrophilic groups). (B) Ionic surfactant (solubilized molecule has a hydrophilic group). (C) Nonionic surfactant (polar solubilize). (From Shinoda K, Nakagawa T, Tamamushi B-I, Isemura T. *Colloidal Surfactants*. New York: Academic Press, 1963.)

However, many water-insoluble drugs also contain polar functional groups such as hydroxyl, carbonyl, ether, amino, amide, and cyano groups. Upon solubilization, these hydrophilic groups are located among the polar head groups of the surfactant in the periphery of the micelle so as to become hydrated (Figure 20-15B). For instance, when cholesterol or dodecanol is solubilized by sodium lauryl sulfate micelles, their hydroxyl groups penetrate between the sulfate ions and are even bound to them through hydrogen bonds, while their hydrocarbon portions are immersed among the dodecyl tails of the surfactant in the micelle core. Micelles of polyoxyethylated nonionic surfactants consist of an outer shell of hydrated PEG moieties and a core of hydrocarbon moieties. Compounds like phenol, cresol, benzoic acid, salicylic acid, and esters of *p*-hydrobenzoic and *p*-aminobenzoic acids have some solubility in water and oils but considerable solubility in liquids of intermediate polarity such as ethanol, propylene glycol, or aqueous solutions of PEGs. When solubilized by nonionic micelles, these compounds are located in the outer hydrated PEG shell as shown in Figure 20-15C. Since these compounds have hydroxyl or amino groups, they frequently form complexes with the ether oxygens of the surfactant through hydrogen bonding.<sup>21,24–26,28</sup>

Micellar solubilization is generally nonspecific; any drug that is appreciably soluble in oils can be solubilized. Each compound has a solubilization limit, which depends upon temperature and the nature and concentration of the surfactant. There are two general categories of solubilizates. The first consists of comparatively large, asymmetric and rigid molecules such as steroids and dyes that form crystalline solids. Because of a dissimilarity in structure, these compounds do not blend in with the normal paraffin tails that make up the micellar cores but remain as distinct solute molecules. They are sparingly solubilized by micelles with only a few molecules per micelle at saturation (Table 20-6). The number of carbon atoms in the micellar hydrocarbon core required to solubilize one molecule of a steroid or dye at saturation is of the same order of magnitude as the number of carbon atoms in bulk liquid dodecane or hexadecane required to dissolve one molecule of steroid or dye at saturation.

Because solubilization depends on the presence of micelles, it does not take place below the CMC. Therefore, such solubilization can be used to determine the CMC, particularly when the solubilize is a dye or another compound easy to assay. Plotting the maximum amount of a water-insoluble dye solubilized by an aqueous surfactant, or the absorbance of its saturated solutions, versus the surfactant concentration produces a straight line that intersects the surfactant concentration axis at the CMC. Above the CMC, the amount of solubilized dye is directly proportional to the number of micelles, and therefore, proportional to the overall surfactant concentration. Below the CMC, no solubilization takes place. This is represented by curve *E* in Figure 20-12.

The second category of compounds that may be solubilized are often liquid at room temperature and consist of relatively small, symmetrical, and/or flexible molecules such as many constituents of essential oils. These molecules mix and freely blend in with the hydrocarbon portions of the surfactants in the core of the micelles and therefore become indistinguishable from them. Such compounds are extensively solubilized and in the process usually swell the micelles. They augment the volume of the hydrocarbon core and increase the number of surfactant molecules per micelle. Their solubilization frequently lowers the CMC.

### Microemulsions

O/W microemulsions are also formulated as aqueous vehicles for oil-soluble drugs to be administered by the percutaneous, oral, or parenteral routes. Oil-soluble drugs are incorporated into O/W emulsions by dissolving them in the oil phase before emulsification. Similarly, oil-soluble drugs are incorporated into microemulsions by prior dissolution within the oil phase. The advantage of microemulsions as dosage forms as compared to conventional emulsions is their smaller droplet size, which increases drug release, and their superior physical stability. Neoral® (Novartis) is a self-microemulsifying formulation of the immunosuppressant ciclosporin. Ciclosporin has a very low water solubility, and was first formulated in an emulsion pre-concentrate incorporated within a soft gelatin capsule, however this emulsion system showed large variation in bioavailability (between 10 and 60% in individual patients). Neoral® which is a microemulsion pre-concentrate, leads to the formation of microemulsion droplets < 50 nm and offers less variability in bioavailability.

### Liposomes

As mentioned liposomes can be used as vehicles to deliver a wide range of drugs including synthetic drugs, polypeptides, proteins (including enzymes and antibodies), and nucleic acid based therapies. Water-soluble drugs are incorporated into the aqueous phase of the liposomes and oil-soluble drugs can also be solubilized by the hydrocarbon chains of the lipid bilayers. There are a range of clinical products that use liposomes to enhance drug targeting so to reduce the side-effect profile of the drug and improve therapeutic outcomes. These include products used for the treatment of certain cancers (e.g. DanoXome® (Gilead)), systemic fungal infections (e.g. AmBisome® (Gilead)), vaccines (e.g. Inflexal V (Janssen-Cilag Ltd)) and macular degeneration (e.g. Visudyne® (Novartis)); the majority of the products are designed for intravenous injection.

After intravenous injection, liposomes (like many particulate delivery systems) interact with blood opsonins, which cause their removal from the blood circulation at rates that are dictated by their vesicle size, lipid composition and surface charge.

**Table 20-6. Micellar Solubilization Capacities of Different Surfactants for Estrone**

Surfactant	Concentration Range (M)	Temperature (°C)	Moles Surfactant per Moles Solubilized Estrone
Sodium laurate	0.025–0.23	40	91
Sodium oleate	0.002–0.35	40	53
Sodium lauryl sulfate	0.004–0.15	40	71
Sodium cholate	0.09–0.23	20	238
Sodium deoxycholate	0.007–0.36	20	476
Diamyl sodium sulfosuccinate	0.08–0.4	40	833
Diocetyl sodium sulfosuccinate	0.002–0.05	40	196
Tetradecyltrimethylammonium bromide	0.005–0.08	20	45
Hexadecylpyridinium chloride	0.001–0.1	20	32
Polysorbate 20	0.002–0.15	20	161
Polysorbate 60	0.0008–0.11	20	83

(Data from Shinoda K, ed. *Solvent Properties of Surfactant Solutions*. New York: Dekker, 1967.)

Due to this interaction, opsonin-coated liposomes accumulate (via opsonin recognition by appropriate cell receptors) in the mononuclear phagocytic system (MPS) and in particular the liver and spleen. This allows liposomes to be used for passive targeting of such sites. When administered via the intramuscular or subcutaneous route, liposomes end up in the lymphatic system including the local lymph nodes. This provides the opportunity for liposomes to be used for the delivery of vaccines.

This passive targeting is exploited in the liposome formulation Myocet® (Cephalon) - a liposomal formulation of doxorubicin. The liposomes within Myocet are ~180 nm in size and composed of egg phosphatidylcholine and cholesterol. Due to their larger size, the liposomes in Myocet® are rapidly taken by the MPS. This is thought to create a 'MPS depot' which produces a slow release of the drug into the blood circulation, mimicking a slow transfusion of doxorubicin.

To avoid uptake by the MPS, liposomes can be designed to avoid opsonin recognition by appropriate engineering of their surface. This allows liposomes to target sites other than MPS. To achieve this liposomes are coated with hydrophilic polymers, such as polysialic acids and polyethylene glycol (PEG). This hydrophilic polymer coating blocks opsonisation, increasing liposome circulation times, and promotes opportunities for the liposomes to interact with target cells other than those of the MPS. Through such means liposomes can accumulate in pathological sites with leaky vasculature, including tumour sites and sites of inflammation, through the 'Enhanced Permeability and Retention effect' which occurs at sites of inflammation and tumour sites. As these sites the integrity of the endothelial barrier is often disrupted by the presence of endothelial fenestrations (gaps) as large as 200–300 nm. The change in the tumour endothelial barrier is a result of angiogenesis occurring during tumour growth which results in defective hypervascularity (enhanced permeability) and a deficient lymphatic drainage system (enhanced retention). These changes in pathophysiology allow liposomes to escape from the circulation and become trapped in the tumour vasculature, hence passively targeting the PEGylated liposomes to tumour sites. Once trapped, the liposomes then slowly release the drug, resulting in a high local

concentration and a low systemic exposure. This increases its effectiveness and decreases its side effects. Examples of a products using this passive targeting to tumor sites is DaunoXome Liposomal Injection (Gilead), which contains daunorubicin citrate, and Caelyx ®/DOXIL Liposome Injection (Janssen Biotech), which contains doxorubicin HCl.

Liposomes are also used to deliver the low solubility drug, Amphotericin B, in the product AmBisome® (Gilead). In this formulation the drug is solubilised in the liposomal bilayer of liposomes ~ 80 nm in diameter and composed of hydrogenated soy phosphatidylcholine, cholesterol, distearoylphosphatidylglycerol and  $\alpha$ -tocopherol.

Liposomes can also be formulated to produce a sustained drug release, multi-vesicle liposomes can be used. Both DepoCyte® (Napp) and DepoDur® (Flynn Pharma Ltd) are large multi-vesicle vesicles which achieve sustained drug release through their slow clearance from the administration site and their slow breakdown. After a single epidural injection, DepoDur® can give relief from post-operative pain for up to 48 hours.

Liposomes dispersed in water are subject to degradation via hydrolysis of ester bonds and oxidation of unsaturated acyl chains, aggregation and fusion, as well as leakage of encapsulated drugs. Freeze-drying followed by rehydration and redispersion just before use is commonly used to extend their shelf-life.

### Microspheres and Microcapsules

These are essentially spherical particles in the micrometer size range which can be manufactured to be solid or porous (microparticles or microspheres) or they can be hollow in nature (microcapsules). They can be formulated from polymers, lipids and proteins, with polymers such as poly(lactide-co-glycolide) (PLGA) and polylactic acid (PLA) being commonly used. Drugs can be incorporated within the matrix systems, and therefore drug release from the particles is dictated by the degradation rate of the matrix. There are a number of polymeric microparticles approved for clinical use. For example Lupron Depot® (Abbott) is a suspension of PLGA microspheres which are injected subcutaneously and act as a drug depot after administration, giving controlled-release release of leuprolide acetate for

up to 6 months. Decapeptyl® SR (Ipsen Ltd) is a sustained release PLGA microsphere formulation of triptorelin. Triptorelin acetate, a gonadorelin (LHRH) analogue and it is prescribed for the treatment of advanced prostate cancer and endometriosis. The microsphere formulation is injected intramuscularly and the bioavailability of triptorelin is reported as approximately 50%. Nutropin Depot for Injectable Suspension (Genentech), which is administered one to two times per month by subcutaneous injection and slowly releases somatropin of recombinant DNA origin.

## Nanoparticles

Nanoparticles is a term applied to many nano-sized structures and there is a strong overlap between nanotechnology and colloidal science, which is not surprising given that nanotechnology refers to pharmaceutical materials, structures and products that have one or more dimension between approximately 1 and 100 nm. However if we are to refine the description to solid nanoparticles, here we can consider solid constructs in the nanometer range. These can be prepared by two general methods either involving size reduction of particles (e.g. by milling) to within the nanoparticle range or molecular agglomeration (e.g. by precipitation methods) to form nanoparticles. Size reduction is used to prepare drug particles in the nanosize range where no carrier material is added, whilst the molecular agglomeration is more commonly used to prepare nanoparticle carriers in which the drug is loaded.

Considering nanoparticles as drug carriers, there are a range of excipients that can be used to form the carrier including polymers (e.g. poly(lactide-co-glycolide), polylactic acid and polysaccharides) and high melting point lipids. Polymeric nanoparticles can be designed to have PEGylated coatings, similar to liposomes, to facilitate drug targeting to tumour sites.

In addition to polymers and lipids, nanoparticles can also be prepared from proteins. The first commercial produced based on protein nanotechnology is Abraxane® (nab<sup>TM</sup>-paclitaxel; Abraxis). Abraxane® is currently approved for use in patients who don't respond to combination chemotherapy for metastatic disease or relapse within 6 months of adjuvant chemotherapy. Abraxane® consists of 130 nm particles of albumin-bound paclitaxel. By binding paclitaxel to albumin this overcomes the low solubility of paclitaxel and also promotes active targeting of the paclitaxel to tumour cells. As mentioned, drug targeting of nanoparticles to tumours results from the EPR effect. In addition, the albumin in the nanoparticles may use 'Albumin-activated gp60 pathway' to improve drug delivery: by albumin binding to gp60 albumin receptors found on the surface of vasculature endothelial cells the paclitaxel-albumin is then transported across blood vesicle walls. The binding of albumin to the gp60 receptors, activates the membrane protein Caveolin-1 and subsequently results in the internalisation of the cell membrane and the formation of transcytotic vesicles (known as Caveolae). These caveolae then transport their contents across the endothelial cell cytoplasm, and release their contents into the tumours interstitium. In the case of tumours this transport system is thought to be upregulated. Therefore Abraxane is able to exploit this this albumin-activated gp60 transport mechanism to target the tumour site. After entering the systemic circulation, the albumin-bound paclitaxel can bind to the gp60 albumin receptors and be carried across the endothelial cells via transcytosis. Once the albumin-bound paclitaxel reaches the interstitium, the albumin may bind to an extracellular matrix glycoprotein known as SPARC (secreted protein acid and rich in cysteine) which is also over-expressed in tumour cells. This can trigger the release of the paclitaxel from the albumin, allowing the free drug to diffuse to the nucleus of tumour cells initiating cell death.

## Drug-Polymer Conjugates

Polymers have also been used to produce soluble drug-polymer conjugates, which are formed by chemical reactions to produce

covalent bonds between a drug and a polymeric molecule. These polymer conjugates include synthetic polymers as well as biological polymers such as globular and fibrous proteins, antibodies, and polysaccharides. For example, *Mylotarg for Injection* (gemtuzumab ozogamicin; Wyeth Pharmaceuticals) consists of a conjugate between an IgG monoclonal antibody and calicheamicin, a chemotherapeutic agent. These conjugates are administered by intravenous infusion, and the antibody targets the CD33 antigen found on the surface of leukemic blasts and immature normal cells of myelomonocytic lineage, but not on normal hematopoietic stem cells. The antibody-drug conjugate is believed to have a lysosomotropic mechanism of action; in other words, the antibody-antigen complex is internalized into the cell through endocytosis and entrapped within endosomal compartments. These endosomes merge with primary lysosomes to form secondary lysosomes, where the drug-antibody bonds are presumably broken by the acidic environment or cleaved by certain lysosomal enzymes. Once cleaved from the antibody, the drug is able to diffuse out of the lysosome and exert its pharmacological effect.

*In-111 and Y-90 Zevalin* (Spectrum Pharmaceuticals) consists of a conjugate between an ibritumomab antibody (a murine IgG) and either an indium-111 or an yttrium-90 radioisotope. These conjugates are administered by intravenous infusion and attach to the CD20 antigen found on the surface of normal and malignant B-lymphocytes. However, the antibody-antigen complex is not internalized. The attachment of the antibody induces cell apoptosis, and the close proximity of the radioisotope creates free radicals that damage nearby cells.

*PEGIntron Powder for Injection* (Schering) also consists of a conjugate. In this case, interferon alfa-2b is conjugated with a PEG derivative. The conjugates are injected subcutaneously. The PEG derivative prevents detection and therefore decreases the clearance of interferon alfa-2b from the body.

The actively targeted conjugates just described can be contrasted to passively targeted macromolecular conjugates for solid-tumor tissue. Passively targeted macromolecular conjugates have shown preferential accumulation in solid tumors because of the Enhanced Permeability and Retention (EPR) effect. The preferential accumulation reduces systemic toxicity by reducing damage to noncancerous organs. In addition, the EPR effect is more effective for macromolecules greater than 40 kDa but negligible for smaller molecules that are cleared more rapidly from the tumor interstitium.<sup>29</sup>

In addition to the PEGylated proteins, OPAXIO<sup>TM</sup> (Cell Therapeutics, Inc.) is currently in clinical trials. In this polymer-drug conjugate, paclitaxel is conjugated to poly-L-glutamic acid (PGA). By conjugation of paclitaxel to the water soluble PGA, this improves the solubility of paclitaxel, and it can be infused into the body without the addition of solvents. This conjugate has a high drug content (~37% w/w) and the conjugate can passively target tumour sites via the EPR effect. The drug is then released intracellularly via degradation of PGA by lysosomal proteases and the ester linker is degraded by esterases or acid hydrolysis.

## EXCIPIENTS

Most of the excipients, adjuvants, or nontherapeutic ingredients of dosage forms listed below are monographs in the NF or USP.

Colloids are also used as pharmaceutical excipients for a variety of purposes including thickening agents. Colloidal thickening agents or viscosity builders belong to four chemical categories.

*Semisynthetic cellulose derivatives* include methylcellulose, carboxymethylcellulose sodium, hydroxypropyl methylcellulose, and hydroxypropyl cellulose. *Natural polymers* include acacia, tragacanth, xanthan gum, sodium alginate, and carrageenan. *Synthetic polymers* include carbomer, a copolymer of acrylic acid; poloxamer, a block copolymer of ethylene oxide and propylene oxide; polyvinyl alcohol; and povidone (polyvinylpyrrolidone). *Particulate colloids* include bentonite,

colloidal silicon dioxide, and microcrystalline cellulose. These viscosity builders may be used to decrease the dissolution rate of controlled-release dosage forms, to decrease the sedimentation or creaming rates of dispersed systems, to improve the taste-masking abilities of liquid vehicles, and to provide consistency to ointments. Many of the water-soluble viscosity builders mentioned above are surface-active and are also used as emulsifying and suspending agents. Even particulate colloids are used to stabilize emulsions and suspensions.

Colloidal silicon dioxide is a white powder consisting of sub-microscopic spherical particles of fairly uniform size in the range of 5–50 nm or higher. It is used to thicken liquid dosage forms and in tablets. The surface of colloidal silicon dioxide particles contains siloxane (Si-O-Si) and silanol (Si-OH) groups. When colloidal silicon dioxide powder is dispersed in nonpolar liquids, the particles tend to adhere to one another through hydrogen bonds between these surface groups. The spherical particles of finer grade colloidal silicon dioxide are linked together into short chain-like aggregates as shown in Figure 20-4. This creates loose three-dimensional networks that increase the viscosity of the liquid vehicles even at levels as low as a few percent. The hydrogen-bonded structures are torn apart by stirring but rebuilt while at rest, conferring a thixotropic nature to the thickened liquids.

Aerosil 200 is the grade of colloidal silicon dioxide most widely used as a pharmaceutical adjuvant. Its primary spheres, which are extensively sintered together, have an average diameter of 12 nm. At levels of 8 to 10 percent, it thickens liquids of low polarity such as vegetable and mineral oils to the consistency of ointments, imparting considerable yield values to them. Hydrogen-bonding liquids such as alcohols and water solvate the silica spheres, thereby reducing the hydrogen bonding between particles. Therefore, the higher silica levels of 12 to 18 percent or more are required to gel these solvents.

The grades that consist of relatively large and unattached spherical particles, such as those in Figure 20-3, are less efficient thickening agents because they lack the high specific surface area and asymmetry of the finer grades. The consistency of ointments thickened with colloidal silicon dioxide is not appreciably reduced at higher temperatures. Incorporation of colloidal silicon dioxide into ointments and pastes, such as those of zinc oxide, also reduces the syneresis or *bleeding* of the liquid vehicles.

Colloidal silicon dioxide is also used in dry dosage forms. The spherical particles are nonporous and have a density of 2.13 g/cm<sup>3</sup>. However, the bulk density of their powder is a mere 0.05 g/cm<sup>3</sup>. Because the powder is extremely light, it is frequently used to increase the fluffiness or bulk volume of powder formulations. In addition, the high porosity of colloidal silica enables it to absorb a variety of liquids from fluid fragrances to viscous tars, transforming them into free-flowing powders that can be incorporated into tablets or capsules. The porosity in colloidal silicon dioxide is due entirely to the enormous void space between the particles, which themselves are solid. When these ultrafine particles are incorporated at levels as low as 0.1 to 0.5 percent into a powder consisting of coarse particles or granules, they coat the surface of the granules and act as tiny ball bearings and spacers. This improves the flowability of the powder and eliminates caking, which is important in tableting. In addition, colloidal silicon dioxide is used to improve tablet disintegration. It is also used as a glidant and as a moisture absorber.

*Microcrystalline cellulose* is manufactured by controlled hydrolysis of purified native cellulose, which dissolves the amorphous matrix but leaves the crystallites intact. The needle- or rod-shaped crystallites act as suspending agents in water, producing thixotropic structured vehicles. At concentrations of about 15 percent, the cellulose microcrystals gel water to an ointment consistency by swelling and producing a continuous network of rods that extends throughout the entire vehicle. Attraction between the elongated particles is presumably due to flocculation in the secondary minimum. Treatment of the

microcrystalline mass with sodium carboxymethylcellulose facilitates its disintegration into primary needle-shaped particles and enhances their thickening action.

Gelatinous precipitates of inorganic hydrophilic compounds such as *aluminum hydroxide gel*, *aluminum phosphate gel*, and *magnesium hydroxide* consist of coarse flocs produced by the agglomeration of colloidal particles formed in the initial stage of precipitation. They possess large internal surface areas, which is one of the reasons why the first two are used as substrates for adsorbed vaccines and toxoids. *Alumina and magnesia oral suspensions*, a mixture of gelatinous precipitated aluminum and magnesium hydroxides, as well as aluminum hydroxide gel, are used as antacids.

*Gelation* is used to manufacture the following suppository bases: glycerinated gelatin suppositories; glycerin suppositories (in which glycerin is solidified with sodium stearate that crystallizes out as a network of needles upon cooling the hot solution); and PEG suppositories (in which low-molecular-weight liquid PEGs, such as PEG 400, are stiffened by high-molecular-weight PEGs such as 3350 or 4000, which are waxy solids). A pharmaceutical application of gelation in a nonaqueous medium is the manufacture of *Plastibase* or *Jelene* (Squibb), which is prepared using 5 percent of a low-molecular-weight polyethylene and 95 percent of mineral oil. The polymer is soluble in mineral oil above 90°C, which is close to its melting point. When the solution is cooled below 90°C, the polymer precipitates and causes gelation. The mineral oil is immobilized in the network of entangled, adhering, insoluble polyethylene chains, which probably even associate into small crystalline regions. Unlike petrolatum, this gel can be heated to about 60°C without any substantial loss in consistency.

Crospovidone and croscarmellose sodium are crosslinked povidone and carboxymethylcellulose sodium, respectively. These crosslinked polymers swell rapidly and extensively in aqueous media and therefore are frequently used as tablet disintegrants. Starch performs the same function; its major constituent, amylopectin, is highly branched and insoluble in water but swells considerably. Because crosslinked hydrophilic polymers swell extensively without dissolution, they are also used as matrices for controlled-release dosage forms.

This chapter includes the formation of suspensions and emulsions and the factors that influence their stability and performance as dosage forms. For the purpose of the present discussion, a dispersed system, or dispersion, will be regarded as a two-phase system in which one phase is distributed as particles or droplets in the second, or continuous, phase. In these systems, the dispersed phase frequently is referred to as the discontinuous or internal phase, and the continuous phase is called the external phase or dispersion medium. Discussion will be restricted to those solid–liquid and liquid–liquid dispersions that are of pharmaceutical significance, namely, suspensions and emulsions. However, more complicated phase systems (e.g., a combination of liquid and liquid crystalline phases) can exist in emulsions. This situation will be discussed in the section dealing with emulsions.

All dispersions may be classified into three groups based on the size of the dispersed particles. Chapter 20 deals with one such group—colloidal dispersions—in which the size of the dispersed particles is in the range of approximately 1 nm to 0.5  $\mu\text{m}$ . Molecular dispersions, the second group in this classification, are discussed in Chapter 19. The third group, consisting of *coarse dispersions* in which the particle size exceeds 0.5  $\mu\text{m}$ , is the subject of this chapter. Knowledge of coarse dispersions is essential for the preparation of both pharmaceutical suspensions (solid–liquid dispersions) and emulsions (liquid–liquid dispersions).

Table 21-1 contains examples of pharmaceutical suspensions and emulsions. Pharmaceutical coarse dispersions are administered via several routes of administration and include many different types of active ingredients.

### THE DISPERSION STEP

The pharmaceutical formulator is concerned primarily with producing a smooth, uniform, easily flowing (pouring or spreading) suspension or emulsion in which dispersion of particles can be effected with minimum expenditure of energy.

In preparing suspensions, particle–particle attractive forces need to be overcome by the high shearing action of such devices as the colloid mill, or by use of surface-active agents. The latter greatly facilitate wetting of lyophobic powders and assist in the removal of surface air that shearing alone may not remove; thus, the clumping tendency of the particles is reduced. Moreover, lowering of the surface free energy by the adsorption of these agents directly reduces the thermodynamic driving force opposing dispersion of the particles.

In emulsification, shear rates are frequently necessary for dispersion of the internal phase into fine droplets. The shear forces are opposed by forces operating to resist distortion and subsequent breakup of the droplets. Again surface-active agents

help greatly by lowering interfacial tension, which is the primary reversible component resisting droplet distortion. Surface-active agents also may play an important role in determining whether an oil-in-water (O/W) or a water-in-oil (W/O) emulsion preferentially survives the shearing action.

Once the process of dispersion begins there develops simultaneously a tendency for the system to revert to an energetically more stable state, manifested by flocculation, coalescence, sedimentation, crystal growth, and caking phenomena. If these physical changes are not inhibited or controlled, successful dispersions will not be achieved or will be lost during shelf-life.

### INTERFACIAL PROPERTIES

Because suspensions and emulsions are dispersions of one phase within another, the process of dispersion creates a tremendous increase in interfacial area between the dispersed particles or droplets and the dispersion medium. When considering the interfacial properties of dispersed particles, two factors must be taken into account, regardless of whether the dispersed phase is solid or liquid. The first relates to an increase in the free energy of the surface as the particle size is reduced and the specific surface increased. The second deals with the presence of an electrical charge on the surface of the dispersed particles.

### SURFACE FREE ENERGY

When solid and liquid materials are reduced in size, they tend to agglomerate or stick together. This clumping, which can occur either in an air or liquid medium, is an attempt by the particles to reduce the excess free energy of the system. The increase in surface free energy is related to the increase in surface area produced when the mean particle size is reduced. It may be expressed as

$$\Delta F = \gamma \Delta A \quad (1)$$

where  $\Delta F$  is the increase in surface free energy in ergs,  $\Delta A$  is the increase in surface area in  $\text{cm}^2$ , and  $\gamma$  is the interfacial tension in  $\text{dyn/cm}$ , between the dispersed particle or droplet and the dispersion medium. The smaller  $\Delta F$  is, the more thermodynamically stable is the suspension of particles. A reduction in  $\Delta F$  is effected often by the addition of a wetting agent (discussed in Chapter 19), which is adsorbed at the interface between the particle and the vehicle, thereby reducing the interfacial tension. This causes the particles to remain dispersed and settle relatively slowly. Unfortunately, in solid–liquid suspensions, the particles can form a hard cake at the bottom of the container when they eventually settle. Such a sediment, which can be extremely difficult to redisperse, can lead to dosing errors when the product is administered to the patient.

**Table 21-1. Examples of Pharmaceutical/Cosmetic Suspension and Emulsion Products**

Suspensions		Emulsions	
Name	Route of Administration	Name	Route of Administration
Milk of Magnesia® (Magnesium Hydroxide)	Oral	Mineral Oil	Oral
Nystatin Oral Suspension, USP	Oral	Restasis® (cyclosporine ophthalmic emulsion)	Eye
Cortisporin® Ophthalmic & Otic suspensions (neomycin/polymyxin, bacitracin, hydrocortisone)	Ear, eye	Intralipid®, Liposyn® (intravenous fat emulsion)	Intravenous
Ibuprofen oral suspension, USP	Oral	Lipomul®	Oral
Tobradex® (tobramycin, dexamethasone)	Eye	Simethicone emulsion, USP	Oral, -manufacturing aid
Tussionex® (chlorpheniramine/hydrocodone sustained release)	Oral	Propofol injectable emulsion, USP	Intravenous
Prednisolone acetate ophthalmic suspension, USP	Eye	Lubriderm® (emollient)	Topical
NPH Insulin	subcutaneous	Lidocaine/prilocaine cream (EMLA®)	topical
Sterile Procaine Penicillin G Injectable Suspension, USP	intramuscular	Diazemuls® (diazepam)	intravenous
Griseofulvin oral suspension, USP	oral		
Phenytoin oral suspension, USP	oral		
Sulfamethoxazole/trimethoprim oral suspension	oral		

## SURFACE POTENTIAL

As discussed in Chapter 19, both attractive and repulsive forces exist between particles in a liquid medium. The balance between these opposing forces determines whether two particles approaching each other actually make contact or are repulsed at a certain distance of separation. Although much of the theoretical work on electrical surface potentials has been carried out on lyophobic colloids, the theories developed in this area have been applied to suspensions and emulsions.

## SUSPENSIONS

A *pharmaceutical suspension* may be defined as a coarse dispersion containing finely divided insoluble material suspended in a liquid medium. Because some products occasionally are prepared in a dry form to be placed in suspension at the time of dispensing by the addition of an appropriate liquid vehicle, this definition is extended to include these products.

Suspension dosage forms are given by the oral route, injected intramuscularly or subcutaneously, instilled intranasally, inhaled into the lungs, applied to the skin as topical preparations, or used for ophthalmic or otic purposes in the eye or ear, respectively. They are an important class of dosage form which can offer several advantages. Suspensions offer an alternative oral dosage form for patients who cannot swallow a tablet or capsule such as pediatric and geriatric patients. Oral antibiotics, analgesic and antipyretic drugs are commonly administered as suspensions to these groups of patients. Suspensions are often used to deliver poorly water-soluble drugs which cannot be formulated as aqueous solutions. In early drug development studies of potentially new drug candidates, suspension dosage forms are frequently used to deliver drugs to animals, particularly when the drug is given orally. In addition, drugs that have an unpleasant taste may preferably be formulated as a suspension to reduce interaction of drug with taste receptors in the mouth. Because suspended drug must undergo a dissolution step prior to crossing biological membranes, suspensions offer a way to provide sustained release of drug by parenteral, topical, and oral routes of administration.

There are certain criteria that a well-formulated suspension should meet. The dispersed particles should be of such a size that they do not settle rapidly in the container. However, in the event that sedimentation does occur, the sediment must not form a hard cake. Rather, it should be capable of redispersion with a minimum of effort on the part of the patient. Finally, the product should be easy to pour, have a pleasant taste, and be resistant to microbial attack.

The three major concerns associated with suspensions are:

1. ensuring adequate dispersion of the particles in the vehicle.
2. minimizing settling of the dispersed particles.
3. preventing caking of these particles when a sediment forms.

Much of the following discussion will deal with the factors that influence these processes and the ways in which settling and caking can be minimized.

## FLOCCULATION AND DEFLOCCULATION

Zeta potential,  $\zeta$ , is a measurable indication of the potential existing at the surface of a particle. When  $\zeta$  is relatively high (25 mV or more), the repulsive forces between two particles exceed the attractive London forces. Accordingly, the particles are dispersed and are said to be *deflocculated*. Even when brought close together by random motion or agitation, deflocculated particles resist collision due to their high surface potential.

The addition of a preferentially adsorbed ion whose charge is opposite in sign to that on the particle leads to a progressive lowering of  $\zeta$ . At some concentration of the added ion, the electrical forces of repulsion are lowered sufficiently and the forces of attraction predominate. Under these conditions the particles may approach each other more closely and form loose aggregates, termed *flocs*. Such a system is said to be *flocculated*.

Some workers restrict the term "flocculation" to the aggregation brought about by chemical bridging; aggregation involving a reduction of repulsive potential at the double layer is referred to as *coagulation*. Other workers regard flocculation as aggregation in the secondary minimum of the potential energy curve of

two interacting particles and coagulation as aggregation in the primary minimum. In the present chapter the term *flocculation* is used for all aggregation processes, irrespective of mechanism.

The continued addition of the flocculating agent can reverse the above process, if the zeta potential increases sufficiently in the opposite direction. Thus, the adsorption of anions onto positively charged, deflocculated particles in suspension will lead to flocculation. The addition of more anions eventually can generate a net negative charge on the particles. When this has achieved the required magnitude, deflocculation may occur again. The only difference from the starting system is that the net charge on the particles in their deflocculated state is negative rather than positive. For further understanding of the processes involved with the electrical double layer, the reader is directed to the chapter on "Colloids." Some of the major differences between suspensions of flocculated and deflocculated particles are presented in Table 21-2.

### FLOCCULATION KINETICS

The rate at which flocculation occurs is a consideration in the stability of suspended dispersions. Whether flocculation is judged to be rapid or slow depends on the presence of a repulsive barrier between adjacent particles. In the absence of such a barrier, and for a monodispersed system, rapid flocculation occurs at a rate given by the Smoluchowski equation.

$$\delta N/\delta t = -4\pi DRN^2 \quad (2)$$

where  $\delta N/\delta t$  is the disappearance rate of particles/mL,  $R$  is the distance between the centers of the two particles in contact,  $N$  is the number of particles per mL, and  $D$  is the diffusion coefficient. Under these conditions the rate is proportional to the square of the particle concentration. The presence or absence of an energy barrier is influenced strongly by the type and concentration of any electrolyte present. When an energy barrier does exist between adjacent particles, the flocculation rate likely will be much smaller than predicted by Equation 2.

### SETTLING AND ITS CONTROL

To control the settling of dispersed material in suspension, the pharmacist must be aware of those physical factors that will affect the rate of sedimentation of particles under ideal and nonideal conditions. Also important are the various coefficients used to express the amount of flocculation in the system and the effect flocculation will have on the structure and volume of the sediment.

### SEDIMENTATION RATE

The rate at which particles in a suspension sediment is related to their size and density and the viscosity of the suspension

medium. Brownian movement may exert a significant effect, as will the absence or presence of flocculation in the system.

### Stokes' Law

The velocity of sedimentation of a uniform collection of spherical particles is governed by *Stokes' law*, expressed as

$$v = \frac{2r^2(\rho_1 - \rho_2)g}{9\eta} \quad (3)$$

where  $v$  is the terminal velocity in cm/sec,  $r$  is the radius of the particles in cm,  $\rho_1$  and  $\rho_2$  are the densities ( $\text{g}/\text{cm}^3$ ) of the dispersed phase and the dispersion medium, respectively,  $g$  is the acceleration due to gravity ( $980.7 \text{ cm}/\text{sec}^2$ ), and  $\eta$  is the Newtonian viscosity of the dispersion medium in poises ( $\text{g}/\text{cm sec}$ ). Stokes' law holds only if the downward motion of the particles is not sufficiently rapid to cause turbulence. Micelles and small phospholipid vesicles do not settle unless they are subjected to centrifugation.

Although conditions in a pharmaceutical suspension are not in strict accord with those laid down for Stokes' law, Equation 3 provides those factors that can be expected to influence the rate of settling. Thus, sedimentation velocity will be reduced by decreasing the particle size, provided that the particles are kept in a deflocculated state. The rate of sedimentation will be an inverse function of the viscosity of the dispersion medium.

However, too high a viscosity is undesirable, especially if the suspending medium is Newtonian rather than shear-thinning (see Chapter 22), because it then becomes difficult to redisperse material that has settled. It also may be inconvenient to remove a viscous suspension from its container. When the size of particles undergoing sedimentation is reduced to approximately  $2 \mu\text{m}$ , random Brownian movement is observed and the rate of sedimentation departs markedly from the theoretical predictions of Stokes' law. The actual size at which Brownian movement becomes significant depends on the density of the particle as well as the viscosity of the dispersion medium.

### Effect of Flocculation

In a deflocculated system containing a distribution of particle sizes, the larger particles naturally settle faster than the smaller particles. The very small particles remain suspended for a considerable length of time, with the result that no distinct boundary is formed between the supernatant and the sediment. Even when a sediment becomes discernible, the supernatant remains cloudy.

When the same system is flocculated (in a manner to be discussed later), two effects are immediately apparent. First, the flocs tend to fall together, so a distinct boundary between the sediment and the supernatant is readily observed; second, the supernatant is clear, showing that the very fine particles have been incorporated into the flocs. The initial rate of settling

**Table 21-2. Relative Properties of Flocculated and Deflocculated Particles in Suspension**

Deflocculated	Flocculated
1. Particles exist in suspension as separate entities.	1. Particles form loose aggregates.
2. Rate of sedimentation is slow, as each particle settles separately and particle size is minimal.	2. Rate of sedimentation is high, as particles settle as a floc, which is a collection of particles.
3. A sediment is formed slowly.	3. A sediment is formed rapidly.
4. The sediment eventually becomes very closely packed, due to weight of upper layers of sedimenting material. Repulsive forces between particles are overcome and a hard cake is formed that is difficult, if not impossible, to redisperse.	4. The sediment is packed loosely and possesses a scaffold-like structure. Particles do not bond tightly to each other and a hard, dense cake does not form. The sediment is easy to redisperse, so as to reform the original suspension.
5. The suspension has a pleasing appearance, as the suspended material remains suspended for a relatively long time. The supernatant also remains cloudy, even when settling is apparent.	5. The suspension is somewhat unsightly, due to rapid sedimentation and the presence of an obvious, clear supernatant region. This can be minimized if the volume of sediment is made large. Ideally, volume of sediment should encompass the volume of the suspension.

in flocculated systems is determined by the size of the flocs and the porosity of the aggregated mass. Under these circumstances it is perhaps better to use the term *subsidence*, rather than sedimentation.

### QUANTITATIVE EXPRESSIONS OF SEDIMENTATION AND FLOCCULATION

Frequently, the pharmacist needs to assess a formulation in terms of the amount of flocculation in the suspension and compare this with that found in other formulations. The two parameters commonly used for this purpose are outlined below.

#### Sedimentation Volume

The *sedimentation volume*,  $F$ , is the ratio of the equilibrium volume of the sediment,  $V_u$ , to the total volume of the suspension,  $V_0$ . Thus,

$$F = V_u/V_0 \quad (4)$$

As the volume of suspension that appears occupied by the sediment increases, the value of  $F$ , which normally ranges from nearly 0 to 1, increases. In the system where  $F = 0.75$ , for example, 75% of the total volume in the container is apparently occupied by the loose, porous flocs forming the sediment. This is illustrated in Figure 21-1. When  $F = 1$ , no sediment is apparent even though the system is flocculated. This is the ideal suspension for, under these conditions, no sedimentation will occur. Caking also will be absent. Furthermore, the suspension is esthetically pleasing, there being no visible, clear supernatant.

#### Degree of Flocculation

A better parameter for comparing flocculated systems is the *degree of flocculation*,  $\beta$ , which relates the sedimentation volume of the flocculated suspension,  $F$ , to the sedimentation volume of the suspension when deflocculated,  $F_\infty$ . It is expressed as

$$\beta = F/F_\infty \quad (5)$$

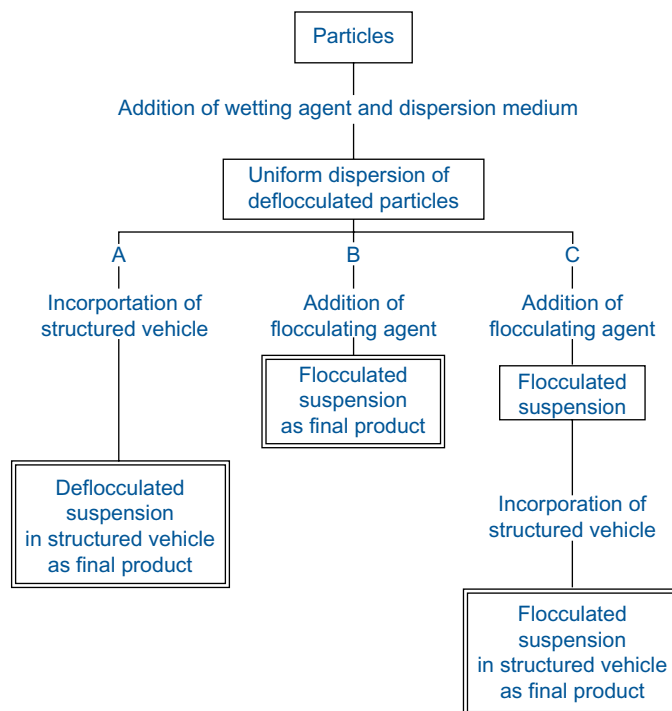

The degree of flocculation is, therefore, an expression of the increased sediment volume resulting from flocculation. If, for example,  $\beta$  has a value of 5.0 (see Figure 21-1), this means that the volume of sediment in the flocculated system is five times that in the deflocculated state. If a second flocculated formulation results in a value for  $\beta$  of say 6.5, this latter suspension obviously is preferred, if the aim is to produce as flocculated a product as possible. As the degree of flocculation in the system decreases,  $\beta$  approaches unity, the theoretical minimum value.

## FORMULATION OF SUSPENSIONS

The formulation of a suspension possessing optimal physical stability depends on whether the particles in suspension are to be flocculated or to remain deflocculated. One approach involves use of a structured vehicle to keep deflocculated particles in suspension; a second depends on controlled flocculation as a means of preventing cake formation. A third, a combination of

**Figure 21-1.** Sedimentation parameters of suspensions. Deflocculated suspension:  $F_\infty = 0.15$ . Flocculated suspension:  $F = 0.75$ ;  $\beta = 5.0$ .

**Figure 21-2.** Alternative approaches to the formulation of suspensions.

the two previous methods, results in a product with optimum stability. The various schemes are illustrated in Figure 21-2.

#### Dispersion of Particles

The dispersion step has been discussed earlier in this chapter. Surface-active agents commonly are used as wetting agents; maximum efficiency is obtained when the HLB value lies within the range of 7 to 9. A concentrated solution of the wetting agent in the vehicle may be used to prepare a slurry of the powder; this is diluted with the required amount of vehicle. Alcohol and glycerin may be used sometimes in the initial stages to disperse the particles, thereby allowing the vehicle to penetrate the powder mass.

Only the minimum amount of wetting agent should be used, compatible with producing an adequate dispersion of the particles. Excessive amounts may lead to foaming or impart an undesirable taste or odor to the product. Invariably, as a result of wetting, the dispersed particles in the vehicle are deflocculated.

#### Structured Vehicles

*Structured vehicles* are generally aqueous solutions of polymeric materials, such as the hydrocolloids, that are usually negatively charged in aqueous solution. Typical examples are methylcellulose, carboxymethylcellulose, bentonite, and carbomer. The concentration employed will depend on the consistency desired for the suspension that, in turn, will relate to the size and density of the suspended particles. They function as viscosity-imparting suspending agents and, as such, reduce the rate of sedimentation of dispersed particles.

The rheological properties of suspending agents are considered elsewhere (Chapter 22). Ideally, these form pseudo-plastic or plastic systems that undergo shear-thinning. Some degree of thixotropy is also desirable. Non-Newtonian materials of this type are preferred over Newtonian systems because, if the particles eventually settle to the bottom of the container, their redispersion is facilitated by the vehicle thinning when shaken. When the shaking is discontinued, the vehicle regains its original consistency and the redispersed particles are held suspended. This process of redispersion, facilitated by a shear-thinning vehicle, presupposes that the deflocculated particles have not

yet formed a cake. If sedimentation and packing have proceeded to the point where considerable caking has occurred, redispersion is virtually impossible.

### Controlled Flocculation

When using the controlled flocculation approach (see Figure 21-2B and C), the formulator takes the deflocculated, wetted dispersion of particles and attempts to bring about flocculation by the addition of a flocculating agent; most commonly, these are electrolytes, polymers, or surfactants. The aim is to *control* flocculation by adding that amount of flocculating agent that results in the maximum sedimentation volume.

### Flocculation using Electrolytes

*Electrolytes* are probably the most widely used flocculating agents. They act by reducing the electrical forces of repulsion between particles, thereby allowing the particles to form the loose flocs so characteristic of a flocculated suspension. As the ability of particles to come together and form a floc depends on their surface charge, zeta potential measurements on the suspension, as an electrolyte is added, provide valuable information as to the extent of flocculation in the system.

This principle is illustrated by reference to the following example, taken from the work of Haines and Martin.<sup>2</sup> Particles of sulfamerazine in water bear a negative charge. The serial addition of a suitable electrolyte, such as aluminum chloride, causes a progressive reduction in the zeta potential of the particles. This is due to the preferential adsorption of the trivalent aluminum cation. Eventually, the zeta potential will reach zero and then become positive as the addition of  $\text{AlCl}_3$  is continued.

If sedimentation studies are run simultaneously on suspensions containing the same range of  $\text{AlCl}_3$  concentrations, a relationship is observed (Figure 21-3) between the sedimentation volume  $F$ , the presence or absence of caking, and the zeta potential of the particles. To obtain a flocculated, noncaking suspension with the maximum sedimentation volume, the zeta potential must be controlled so as to lie within a certain range (generally less than 25 mV). This is achieved by the judicious use of an electrolyte. A comparable situation is observed when a negative ion such as  $\text{PO}_4^{3-}$  is added to a suspension of positively charged particles such as bismuth subnitrate.

**Figure 21-3.** Typical relationship between caking, zeta potential, and sedimentation volume, as a positively charged flocculating agent is added to a suspension of negatively charged particles.: zeta potential.: sedimentation volume.

Work by Matthews and Rhodes<sup>3-5</sup> involving both experimental and theoretical studies has confirmed the formulation principles proposed by Martin and Haines. The suspensions used by Matthews and Rhodes contained 2.5%  $w/v$  of griseofulvin as a fine powder together with the anionic surfactant sodium dioxyethylated dodecyl sulfate ( $10^{-3}$  molar) as a wetting agent. Increasing concentrations of aluminum chloride were added and the sedimentation height (equivalent to the sedimentation volume, see Chapter 20) and the zeta potential recorded. Flocculation occurred when a concentration of  $10^{-3}$  molar aluminum chloride was reached. At this point the zeta potential had fallen from  $-46.4$  to  $-17.0$  mV. Further reduction of the zeta potential, to  $-4.5$  mV by use of  $10^{-2}$  molar aluminum chloride did not increase sedimentation height, in agreement with the principles shown in Figure 21-3.

Matthews and Rhodes then went on to show, by computer analysis, that the DLVO theory (see Chapter 20) predicted the results obtained—namely, that the griseofulvin suspensions under investigation would remain deflocculated when the concentration of aluminum chloride was  $10^{-4}$  molar or less. Only at concentrations in the range of  $10^{-3}$  to  $10^{-2}$  molar aluminum chloride did the theoretical plots show deep primary minima, indicative of flocculation. These occurred at a distance of separation between particles of approximately  $50 \text{ \AA}$ , which led Matthews and Rhodes to conclude that coagulation had taken place in the primary minimum.

Schneider *et al.*<sup>6</sup> have published details of a laboratory investigation (suitable for undergraduates) that combines calculations based on the DLVO theory carried out with an interactive computer program with actual sedimentation experiments performed on simple systems.

### Flocculation by Polymers

In addition to electrolytes, *polymers* play an important role as flocculating agents in pharmaceutical suspensions. Many of the hydrocolloids that produce structured vehicles can also be used to flocculate drug particles. Flocculation by polymers is generally less well understood than flocculation by inorganic electrolytes and their successful use as flocculants may require trial and error in order to identify optimal selection of a polymer and an appropriate concentration. Nonetheless, the production of stable and elegant suspensions using polymers is common in pharmaceutical suspensions.

The effectiveness of a polymer as a stabilizing agent for suspensions primarily depends on the affinity of the polymer for the particle surface as well as the charge, size, and orientation of the polymer molecule in the continuous phase. Many pharmaceutically useful polymers contain polar functional groups that are separated by a hydrocarbon backbone. As a result of this structure, a polymer molecule may adsorb to particle surfaces while maintaining a degree of interaction with the solvent. As observed with inorganic ionic flocculating agents, polymers can produce both flocculated and deflocculated suspensions. An ionic polymer has the potential to affect the zeta potential of a particle in a manner similar to inorganic electrolytes. However, it is believed that polymers can also act as flocculating agents due to the bridging of the polymer between the surfaces of different particles.<sup>1</sup> The effect can be highly concentration dependent as illustrated in Figure 21-4.

At very low concentrations of polymer, bridging between particles occurs as a result of the simultaneous adsorption of a polymer molecule onto the surfaces of different particles. At somewhat higher concentrations of polymer, sufficient binding sites are still available on the particles, permitting additional interparticle attachments to form. It is these intermediate concentrations that result in optimum flocculation and sedimentation volume. At high concentrations of polymer, complete coverage of the particle surface with polymer occurs and insufficient binding sites remain on the particles to permit interparticle bridging. In this case, the degree of flocculation is low, but the close association of individual particles is inhibited by

**Figure 21-4.** Flocculation by hydrophilic polymers. Optimal degree of flocculation and sedimentation volume occurs when a large number of interparticle bridges are formed. High concentrations of polymer result in a deflocculated suspension via steric repulsion.

a phenomenon known as steric stabilization. In general, *steric stabilization* refers to the ability of adsorbed polymers to prevent close approach and cohesion of dispersed particles due to the fact that the mixing of polymers adsorbed at the particle surfaces is energetically unfavorable. Suspensions formulated with relatively high concentrations of polymer would be deflocculated and therefore tend to have small sedimentation volumes. For further information on the practical considerations in the formulation of suspensions using polymers the reader is directed to an article by Scheer.<sup>7</sup>

The sedimentation volume achieved by addition of polymeric flocculating agents may or may not agree with DLVO theory. For example, Kellaway and Najib<sup>8</sup> found that sulfadimidine suspensions stabilized with the anionic polymer sodium carboxymethylcellulose obeyed the expected relationship between electrophoretic mobility, a measurement that is proportional to zeta potential, and to sedimentation volume in agreement with Figure 21-3. However, stabilization of the suspension with the nonionic polymer polyvinylpyrrolidone (PVP) did not obey the expected relationship between electrophoretic mobility and sedimentation volume. At high concentrations of PVP, particles had a low zeta potential, but contrary to the predictions of Figure 21-3 a low sedimentation volume was observed. Although adsorption of the polymer reduced the charge at the plane of shear, flocculation did not occur. This is believed to be due to steric stabilization of the particles at high concentrations of PVP with few interparticle bonds resulting in a low degree of flocculation.

The conformation of the polymers in the continuous phase may also have an effect on the degree of flocculation. At concentrations where flocculation occurs, polymers that have a

linear conformation in the continuous phase will generally be more effective flocculants than polymers that are coiled in the continuous phase.

In some situations, a combination of polymeric and ionic flocculating agents have been used. In general, the sensitivity of the dispersed solid to flocculation by added electrolyte is enhanced by the presence of the polymer.

Table 21-3 contains a list of suspending agents that have been used in the formulation of pharmaceutical suspensions. Many of these can serve dual functions as flocculating/stabilizing and viscosity enhancing agents.

### Flocculation using Detergents

*Detergents* can be used to produce flocculation in suspensions. Ionic detergents can produce flocculation by neutralization of the charges on the surface of the drug particle. Direct neutralization of particle surface charge occurs due to the adsorption of the detergent to the particle surface. As a result, repulsive forces between particles is reduced and close association of particles can occur. When used as flocculating agents, ionic detergents would need to have a charge that is opposite of the drug particle charge. The optimum concentration required to achieve flocculation is generally determined by experimentation.

### Flocculation in Structured Vehicles

The ideal formulation for a suspension would seem to be when flocculated particles are supported in a structured vehicle. As shown in Figure 21-2 (under C), the process involves dispersion of the particles and their subsequent flocculation. Finally, a lyophilic polymer is added to form the structured vehicle. In developing the formulation, care must be taken to ensure the absence of any incompatibility between the flocculating agent and the polymer used for the structured vehicle. A limitation is that virtually all the structured vehicles in common use are hydrophilic colloids and carry a negative charge. This means that an incompatibility arises if the charge on the particles is originally negative. Flocculation in this instance requires the addition of a positively charged flocculating agent or ion; in the presence of such a material, the negatively charged suspending agent may coagulate and lose its suspendability. This situation does not arise with particles that bear a positive charge, as the negative flocculating agent that the formulator must employ is compatible with the similarly charged suspending agent.

A method that can be used to circumvent incompatibilities between an anionic suspending agent and a cationic flocculating agent is to reverse the charge on the particle through the use of a positively charged surface active material such as gelatin. Adsorption of gelatin to the surface of a negatively charged particle can reverse the particle charge when the continuous phase is adjusted to a relatively low pH. This may permit flocculation to be achieved with an anionic flocculating agent such as citrate ion or phosphate ion. Addition of these flocculating agents would be compatible with polymeric suspending agents that largely consist of molecules of anionic charge. Martin *et al.*<sup>9</sup> have suggested that this effect can also be achieved using surface active amines, provided their toxicity does not prevent their use.

### Particle Size and Distribution

Particle size is an important consideration for the physical stability of a suspension. As predicted by Stokes' law, particles of small diameter tend to settle more slowly compared to larger particles; however, small particles will have an increased tendency to cake upon settling if they are not flocculated. In addition, particle-particle interactions can also have a significant effect on suspension stability. For suspensions with a relatively high percentage of solids, interparticle interactions may produce more viscous or thixotropic dispersions. Smaller particles will have a high surface area/weight ratio that favors interactions between the particles and may produce desirable rheological characteristics.

**Table 21-3. Suspending Agents Used in the Formulation of Pharmaceutical Suspensions**

Type of Polymer	Examples	Structure	Commercial Names
<i>Cellulose derivatives</i>			
Anionic	Carboxymethylcellulose (CMC)	Cellulose ether	
	Microcrystalline cellulose blends	Crystalline cellulose + cellulose ether	Avicel
Nonionic	Methylcellulose (MC) Ethylcellulose (EC) Hydroxyethylcellulose (HEC) Hydroxypropylcellulose (HPC) Hydroxypropylmethylcellulose (HPMC)	Cellulose ether	MC - Methocel, Metocel, Tylopur, Culminol, Celocol, Walsroder EC - Ethocel HEC - Natrasol, Cellocize, Bermocol, Tylose, Blanose HPC-Klucel, Lacrisert HPMC - Methocel, Methlose, Pharmacoat, Culminol, Tylose, Celocol
<i>Natural polymers</i>			
Anionic	alginates, carageenan, xanthan gum, acacia, tragacanth	polysaccharide	
Nonionic	locust bean gum, guar gum	polysaccharide	
<i>Synthetic polymers</i>			
Anionic	Carbomers	Crosslinked polyacrylate	Carbopol
Nonionic	Polyvinyl pyrrolidone (PVP), polyvinyl alcohol (PVA) poloxamer		Plasdone, Povidone, Kollidon
<i>Clays</i>	Magnesium aluminum silicate (Veegum), bentonite, Hectorite	Hydrated aluminum silicate, Magnesium hectorite	

In addition to the effects on the physical properties of a suspension, particle size has important implications on the biopharmaceutical performance of the drug. Aqueous suspensions can effectively serve as a means to deliver poorly water-soluble drugs by the enteral, parenteral, and topical routes. For drugs whose solubility in water is low, the dissolution rate of the drug particles may be a primary factor that limits absorption of the drug. In these cases, the rate and extent of absorption of the drug may be enhanced through the use of small particles. Small particles dissolve faster than larger particles due to the increased surface area per unit weight of drug of the former. Lastly, the uniformity of dosing over the life of the product will be enhanced by ensuring that a relatively small particle size is achieved. This is especially true for suspensions whose individual doses are withdrawn from a larger container, such as suspensions for oral use. Additional information on the bioavailability of drug from suspensions is presented at the end of this chapter.

As most pharmaceutical powders are polydisperse rather than monodisperse, the distribution of particle sizes may also play an important role in the physical stability of a suspension. A relatively narrow distribution of particle sizes is desirable for good stability. A narrow particle size distribution provides a more uniform settling rate and allows for better predictability of suspension properties from batch to batch of finished suspension. In addition, the phenomenon of Ostwald ripening will be minimized when the distribution of particles is narrow. *Ostwald ripening* is the phenomenon in which larger particles grow in size due to the dissolution of smaller particles. This phenomenon could result in pharmaceutically unstable suspensions (caking) and alter the bioavailability of the product through an alteration in the dissolution rate. The use of an appropriate polymer with an affinity for the surface of the dispersed solid reduces or eliminates crystallization in suspensions that may occur due to Ostwald ripening or dissolution/crystallization phenomenon caused by temperature fluctuations. This effect

occurs at concentrations of polymer that provide complete surface coverage of the particles. Thus, a hydrophilic colloid, such as a cellulose derivative, with high affinity for the particle surface is often added initially to the suspension formulation to provide a protective action.

In flocculated suspensions, a narrow distribution of particles also tends to result in floccules with a more opened structure. If a flocculated suspension is prepared using a powder with a wide distribution of particles, the floccules would consist of links between larger particles with small particles filling the voids created by the interparticle links between larger particles. This would create a floccule that is more dense compared to the more open structure that would be expected from a floccule composed of particles of more uniform size. The more opened floccule structure is desirable, as it may exhibit thixotropic properties in addition to a large sedimentation volume.

### Nonaqueous Suspensions

Although most pharmaceutical suspensions have a primarily aqueous continuous phase, formulation of a drug in a nonaqueous continuous phase is occasionally required. Suspension of a water-soluble drug in a nonaqueous vehicle may provide a means to prepare a liquid formulation of a drug that has poor long-term stability in aqueous solution. Dispersions of drugs in oleaginous vehicles can also provide a sustained release form of drug as observed with certain depot injections and topical products.

Aerosols represent another important class of nonaqueous suspensions. The physical stability of suspended drugs in nonaqueous propellants for aerosol products can have a significant impact on the uniformity of dose and operation of the aerosol system. Caking of the suspended particles can cause clogging of the various mechanical components of the aerosol system.

According to Coulomb's law, the force between two charges is inversely proportional to the dielectric constant of the medium between the charges:

$$f_{\infty} \frac{q_1 q_2}{Dx^2} \quad (6)$$

where  $f$  is the force between the particles,  $q_1$  and  $q_2$  are the charges on the particles,  $D$  is the dielectric constant, and  $x$  is the distance between the charges.

In general, most nonaqueous pharmaceutical liquids have a dielectric constant that is lower than water. This would result in a greater attraction between ions or particles of opposite charge and greater repulsion between ions or particles of similar charge. The effect of a continuous phase of low dielectric constant can therefore affect a suspension formulation in different ways. The use of added electrolytes will be less useful due to their low degree of ionization and poor solubility in some nonaqueous media. In addition, the density of charges on the particle surfaces will be reduced, but repulsion between particles may be facilitated. The result is that controlled flocculation using electrolytes is difficult to achieve as with aqueous suspensions, and caking may occur upon settling. Thus, alternate means of producing pharmaceutically acceptable suspensions must be employed.

Nonionic surfactants of low HLB values can be used to improve the physical stability of the suspensions. Stearic and other aliphatic acids and stearate salts, particularly aluminum monostearate, have been used as suspending agents. These materials increase the viscosity of the oil and produce a structured medium that can hinder the settling of drug particles. Alternatively, thickening agents such as Avicel, colloidal silicon dioxide, and long-chain alcohols can be used to reduce the sedimentation rate in nonaqueous suspensions.

Few studies have been performed to predict formulation and physical stability of drugs in nonaqueous suspensions. Parsons *et al.*<sup>10</sup> found that the suspension properties of a number of solids in a nonaqueous aerosol propellant depended on the surface properties of the solids. Solids that had relatively polar surfaces tended to aggregate to larger extents than solids with relatively nonpolar surfaces. The moisture content of the dispersed solid and continuous phase may also play an important role on the aggregation of the solid. Adsorbed moisture on the dispersed solid may help to create a liquid bridge between particles when dispersed in certain nonaqueous solvents. If carefully controlled, this could provide a means to obtain some degree of flocculation in certain nonaqueous vehicles. Examples are discussed by Hiestand.<sup>1</sup>

### Chemical Stability of Suspensions

Particles that are completely insoluble in a liquid vehicle are unlikely to undergo most chemical reactions leading to degradation. However, most drugs in suspension have a finite solubility, even though this may be of the order of fractions of a microgram per milliliter. As a result, the material in solution may be susceptible to degradation. However, Tingstad *et al.*<sup>11</sup> developed a simplified method for determining the stability of drugs in suspension. The approach is based on the assumptions that

1. degradation takes place only in the solution and is first order.
2. the effect of temperature on drug solubility and reaction rate conforms with classical theory.
3. dissolution is not rate-limiting on degradation.

### Preparation of Suspensions

The small-scale preparation of suspensions may be undertaken readily by the practicing pharmacist with the minimum of equipment. The initial dispersion of the particles is best carried out by trituration in a mortar, the wetting agent being added in small increments to the powder. Once the particles have been wetted adequately, the slurry may be transferred to the final container. The next step depends on whether the deflocculated particles are to be suspended in a structured vehicle, flocculated, or flocculated and then suspended. Regardless of

**Table 21-4. Commercially Available Vehicles used for the Extemporaneous Preparation of Pharmaceutical Suspensions**

Commercial Name	pH	Supplier/Manufacturer
Ora-Plus	4.2	Paddock
Ora-Blend	4.2	Paddock
Suspendol-S	5.3–6.0	Paddock

Syrspend SF Alka*	Alkaline	Gallipot

\* Supplied as dry powder to be reconstituted prior to use.

which of the alternative procedures outlined in Figure 21-2 is employed, the various manipulations can be carried out easily in the bottle, especially if an aqueous solution of the suspending agent has been prepared beforehand. Pre-formulated vehicles are commercially available to pharmacists to facilitate the extemporaneous preparation of suspensions. These products are essentially aqueous structured vehicles that contain cellulosic suspending agents, surfactants, buffering agents, and electrolytes. Some products may contain sweetening agents. Pre-formulated suspending vehicles are available at acidic or basic pH to match physical and chemical stability requirements of different drugs. Table 21-4 list some commercially available suspension vehicles that can be used for extemporaneous compounding.

It is most common in modern pharmacy practice to prepare suspensions using commercially available tablets or capsules as a source of the active ingredient. Examples of compounding using solid oral dosage forms as starting material can be found in the pharmaceutical literature<sup>12</sup>

For detailed discussion of the methods used in the large-scale production of suspensions, see the relevant section in Chapter 24.

## EMULSIONS

An *emulsion* is a dispersed system containing at least two immiscible liquid phases. The majority of conventional emulsions in pharmaceutical use have dispersed particles ranging in diameter from 0.1 to 100  $\mu\text{m}$ . As with suspensions, emulsions are thermodynamically unstable as a result of the excess free energy associated with the surface of the droplets. The dispersed droplets, therefore, strive to come together and reduce the surface area. In addition to this flocculation effect, also observed with suspensions, the dispersed particles can coalesce, or fuse, and this can result in the eventual destruction of the emulsion. To minimize this effect, a third component, the *emulsifying agent*, is added to the system to improve its stability. The choice of emulsifying agent is critical to the preparation of an emulsion possessing optimum stability. The efficiency of present-day emulsifiers permits the preparation of emulsions that are stable for many months and even years, even though they are thermodynamically unstable.

In recent years, it has been recognized that complex multiple-phase combinations can exist in emulsions. Thus, liquid crystalline phases and gel structures can form from the combination of the basic three-component mixture of water, oil, and surfactant (emulsifying agent). Often, these structures confer significant stability to the emulsion and therefore are to be desired. Such multiple-phase emulsions and their stability have been reviewed by Eccleston.<sup>13</sup>

Emulsions are widely used in pharmacy and medicine, and emulsified materials can possess advantages not observed in formulations in other dosage forms. For example, certain medicinal agents that have an objectionable taste have been made

more palatable for oral administration when formulated in an emulsion. The principles of emulsification have been applied extensively in the formulation of dermatological creams and lotions. Intravenous emulsions of contrast media have been developed to assist the physician in undertaking x-ray examinations of the body organs while exposing the patient to the minimum of radiation. Considerable attention has been directed towards the use of sterile, stable intravenous emulsions containing fat, carbohydrate, and vitamins all in one preparation. Such products are administered to patients unable to assimilate these vital materials by the normal oral route. Emulsions are also used to deliver nutrients via the enteral route in the form of nutritional supplements. More recently, emulsions have been used to deliver poorly water-soluble drugs, such as general anesthetics and anti-cancer compounds, via the intravenous route.

Emulsions offer potential in the design of systems capable of giving controlled rates of drug release and affording protection to drugs susceptible to oxidation or hydrolysis. There is still a need for well-characterized dermatologic products with reproducible properties, regardless of whether these products are antibacterial, sustained-release, protective, or emollient lotions, creams, or ointments. In addition, emulsions may provide a useful way to deliver poorly water-soluble drugs via enteral and parenteral routes. The principle of emulsification is also involved in an increasing number of aerosol products.

The pharmacist must be familiar with the types of emulsions and the properties and theories underlying their preparation and stability; such is the purpose of the remainder of this chapter. Microemulsions, which can be regarded as isotropic, swollen micellar systems are discussed in Chapter 24.

## EMULSION TYPE AND MEANS OF DETECTION

A stable emulsion must contain at least three components: the *dispersed phase*, the *dispersion medium*, and the *emulsifying agent*. Invariably, one of the two immiscible liquids is aqueous, and the second is an oil. Whether the aqueous or the oil phase becomes the dispersed phase depends primarily on the emulsifying agent used and the relative amounts of the two liquid phases. Hence, an emulsion in which the oil is dispersed as droplets throughout the aqueous phase is termed an *oil-in-water (O/W) emulsion*. When water is the dispersed phase and an oil the dispersion medium, the emulsion is of the *water-in-oil (W/O) type*. Most pharmaceutical emulsions designed for oral administration are of the O/W type; emulsified lotions and creams are either O/W or W/O, depending on their use. Butter and salad creams are W/O emulsions.

So-called *multiple emulsions* have been developed with a view to delaying the release of an active ingredient. In these types of emulsions three phases are present: the emulsion has the form W/O/W or O/W/O. In these “emulsions within emulsions,” any drug present in the innermost phase must now cross two phase boundaries to reach the external, continuous phase.

It is important for pharmacists to know the type of emulsion they have prepared or are dealing with, because this can affect its properties and performance. Unfortunately, the several methods available can give incorrect results, so the type of emulsion determined by one method should always be confirmed by means of a second method.

### DILUTION TEST

The dilution method depends on the fact that an O/W emulsion can be diluted with water and a W/O emulsion with oil. When oil is added to an O/W emulsion or water to a W/O emulsion, the additive is not incorporated into the emulsion and separation is apparent. The test is greatly improved if the addition of the water or oil is observed microscopically.

### CONDUCTIVITY TEST

An emulsion in which the continuous phase is aqueous can be expected to possess a much higher conductivity than an

emulsion in which the continuous phase is an oil. Accordingly, it frequently happens that when a pair of electrodes, connected to a lamp and an electrical source, are dipped into an O/W emulsion, the lamp lights because of the passage of a current between the two electrodes. If the lamp does not light, it is assumed that the system is W/O.

### DYE-SOLUBILITY TEST

The knowledge that a water-soluble dye will dissolve in the aqueous phase of an emulsion while an oil-soluble dye will be taken up by the oil phase provides a third means of determining emulsion type. Thus, if microscopic examination shows that a water-soluble dye has been taken up by the continuous phase, we are dealing with an O/W emulsion. If the dye has not stained the continuous phase, the test is repeated using a small amount of an oil-soluble dye. Coloring of the continuous phase confirms that the emulsion is of the W/O type.

## FORMATION AND BREAKDOWN OF DISPERSED LIQUID DROPLETS

An emulsion exists as the result of two competing processes: the dispersion of one liquid throughout another as droplets, and the combination of these droplets to reform the initial bulk liquids. The first process increases the free energy of the system, while the second works to reduce the free energy. Accordingly, the second process is spontaneous and continues until breakdown is complete—that is, until the bulk phases are reformed.

It is of little use to form a well-dispersed emulsion if it quickly breaks down. Similarly, unless adequate attention is given to achieving an optimum dispersion during preparation, the stability of an emulsion system may be compromised from the start. Dispersion is brought about by well-designed and well-operated machinery, capable of producing droplets in a relatively short period of time. Such equipment is discussed in Chapter 24. The reversal back to the bulk phases is minimized by using those parameters that influence the stability of the emulsion once it is formed.

### DISPERSION PROCESS TO FORM DROPLETS

Consider two immiscible liquid phases in a test tube. To disperse one liquid as droplets within the other, the interface between the two liquids must be disturbed and expanded to a sufficient degree so that “fingers” or threads of one liquid pass into the second liquid, and *vice versa*. These threads are unstable, and become varicose or beaded. The beads separate and become spherical, as illustrated in Figure 21-5. Depending on the agitation or the shear rate used, larger droplets are also deformed to give small threads, which in turn produce smaller drops.

The time of agitation is important. Thus, the mean size of droplets decreases rapidly in the first few seconds of agitation. The limiting size range is generally reached within 1 to 5 min, and results from the number of droplets coalescing being equivalent to the number of new droplets being formed. It is uneconomical to continue agitation any further.

The liquids may be agitated or sheared by several means. *Shaking* is employed commonly, especially when the components are of low viscosity. Intermittent shaking is frequently more efficient than continual shaking, possibly because the short time interval between shakes allows the thread that is forced across the interface time to break down into drops that are then isolated in the opposite phase. Continuous, rapid agitation tends to hinder this breakdown to form drops. A mortar and pestle is employed frequently in the extemporaneous preparation of emulsions. It is not a very efficient technique and is not used on a large scale. Improved dispersions are achieved by the use of high-speed mixers, blenders, colloid mills, or homogenizers. Ultrasonic techniques also have been employed and are described in Chapter 24.

The phenomenon of *spontaneous emulsification*, as the name implies, occurs without any external agitation. There

**Figure 21-5.** Effect of rate of coalescence on emulsion type. Rate 1: O/W coalescence rate. Rate 2: W/O coalescence rate.; oil.: water. For an explanation of Rates 1 and 2, refer to the discussion of Davies on page 329<sup>14</sup>.

is, however, an internal agitation arising from certain physicochemical processes that affect the interface between the two bulk liquids. For a description of this process, see Davies and Rideal in the bibliography.

### COALESCENCE OF DROPLETS

*Coalescence* is a process distinct from flocculation (aggregation), which commonly precedes it. Flocculation is the clumping together of particles, but coalescence is the fusing of the agglomerates into a larger drop, or drops. Coalescence usually is rapid when two immiscible liquids are shaken together, as there is no large energy barrier to prevent fusion of drops and reformation of the original bulk phases. When an emulsifying agent is added to the system, flocculation still may occur but coalescence is reduced to an extent depending on the efficacy of the emulsifying agent to form a stable, coherent interfacial film. It is therefore possible to prepare emulsions that are flocculated yet do not coalesce. In addition to the interfacial film around the droplets acting as a mechanical barrier, the drops also are prevented from coalescing by the presence of a thin layer of continuous phase between particles clumped together. Davies<sup>14</sup> showed the importance of coalescence rates in determining emulsion type; this work is discussed in more detail on page 329.

### EMULSIFYING AGENT

The process of coalescence can be reduced to insignificant levels by the addition of a third component—the emulsifying agent or *emulsifier*. The choice of emulsifying agent is frequently critical in developing a successful emulsion, and the pharmacist should be aware of

- the desirable properties of emulsifying agents.
- how different emulsifiers act to optimize emulsion stability.
- how the type and physical properties of the emulsion can be affected by the emulsifying agent.

### DESIRABLE PROPERTIES

Some of the desirable properties of an emulsifying agent are that it should

1. be surface active and reduce surface tension to below 10 dynes/cm.
2. be adsorbed quickly around the dispersed drops as a condensed, nonadherent film that will prevent coalescence.
3. impart to the droplets an adequate electrical potential so that mutual repulsion occurs.
4. increase the viscosity of the emulsion.
5. be effective in a reasonably low concentration.

Not all emulsifying agents possess these properties to the same degree; in fact, not every good emulsifier necessarily possesses all these properties. Further, there is no one ideal emulsifying agent because the desirable properties of an emulsifier depend, in part, on the properties of the two immiscible phases in the particular system under consideration.

### Interfacial Tension

Lowering of interfacial tension is one way in which the increased surface free energy associated with the formation of droplets, and hence surface area, in an emulsion can be reduced (Equation 1). Assuming the droplets to be spherical, it can be shown that

$$\Delta F = \frac{6\gamma V}{d} \quad (7)$$

where  $V$  is the volume of dispersed phase in milliliters, and  $d$  is the mean diameter of the particles. To disperse 100 mL of oil as 1- $\mu\text{m}$  ( $10^{-4}$ -cm) droplets in water when  $\gamma_{O/W} = 50$  dynes/cm, requires an energy input of

$$\begin{aligned} \Delta F &= \frac{6 \times 50 \times 100}{1 \times 10^{-4}} = 30 \times 10^7 \text{ ergs} \\ &= 30 \text{ joules or } 30/4.184 = 7.2 \text{ cal} \end{aligned}$$

In the above example the addition of an emulsifier that will reduce  $\gamma$  from 50 to 5 dynes/cm will reduce the surface free energy from 7.2 to around 0.7 cal. Likewise, if the interfacial tension is reduced to 0.5 dynes/cm (a common occurrence), the original surface free energy is reduced a hundredfold. Such a reduction can help to maintain the surface area generated during the dispersion process.

### Film Formation

The major requirement of a potential emulsifying agent is that it readily form a *film* around each droplet of dispersed material. The main purpose of this film—which can be a monolayer, a multilayer, or a collection of small particles adsorbed at the interface—is to form a barrier that prevents the coalescence of droplets that come into contact with one another. For the film to be an efficient barrier, it should possess some degree of surface elasticity and should not thin out and rupture when sandwiched between two droplets. If broken, the film should have the capacity to reform rapidly.

### Electrical Potential

The origin of an electrical potential at the surface of a droplet has been discussed earlier in the chapter. Insofar as emulsions are concerned, the presence of a well-developed charge on the droplet surface is significant in promoting stability by causing repulsion between approaching drops. This potential is likely to be greater when an ionized emulsifying agent is employed. Electrical potential has been shown to be a significant factor for maintaining the stability of intravenous fat emulsions that are stabilized with lecithin.

## Concentration of Emulsifier

The main objective of an emulsifying agent is to form a condensed film around the droplets of the dispersed phase. An inadequate concentration will do little to prevent coalescence. Increasing the emulsifier concentration above an optimum level achieves little in terms of increased stability. In practice the aim is to use the minimum amount consistent with producing a satisfactory emulsion.

It frequently helps to have some idea of the amount of emulsifier required to form a condensed film, one molecule thick, around each droplet. Suppose we wish to emulsify 50 g of an oil, density = 1.0, in 50 g of water. The desired particle diameter is 1  $\mu\text{m}$ . Thus,

$$\text{Particle diameter} = 1 \mu\text{m} = 1 \times 10^{-4} \text{ cm}$$

$$\text{Volume of particle} = (\pi d^3 / 6) = 0.524 \times 10^{-12} \text{ cm}^3$$

$$\text{Total number of particles in 50 g} = (50 / 0.524 \times 10^{-12}) = 95.5 \times 10^{12}$$

$$\text{Surface area of particle} = \pi d^2 = 3.142 \times 10^{-8} \text{ cm}^2$$

$$\text{Total surface area} = 3.142 \times 10^{-8} \times 95.5 \times 10^{12} = 300 \times 10^4 \text{ cm}^2$$

If the area each molecule occupies at the oil–water interface is 30  $\text{\AA}^2$  ( $30 \times 10^{-16} \text{ cm}^2$ ), we require

$$\frac{300 \times 10^4}{30 \times 10^{-16}} = 1 \times 10^{21} \text{ molecules}$$

A typical emulsifying agent might have a molecular weight of 1000. Thus, the required weight is

$$\frac{1000}{6.023 \times 10^{23}} \times 1 \times 10^{21} = 1.66 \text{ g}$$

To emulsify 10 g of oil would require 0.33 g of the emulsifying agent.

Although the approach is an oversimplification of the problem, it does at least allow the formulator to make a reasonable estimate of the required concentration of emulsifier.

## Emulsion Rheology

The emulsifying agent and other components of an emulsion can affect the rheologic behavior of an emulsion in several ways, as summarized in Table 21-5.<sup>15</sup> It should be borne in mind that the droplets of the internal phase are deformable under shear and that the adsorbed layer of emulsifier affects the interactions between adjacent droplets and also between a droplet and the continuous phase. The means by which the rheological behavior of emulsions can be controlled have been discussed by Rogers.<sup>16</sup>

### MECHANISM OF ACTION

Emulsifying agents may be classified in accordance with the type of film they form at the interface between the two phases.

#### Monomolecular Films

Those surface-active agents that are capable of stabilizing an emulsion do so by forming a monolayer of adsorbed molecules or ions at the oil–water interface (Figure 21-6). In accordance with Gibbs' law (Chapter 19) the presence of an interfacial excess necessitates a reduction in interfacial tension. This results in a more stable emulsion because of a proportional reduction in the surface free energy. Of itself, this reduction is probably not the main factor promoting stability. More significant is the fact that the droplets are surrounded now by a coherent monolayer that prevents coalescence between approaching droplets. If the emulsifier forming the monolayer is ionized, the presence of strongly charged and mutually repelling droplets increases the stability of the system. With un-ionized, nonionic surface-active agents, the particles may still carry a charge; this arises from adsorption of a specific ion or ions from solution.

**Table 21-5. Factors Influencing Emulsion Viscosity**

1. Internal phase
  - a. Volume concentration ( $\phi$ ); hydrodynamic interaction between globules; flocculation, leading to formation of globule aggregates.
  - a. Viscosity ( $\eta_i$ ); deformation of globules in shear.
  - b. Globule size, and size distribution, technique used to prepare emulsion; interfacial tension between the two liquid phases; globule behavior in shear; interaction with continuous phase; globule interaction.
2. Chemical constitution.
  - a. Continuous phase
  - b. Viscosity ( $\eta_0$ ), and other rheological properties.
  - c. Chemical constitution, polarity, pH; potential energy of interaction between globules.
  - d. Electrolyte concentration if polar medium.
3. Emulsifying agent
  - a. Chemical constitution; potential energy of interaction between globules.
  - b. Concentration, and solubility in internal and continuous phases; emulsion type; emulsion inversion; solubilization of liquid phases in micelles.
  - c. Thickness of film adsorbed around globules, and its rheological properties, deformation of globules in shear; fluid circulation within globules.
  - d. Electroviscous effect.
4. Additional stabilizing agents
  - a. Pigments, hydrocolloids, hydrous oxides.
  - b. Effect on rheological properties of liquid phases, and interfacial boundary region.

(From Davies JT. In: *Proceedings of the International Congress on Surface Activity*, 2nd ed. London: Butterworth/Academic, 1957, p 426.)

**Figure 21-6.** Types of films formed by emulsifying agents at the oil–water interface. Orientations are shown for O/W emulsions.: oil.: water.

### Multimolecular Films

Hydrated lyophilic colloids form multimolecular films around droplets of dispersed oil (see Figure 21-6). The use of these agents has declined in recent years because of the large number of synthetic surface-active agents available that possess well-marked emulsifying properties. Although these hydrophilic colloids are adsorbed at an interface (and can be regarded therefore as surface active), they do not cause an appreciable lowering in surface tension. Rather, their efficiency depends on their ability to form strong coherent multimolecular films. These act as a coating around the droplets and render them highly resistant to coalescence, even in the absence of a well-developed surface potential. Furthermore, any hydrocolloid not adsorbed at the interface increases the viscosity of the continuous aqueous phase; this enhances emulsion stability.

### Solid Particle Films

Small solid particles that are wetted to some degree by both aqueous and nonaqueous liquid phases act as emulsifying agents. If the particles are too hydrophilic, they remain in the aqueous phase; if too hydrophobic, they are dispersed completely in the oil phase. A second requirement is that the particles are small in relation to the droplets of the dispersed phase (see Figure 21-6).

### CHEMICAL TYPES

Emulsifying agents also may be classified in terms of their chemical structure; there is some correlation between this classification and that based on the mechanism of action. For example, the majority

of emulsifiers forming monomolecular films are synthetic, organic materials. Most of the emulsifiers that form multimolecular films are obtained from natural sources and are organic. A third group is composed of solid particles, invariably inorganic, that form films composed of finely divided solid particles.

Accordingly, the classification, adopted divides emulsifying agents into *synthetic*, *natural*, and *finely dispersed solids* (Table 21-6). A fourth group, the *auxiliary materials* (Table 21-7) are weak emulsifiers. The list of agents is not meant to be exhaustive, but rather merely illustrates the various types available.

### Synthetic Emulsifying Agents

Synthetic emulsifying agents, a group of surface-active agents that act as emulsifiers, may be subdivided into anionic, cationic, and nonionic, depending on the charge possessed by the surfactant.

*Anionics*—In the anionic subgroup, the surfactant ion bears a negative charge. The potassium, sodium, and ammonium salts of lauric and oleic acid are soluble in water and are good O/W emulsifying agents. They do, however, have a disagreeable taste and are irritating to the gastrointestinal (GI) tract; this limits them to emulsions prepared for external use. Potassium laurate, a typical example, has the structure

Solutions of *alkali soaps* have a high pH; they start to precipitate out of solution below pH 10 because the unionized fatty acid is now formed, and this has a low aqueous solubility.

**Table 21-6. Classification of Emulsifying Agents**

Type	Type of Film	Examples	
Synthetic (surface-active agents)	Monomolecular	<i>Anionic</i> Soaps Potassium laurate Triethanolamine stearate Sulfates Sodium lauryl sulfate Alkyl polyoxyethylene sulfates Sulfonates Dioctyl sodium sulfosuccinate	<i>Cationic</i>
			Quaternary ammonium compounds Cetyltrimethylammonium bromide Lauryldimethylbenzylammonium chloride
			<i>Nonionic</i>
			Polyoxyethylene fatty alcohol ethers Sorbitan fatty acid esters Polyoxyethylene sorbitan fatty acid esters Polyoxyethylene polyoxypropylene block copolymers (poloxamers) Lanolin alcohols and ethoxylated lanolin alcohols
Natural	Multimolecular	<i>Hydrophilic colloids</i> Acacia Gelatin	
	Monomolecular	Lecithin Cholesterol	
Finely divided solids	Solid particle	<i>Colloidal clays</i> Bentonite Veegum <i>Metallic hydroxides</i> Magnesium hydroxide	

**Table 21-7. Auxiliary Emulsifying Agents**

Product	Source and Composition	Principal Use
Cetyl alcohol	Chiefly C <sub>16</sub> H <sub>33</sub> OH	Lipophilic thickening agent and stabilizer for O/W lotions and ointments
Glyceryl monostearate	C <sub>17</sub> H <sub>35</sub> COOCH <sub>2</sub> CHOHCH <sub>2</sub> OH	Lipophilic thickening agent and stabilizer for O/W lotions and ointments
Methylcellulose	Series of methyl ethers of cellulose	Hydrophilic thickening agent and stabilizer for O/W emulsions; weak O/W emulsifier
Sodium carboxymethylcellulose	Sodium salt of the carboxymethyl esters of cellulose	Hydrophilic thickening agent and stabilizer for O/W emulsions
Stearic acid	A mixture of solid acids from fats, chiefly stearic and palmitic	Lipophilic thickening agent and stabilizer for O/W lotions and ointments. Forms a true emulsifier when reacted with an alkali

Further, the free fatty acid is ineffective as an emulsifier, so emulsions formed from alkali soaps are not stable at pH values less than about 10.

The calcium, magnesium, and aluminum salts of fatty acids, often termed the *metallic soaps*, are water insoluble and result in W/O emulsions.

Another class of soaps are salts formed from a fatty acid and an organic amine such as triethanolamine. These O/W emulsifiers also are limited to external preparations, but their alkalinity is considerably less than that of the alkali soaps and they are active as emulsifiers down to around pH 8. These agents are less irritating than the alkali soaps.

Sulfated alcohols are neutralized sulfuric acid esters of such fatty alcohols as lauryl and cetyl alcohol. These compounds are an important group of pharmaceutical surfactants. They are used chiefly as wetting agents, although they do have some value as emulsifiers, particularly when used in conjunction with an auxiliary agent.

*Sulfonates* are a class of compounds in which the sulfur atom is connected directly to the carbon atom, giving the general formula

A frequently used compound is sodium lauryl sulfate. Sulfonates have a higher tolerance to calcium ions and do not hydrolyze as readily as the sulfates. A widely used surfactant of this type is dioctyl sodium sulfosuccinate.

*Cationics*—The surface activity in the cationic group resides in the positively charged cation. These compounds have marked bactericidal properties. This makes them desirable in emulsified anti-infective products such as skin lotions and creams. The pH of an emulsion prepared with a cationic emulsifier lies in the pH 4 to 6 ranges. Because this includes the normal pH of the skin, cationic emulsifiers are advantageous in this regard also.

Cationic agents are weak emulsifiers and generally are formulated with a stabilizing or auxiliary emulsifying agent such as cetostearyl alcohol. The only group of cationic agents used extensively as emulsifying agents are the quaternary ammonium compounds. An example is cetyltrimethyl-ammonium bromide.

Cationic emulsifiers should not be used in the same formulation with anionic emulsifiers because they will interact. The incompatibility may not be immediately apparent as a precipitate, but virtually all of the desired antibacterial activity will generally have been lost.

*Nonionics*—Nonionics, undissociated surfactants, find widespread use as emulsifying agents when they possess the proper balance of hydrophilic and lipophilic groups within the molecule. Their popularity is based on the fact that, unlike the anionic and cationic types, nonionic emulsifiers are

not susceptible to pH changes and the presence of electrolytes. The number of nonionic agents available is legion; the most frequently used are the glyceryl esters, polyoxyethylene glycol esters and ethers, and the sorbitan fatty acid esters and their polyoxyethylene derivatives. More recently, the polyoxyethylene/polyoxypropylene block copolymers have become popular surfactants and emulsifying agents.

A glyceryl ester, such as glyceryl monostearate, is too lipophilic to serve as a good emulsifier; it is used widely as an auxiliary agent (see Table 21-7) and has the structure

Sorbitan fatty acid esters, such as sorbitan monopalmitate

are nonionic oil-soluble emulsifiers that promote W/O emulsions. The polyoxyethylene sorbitan fatty acid esters, such as polyoxyethylene sorbitan monopalmitate

[R is (C<sub>15</sub>H<sub>31</sub>)COO; Sum or w, x, y, and z is 20] are hydrophilic water-soluble derivatives that favor O/W emulsions.

Polyoxyethylene glycol esters, such as the monostearate, C<sub>17</sub>H<sub>35</sub>COO(CH<sub>2</sub>OCH<sub>2</sub>)<sub>n</sub>H, also are used widely.

Polyoxyethylene/polyoxypropylene block copolymers

also known as *poloxamers* consist of combined chains of oxyethylene with oxypropylene where the oxyethylene portion imparts hydrophilicity and the oxypropylene portion imparts lipophilicity. The molecules are synthesized as long segments of the hydrophilic portions combined with long segments of the hydrophobic portions, with each portion referred to as a *block*. This organization produces hydrophilic and hydrophobic domains that impart the surface active character to these agents. Poloxamers have been used in the formulation of intravenous emulsions and can impart structure to vehicles and interfacial films that can protect the dispersed phase against coalescence. The polymeric nature of these surfactants protects emulsions against coalescence via steric stabilization at the droplet interface.

In general, for nonionic emulsifiers, emulsion stability is best when blends of emulsifiers are used. Thus, an O/W emulsifier customarily will be used in an emulsion with a W/O emulsifier. When blended properly, the nonionics produce fine-textured stable emulsions. For example, an emulsifier blend of polysorbates (O/W emulsifier) with sorbitan esters (W/O emulsifier) are frequently used as opposed to the use of either class of emulsifier alone. The rationale for the use of mixed emulsifiers is further discussed below in the discussion of HLB System and Mixed emulsifiers.

### Natural Emulsifying Agents

Of the numerous emulsifying agents derived from natural (i.e., plant and animal) sources, consideration will be given only to acacia, gelatin, lecithin, and cholesterol. Many other natural materials are only sufficiently active to function as auxiliary emulsifying agents or stabilizers.

*Acacia* is a carbohydrate gum that is soluble in water and forms O/W emulsions. Emulsions prepared with acacia are stable over a wide pH range. Because it is a carbohydrate it is necessary to preserve acacia emulsions against microbial attack by the use of a suitable preservative.

*Gelatin*, a protein, has been used for many years as an emulsifying agent. Gelatin can have two isoelectric points, depending on the method of preparation. So-called Type A gelatin, derived from an acid-treated precursor, has an isoelectric point of between pH 7 and 9. Type B gelatin, obtained from an alkali-treated precursor, has an isoelectric point of approximately pH 5. Type A gelatin acts best as an emulsifier around pH 3, where it is positively charged; on the other hand, Type B gelatin is best used around pH 8, where it is negatively charged. The question as to whether the gelatin is positively or negatively charged is fundamental to the stability of the emulsion when other charged emulsifying agents are present. To avoid an incompatibility, all emulsifying agents should carry the same sign. Thus, if gums (such as tragacanth, acacia, or agar) that are negatively charged are to be used with gelatin, then Type B material should be used at an alkaline pH. Under these conditions the gelatin is similarly negatively charged.

*Lecithin* is an emulsifier obtained from both plant (e.g., soybean) and animal (e.g., egg yolk) sources and is composed of various phosphatides. The primary component of most lecithins is phosphatidylcholine and the term "lecithin" is often used to describe purified samples of phosphatidylcholine. Frequently, lecithins that are used as emulsifiers also contain mixtures of phosphatides, including phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, and phosphatidic acid in addition to phosphatidylcholine. Although phosphatidylcholine is a zwitterionic compound, the presence of other phosphatides such as phosphatidylinositol and phosphatidic acid, as well as small quantities of lysophosphatides, result in an emulsifier that imparts a net negative charge to dispersed particles.

Lecithin can be an excellent emulsifier for naturally occurring oils such as soy, corn, or safflower. Highly stable O/W emulsions can be formed with these oils. Purified lecithins from soy or egg yolk are the principal emulsifiers for intravenous fat emulsions. Lecithin provides stable emulsions with droplet sizes of

less than 1  $\mu\text{m}$  in diameter. It is critical that a small, uniform particle size be maintained in these emulsions to eliminate the risks of fat embolism after intravenous injection. Commercially available intravenous fat emulsions generally resist coalescence for several years and are able to withstand high temperature sterilization by autoclaving. The excellent physical stability observed with these emulsions is believed to be the result of the large negative zeta potential that results from the small quantity of charged lipids present in lecithin as well as the ability of the lecithin to form mesophases resembling liposomes. During manufacture of the emulsions, homogenization produces small droplets that are surrounded by concentric layers of phospholipids. The latter may form a protective layer that prevents coalescence of the droplets. As an emulsifier, lecithin produces the best results at a pH of around 8.

As with any natural product, the content of lecithins will vary from source to source and their emulsifying properties and toxicity may also vary. For highly critical applications, such as intravenous emulsions, the source and composition of the lecithin must be carefully controlled and monitored.

*Cholesterol* is a major constituent of wool alcohols, obtained by the saponification and fractionation of wool fat. It is cholesterol that gives wool fat its capacity to absorb water and form a W/O emulsion.

### Finely Dispersed Solids

Finely dispersed solids are emulsifiers that form particulate films around the dispersed droplets, producing emulsions that are coarse-grained but have considerable physical stability. It appears possible that any solid can act as an emulsifying agent of this type, provided it is reduced to a sufficiently fine powder. In practice, the group of compounds used most frequently are the colloidal clays.

*Bentonite* is a white to gray, odorless and tasteless powder that swells in the presence of water to form a translucent suspension with a pH of about 9. Depending on the sequence of mixing it is possible to prepare both O/W and W/O emulsions. When an O/W emulsion is desired, the bentonite is first dispersed in water and allowed to hydrate so as to form a magma. The oil phase is then added gradually with constant titration. Because the aqueous phase is always in excess, the O/W emulsion type is favored. To prepare a W/O emulsion, the bentonite is first dispersed in oil; the water is then added gradually.

Although *Veegum* is used as a solid particle emulsifying agent, it is employed most extensively as a stabilizer in cosmetic lotions and creams. Concentrations of less than 1% *Veegum* will stabilize an emulsion containing anionic or nonionic emulsifying agents.

### Auxiliary Emulsifying Agents

Auxiliary emulsifying agents include those compounds that are normally incapable themselves of forming stable emulsions. Their main value lies in their ability to function as thickening agents and thereby help stabilize the emulsion. Agents in common use are listed in Table 21-7. Auxiliary emulsifying agents that are amphiphilic in nature are, in some cases, capable of forming gel or liquid crystalline phases with the primary emulsifying agent when combined with water and oil. This type of behavior may help to stabilize emulsions due to an increased viscosity, as observed in topical creams. Alternatively, gel or liquid crystalline phases may prevent coalescence by reducing van der Waals forces between particles or by providing a physical barrier between approaching particles of the internal phase. This latter effect is thought to be an important function in phospholipid-stabilized emulsions that must maintain a low viscosity to permit administration via the intravenous route. Additional information is provided by Eccleston.<sup>12</sup>

### EMULSIFYING AGENTS AND EMULSION TYPE

For a molecule, ion, colloid, or particle to be active as an emulsifying agent, it must have some affinity for the interface

between the dispersed phase and the dispersion medium. With the monolayer and multilayer films, the emulsifier is in solution, and therefore it must be soluble to some extent in one or both of the phases. At the same time it must not be overly soluble in either phase; otherwise, it will remain in the bulk of that phase and not be adsorbed at the interface. This balanced affinity for the two phases also must be evident with finely divided solid particles used as emulsifying agents. If their affinity, as evidenced by the degree to which they are wetted, is either predominantly hydrophilic or hydrophobic, they will not function as effective wetting agents.

The great majority of the work on the relation between emulsifier and emulsion type has been concerned with surface-active agents that form interfacial monolayers. Thus, the present discussion will concentrate on this class of agents.

### Hydrophile–Lipophile Balance

As the emulsifier becomes more hydrophilic, its solubility in water increases and the formation of an O/W emulsion is favored. Conversely, W/O emulsions are favored with the more lipophilic emulsifiers. This led to the concept that the type of emulsion is related to the balance between hydrophilic and lipophilic solution tendencies of the surface-active emulsifying agent.

Griffin<sup>17</sup> developed a scale based on the balance between these two opposing tendencies. This so-called *HLB scale* is a numerical scale, extending from 1 to approximately 50. The more hydrophilic surfactants have high HLB numbers (in excess of 10), whereas surfactants with HLB numbers from 1 to 10 are considered to be lipophilic. Surfactants with a proper balance in their hydrophilic and lipophilic affinities are effective emulsifying agents because they concentrate at the oil–water interface. The relationship between HLB values and the application of the surface-active agent is shown in Table 21-8. Some commonly used emulsifiers and their HLB numbers are listed in Table 21-8. The utility of the HLB system in rationalizing the choice of emulsifying agents when formulating an emulsion will be discussed in a later section.

### Rate of Coalescence and Emulsion Type

Davies<sup>14</sup> indicated that the type of emulsion produced in systems prepared by shaking is controlled by the relative coalescence rates of oil droplets dispersed in the oil. Thus, when a mixture of oil and water is shaken together with an emulsifying agent, a multiple dispersion is produced initially that contains oil dispersed in water and water dispersed in oil (see Figure 21-5). The type of the final emulsion that results depends on whether the water or the oil droplets coalesce more rapidly. If the O/W coalescence rate (Rate 1) is much greater than W/O coalescence rate (Rate 2), a W/O emulsion is formed because the dispersed water droplets are more stable than the dispersed oil droplets. Conversely, if Rate 2 is significantly faster than Rate 1, the final emulsion is an O/W dispersion because the oil droplets are more stable.

According to Davies,<sup>14</sup> the rate at which oil globules coalesce when dispersed in water is given by the expression

$$\text{Rate 1} = C_1 e^{-W_1/RT} \quad (8)$$

The term  $C_1$  is a collision factor that is directly proportional to the phase volume of the oil relative to the water, and is an inverse function of the viscosity of the continuous phase (water).  $W_1$  defines an energy barrier made up of several contributing factors that must be overcome before coalescence can take place. First, it depends on the electrical potential of the dispersed oil droplets, as this affects repulsion. Second, with an O/W emulsion, the hydrated layer surrounding the polar portion of emulsifying agent must be broken down before coalescence can occur. This hydrated layer is probably around 1 nm thick with a consistency of butter. Finally, the total energy barrier depends on the fraction of the interface covered by the emulsifying agent.

Equation 9 describes the rate of coalescence of water globules dispersed in oil:

$$\text{Rate 2} = C_2 e^{-W_2/RT} \quad (9)$$

Here, the collision factor  $C_2$  is a function of the water–oil phase volume ratio divided by the viscosity of the oil phase. The energy barrier  $W_2$  is, as before, related to the fraction of the interface covered by the surface-active agent. Another contributing factor is the number of  $-\text{CH}_2-$  groups in the emulsifying agent; the longer the alkyl chain of the emulsifier, the greater the gap that has to be bridged if one water droplet is to combine with a second drop.

Davies<sup>14</sup> showed that the HLB concept is related to the distribution characteristics of the emulsifying agent between the two immiscible phases. An emulsifier with an HLB of less than 7 will be preferentially soluble in the oil phase and will favor formation of a W/O emulsion. Surfactants with an HLB value in excess of 7 will be distributed in favor of the aqueous phase and will promote O/W emulsions.

## PREPARATION OF EMULSIONS

Several factors must be taken into account in the successful preparation and formulation of emulsified products. Usually, the type of emulsion (i.e., O/W or W/O) is specified; if not, it probably will be implied from the anticipated use of the product. The formulator's attention is focused primarily on the selection of the emulsifying agent, or agents, necessary to achieve a satisfactory product. No incompatibilities should occur between the various emulsifiers and the several components commonly present in pharmaceutical emulsions. Finally, the product should be prepared in such a way as not to prejudice the formulation.

### SELECTION OF EMULSIFYING AGENTS

The selection of the emulsifying agent or agents is of prime importance in the successful formulation of an emulsion. The pharmacist must ensure that, in addition to its emulsifying properties, the material chosen is nontoxic and that the taste, odor, and chemical stability are compatible with the product. Thus, an emulsifying agent that is entirely suitable for inclusion in a skin cream may be unacceptable in the formulation of an oral preparation due to its potential toxicity. This consideration is most important when formulating intravenous emulsions.

### The HLB System

With the increasing number of available emulsifiers, particularly the nonionics, the selection of emulsifiers for a product was essentially a trial-and-error procedure. Fortunately, the work of Griffin<sup>17,18</sup> provided a logical means of selecting emulsifying agents. Griffin's method, based on the balance between the hydrophilic and lipophilic portions of the emulsifying agent, is now widely used and has come to be known as the HLB system. It is used most in the rational selection of combinations of non-ionic emulsifiers, and we shall limit our discussion accordingly.

As shown in Table 21-8, if an O/W emulsion is required, the formulator should use emulsifiers with an HLB in the range of 8 to 18. Emulsifiers with HLB values in the range of 4 to 6 are given consideration when a W/O emulsion is desired. Some typical examples are given in Table 21-9.

**Table 21-8. Relationship between HLB Range and Surfactant Application**

HLB Range	Use
0–3	Antifoaming agents
4–6	W/O emulsifying agents
7–9	Wetting agents
8–18	O/W emulsifying agents
13–15	Detergents
10–18	Solubilizing agents

**Table 21-9. Approximate HLB Values for a Number of Emulsifying Agents**

Generic or Chemical Name	HLB	Water Dispersibility
Sorbitan trioleate	1.8	No dispersion
Sucrose distearate	3.0	
Propylene glycol monostearate	3.4	
Glycerol monostearate (non-self-emulsifying)	3.8	Poor dispersion
Propylene glycol monolaurate	4.5	
Sorbitan monostearate	4.7	
Glycerol monostearate (self-emulsifying)	5.5	
Sorbitan monolaurate	8.6	Milky dispersion
Polyoxyethylene-4-lauryl ether	9.5	
Polyethylene glycol 400 monostearate	11.6	Translucent to clear
Polyoxyethylene-4-sorbitan monolaurate	13.3	Clear solution
Sucrose stearate	14.5	
Polyoxyethylene-20-sorbitan monopalmitate	15.6	
Polyoxyethylene-40-stearate	16.9	
Sodium oleate	18.0	
Sodium lauryl sulfate	40.0	

**Table 21-10. Required HLB Values for Some Common Emulsion Ingredients**

Substance	W/OO/W	
Acid, stearic	—	17.0
Alcohol, cetyl	—	13.0
Lanolin, anhydrous	8	15.0
Oil, cottonseed	—	7.5
Mineral oil, light	4	10–12.0
Mineral oil, heavy	4	10.5
Wax, beeswax	5	10–16.0
Microcrystalline	—	9.5
Paraffin	—	9.0

Another factor is the presence or absence of any polarity in the material being emulsified, because this will affect the polarity required in the emulsifier. Again, as a result of extensive experimentation, Griffin evolved a series of “required HLB” values—that is, the HLB value required by a particular material if it is to be emulsified effectively. Some values for oils and related materials are contained in Table 21-10. Naturally, the required HLB value differs depending on whether the final emulsion is O/W or W/O.

Fundamental to the utility of the HLB concept is the fact that the HLB values are algebraically additive. Thus, by using a low HLB surfactant with one having a high HLB it is possible to prepare blends having HLB values intermediate between those of the two individual emulsifiers. The following formula serves as an example.

**O/W EMULSION**

Liquid petrolatum (Required HLB 10.5)	50 g
Emulsifying agents	5 g
Sorbitan monooleate	(HLB 4.3)
Polyoxyethylene 20 sorbitan monooleate	(HLB 15.0)
Water, qs.	100 g

**Table 21-11. Nonionic Blends Having HLB Values of 10.5**

Surfactant Blend	HLB	Required Amounts (%) to Give HLB = 10.5
Sorbitan tristearate	2.1	34.4
Polyoxyethylene 20 sorbitan monostearate	14.9	65.6
Sorbitan monopalmitate	6.7	57.3
Polyoxyethylene 20 sorbitan monopalmitate	15.6	42.7
Sorbitan sesquioleate	3.7	48.5
Polyoxyethylene lauryl ether	16.9	51.5

By simple algebra it can be shown that a mixture containing 42% of sorbitan monooleate blended with 58% of polyoxyethylene 20 sorbitan monooleate will result in a mixed emulsifying agent having the required HLB of 10.5. Because the formula calls for 5 g, the required weights are 2.1 and 2.9 g, respectively. The oil-soluble sorbitan monooleate is dissolved in the oil and heated to 75°; the water-soluble polyoxyethylene 20 sorbitan monooleate is added to the aqueous phase that is heated to 70°. At this point the oil phase is mixed with the aqueous phase and the whole is stirred continuously until cool.

The formulator is not restricted to these two agents to produce a blend with an HLB of 10.5. Table 21-11 shows the various proportions required, using other pairs of emulsifying agents, to form a blend of HLB 10.5. When carrying out preliminary investigations with a particular material to be emulsified, it is advisable to try several pairs of emulsifying agents. Based on an evaluation of the emulsions produced, it becomes possible to choose the best combination.

Occasionally, the required HLB of the oil may not be known, in which case it becomes necessary to determine this parameter. Various blends are prepared to give a wide range of HLB mixtures and emulsions are prepared in a standardized manner. The HLB of the blend used to emulsify the best product, selected on the basis of physical stability, is taken to be the required HLB of the oil. The experiment should be repeated using another combination of emulsifiers to confirm the value of the required HLB of the oil to within, say,  $\pm 1$  HLB unit.

There are methods for finding the HLB value of a new surface-active agent. Griffin<sup>17</sup> developed simple equations that can be used to obtain an estimate with certain compounds. It has been shown that the ability of a compound to spread at a surface is related to its HLB. In another approach a linear relation between HLB and the logarithm of the dielectric constant for a number of nonionic surfactants has been observed.

An interesting approach, developed by Davies,<sup>14</sup> is related to his studies on the relative rates of coalescence of O/W and W/O emulsions (page 329). According to Davies, hydrophilic groups on the surfactant molecule make a positive contribution to the HLB number, whereas lipophilic groups exert a negative effect. Davies calculated these contributions and termed them HLB Group Numbers (Table 21-12). Provided the molecular structure of the surfactant is known, one simply adds the various group numbers in accordance with the following formula:

$$\text{HLB} = \sum (\text{hydrophilic group numbers}) - \sum (\text{lipophilic group numbers}) + 7$$

Poor agreement is found between the HLB values calculated by the use of group numbers and the HLB values obtained using the simple equations developed by Griffin. However, the student should realize that the absolute HLB values per

**Table 21-12. HLB Group Numbers**

	Group Number

—(CH <sub>2</sub> —CH <sub>2</sub> —CH <sub>2</sub> —O)—	-0.15

(From Wedderburn DL. In: *Advances in Pharmaceutical Sciences*, vol 1. London: Academic Press, 1964, p 195.)

are of limited significance. The utility of the HLB approach (using values calculated by either Griffin's or Davies' equations) is to:

1. provide the formulator with an idea of the relative balance of hydrophilicity and lipophilicity in a particular surfactant.
2. relate that surfactant's emulsifying and solubilizing properties to other surfactants. The formulator still needs to confirm experimentally that a particular formulation will produce a stable emulsion.

Later, Davies and Rideal<sup>19</sup> attempted to relate HLB to the  $C_{\text{water}}/C_{\text{oil}}$  partition coefficient and found good agreement for a series of sorbitan surfactants. Schott showed, however, that the method does not apply to polyoxyethylated octylphenol surfactants. Schott concluded that "so far, the search for a universal correlation between HLB and another property of the surfactant that could be determined more readily than HLB has not been successful."<sup>20</sup>

The HLB system gives no information as to the *amount* of emulsifier required. Having once determined the correct blend, the formulator must prepare another series of emulsions, all at the same HLB, but containing increasing concentrations of the emulsifier blend. Usually, the minimum concentration giving the desired degree of physical stability is chosen.

When varying the amounts of emulsifier in an emulsion it is useful to consider the use of a phase diagram to select the proper ratio of oil/water/surfactant. The use of the phase diagram to aid in the formulation of emulsions has been discussed by Swarbrick.<sup>21</sup> This approach can provide a systematic way to optimize an emulsion formulation and help to identify the existence of liquid crystalline phases that, when present in an emulsion formulation, can enhance the stability. Because liquid crystals exhibit birefringence, observation of prototype emulsions under polarized light microscopy can be a useful tool to identify combinations of water-oil and emulsifier that produce liquid crystals. It should be noted that liquid crystals are often formed when relatively high concentrations (e.g., 20% or more) of surfactant are used in a formulation. The toxicity of the

emulsifier for the intended use (e.g., topical, oral, or parenteral) must be considered in addition to the physical characteristics.

### Mixed Emulsifying Agents

Emulsifying agents are frequently used in combination because a better emulsion usually is obtained. This enhancement may be due to several reasons, one or more of which may be operative in any one system. Thus, the use of a blend or mixture of emulsifiers may

1. produce the required hydrophile-lipophile balance in the emulsifier.
2. enhance the stability and cohesiveness of the interfacial film.
3. affect the consistency and feel of the product.

The first point has been considered in detail in the previous discussion of the HLB system.

With regard to the second point, Schulman and Cockbain in 1940 showed that combinations of certain amphiphiles formed stable films at the air-water interface. It was postulated that the complex formed by these two materials (one, oil-soluble; the other, water-soluble) at the air-water interface was also present at the O/W interface. This interfacial complex was held to be responsible for the improved stability. For example, sodium cetyl sulfate, a moderately good O/W emulsifier, and elaidyl alcohol or cholesterol, both stabilizers for W/O emulsions, show evidence of an interaction at the air-water interface. Furthermore, an O/W emulsion prepared with sodium cetyl sulfate and elaidyl alcohol is much more stable than an emulsion prepared with sodium cetyl sulfate alone.

Elaidyl alcohol is the *trans* isomer. When oleyl alcohol, the *cis* isomer, is used with sodium cetyl sulfate, there is no evidence of complex formation at the air-water interface. Significantly, this combination does not produce a stable O/W emulsion either. Such a finding strongly suggests that a high degree of molecular alignment is necessary at the O/W interface to form a stable emulsion. This high degree of molecular alignment may be a prerequisite event for the formation of lamellar liquid crystalline or gel phases. As illustrated in Figure 21-7, the combination of certain long chain acids and alcohols with water can result in the formation of micelles and liquid crystals. It has also been observed that when liquid crystals or gels form in an emulsion, increased stability is generally observed. As discussed

**Figure 21-7.** Phase diagram illustrating the formation of micellar and liquid crystalline phases in mixtures of a long-chain alcohol, long-chain acid, and water. Compositions that form the lamellar liquid crystalline phase can provide enhanced emulsion stability. (From Friberg S, Larson K. In: Brown GH, ed. *Advances in Liquid Crystals*, vol 2. New York: Academic Press, 1976, p 173.)

previously, gel or liquid crystalline phases can have an important effect in inhibiting coalescence in emulsions.

When using combinations of emulsifiers, care must be taken to ensure their compatibility, as charged emulsifying agents of opposite sign are likely to interact and coagulate when mixed.

### Steric Stabilization

Many useful nonionic surfactants consist of hydrophobic portions composed of fatty acids or other lipophilic organic compounds and hydrophilic portions composed of polyoxyethylene chains. When used to prepare O/W emulsions, the oxyethylene chains protrude into the aqueous side of the O/W interface while the hydrophobic portion of the emulsifier will be primarily located in the oil side. As in the case of suspensions, approaching oil droplets will be influenced by van der Waals attractive forces as well as repulsive forces. For an emulsion that is stabilized by a non-ionic surfactant, the repulsive forces consist of electrostatic and non-electrostatic forces. The electrostatic repulsive forces are similar to those discussed for suspensions and depend largely upon the zeta potential of the oil droplets.

Non-electrostatic forces may also arise from a phenomenon that is frequently described as *steric stabilization*. This effect has been explained as follows. First, as emulsion droplets approach, the adsorbed layers of surfactant on each droplet begin to mix. The hydrophilic oxyethylene chains behave as soluble polymers; as their concentration increases in the region of interfacial mixing, segments of the polymers from separate droplets compete for water molecules. This results in restricted movement of the polymer chains or a loss of entropy. Likewise, a positive heat of solution (enthalpy) may result from the mixing of the polymers in the interfaces. The loss of entropy and/or increase in enthalpy results in an increase in the free energy of mixing, meaning that spontaneous mixing in the interfacial region is not favorable. The particles will tend to separate in order to reverse the temporary increase in the free energy of mixing.

An additional effect that causes repulsion of the droplets may be a result of the increased osmotic pressure that results in the area of contact between the two emulsion droplets. The concentration of oxyethylene groups in the region of overlap between the two droplets increases, necessitating an influx of water into the region. This increase in osmotic pressure has the effect of forcing the droplets apart. Thus, in addition to their favorable effect of reducing interfacial tension, nonionic surfactants that possess long, hydrophilic chains provide additional emulsion stabilization via the energetically unfavorable result of mixing of polymer chains at the droplet-droplet interface.

### METHOD OF PREPARATION

Different methods are employed, depending on the type of emulsifying agent used and the scale of manufacture. Traditionally, the mortar and pestle was used for the small scale preparation of emulsions stabilized by the presence of such agents as acacia and tragacanth. However, the use of these agents has declined drastically in recent years; as a result, the use of the mortar and pestle has declined as well. (Refer to the 18th edition of this text, page 306, for details of the mortar and pestle method.)

An increasing number of emulsions are being formulated with synthetic emulsifying agents, especially of the nonionic type. The components in such a formulation are separated into those that are oil-soluble and those that are water-soluble. These are dissolved in their respective solvents by heating to about 70° to 75°. When solution is complete, the two phases are mixed and the product is stirred until cool. This method, which requires nothing more than two beakers, a thermometer, and a source of heat, is necessarily used in the preparation of emulsions containing waxes and other high-melting-point materials that must be melted before they can be dispersed in the emulsion. The relatively simple methodology involved in the use of synthetic surfactant-type emulsifiers is one factor that has led to their

widespread use in emulsion preparation. This, in turn, has led to a decline in the use of the natural emulsifying agents.

With hand homogenizers, an initial rough emulsion is formed by trituration in a mortar or shaking in a bottle. The rough emulsion then is passed several times through the homogenizer. A reduction in particle size is achieved as the material is forced through a narrow aperture under pressure. A satisfactory product invariably results from the use of a hand homogenizer and overcomes any deficiencies in technique. Should the homogenizer fail to produce an adequate product, the formulation, rather than the technique, should be suspected.

For a discussion of the techniques and equipment used in the large-scale manufacture of emulsions, see Chapter 24.

## STABILITY OF EMULSIONS

Several criteria must be met in a well-formulated emulsion. Probably the most important and most readily apparent requirement is that the emulsion possess adequate physical stability; without this, any emulsion soon will revert back to two separate bulk phases. In addition, if the emulsified product is to have some antimicrobial activity (e.g., a medicated lotion), care must be taken to ensure that the formulation possesses the required degree of activity. Frequently, a compound exhibits a lower antimicrobial activity in an emulsion than, say, in a solution. Generally, this is because of partitioning effects between the oil and water phases, which cause a lowering of the *effective* concentration of the active agent. Partitioning has also to be taken into account when considering preservatives to prevent microbiological spoilage of emulsions. Finally, the chemical stability of the various components of the emulsion should receive some attention, as such materials may be more prone to degradation in the emulsified state than when they exist as a bulk phase.

In the present discussion, detailed consideration will be limited to the question of physical stability. Reviews of this topic have been published by Garrett<sup>22</sup> and Kitchener and Mussellwhite.<sup>23</sup> For information on the effect that emulsification can have on the biologic activity and chemical stability of materials in emulsions, see Wedderburn,<sup>24</sup> Burt<sup>25</sup> and Swarbrick.<sup>21</sup>

The theories of emulsion stability have been discussed by Eccleston<sup>26</sup> in an attempt to understand the situation in both a simple O/W emulsion and complex commercial systems. A recent review by the same author<sup>13</sup> has discussed the stability of multiple phase emulsions and the role of bilayer gels and liquid crystalline phases on the physical stability of these systems.

The three major phenomena associated with physical stability are

1. the upward or downward movement of dispersed droplets relative to the continuous phase, termed *creaming* or *sedimentation*, respectively.
2. the *aggregation* and possible *coalescence* of the dispersed droplets to reform the separate, bulk phases.
3. *inversion*, in which an O/W emulsion inverts to become a W/O emulsion and *vice versa*.

### CREAMING AND SEDIMENTATION

*Creaming* is the upward movement of dispersed droplets relative to the continuous phase; *sedimentation*, the reverse process, is the downward movement of particles. In any emulsion one process or the other takes place, depending on the densities of the disperse and continuous phases. This is undesirable in a pharmaceutical product where homogeneity is essential for the administration of the correct and uniform dose. Furthermore, creaming, or sedimentation, brings the particles closer together and may facilitate the more serious problem of coalescence.

The rate at which a spherical droplet or particle sediments in a liquid is governed by Stokes' law (Equation 3). Other equations have been developed for bulk systems, but Stokes' equation is still useful because it points out the factors that influence

the rate of sedimentation or creaming. These are the diameter of the suspended droplets, the viscosity of the suspending medium, and the difference in densities between the dispersed phase and the dispersion medium.

Usually, only the use of the first two factors is feasible in affecting creaming or sedimentation. Reduction of particle size contributes greatly toward overcoming or minimizing creaming, because the rate of movement is a square-root function of the particle diameter. There are, however, technical difficulties in reducing the diameter of droplets to below about 0.1  $\mu\text{m}$ . The most frequently used approach is to raise the viscosity of the continuous phase, although this can be done only to the extent that the emulsion still can be removed readily from its container and spread or administered conveniently.

### AGGREGATION AND COALESCENCE

Even though creaming and sedimentation are undesirable, they do not necessarily result in the breakdown of the emulsion, as the dispersed droplets retain their individuality. Furthermore, the droplets can be redispersed with mild agitation. More serious to the stability of an emulsion are the processes of aggregation and coalescence. In *aggregation* (flocculation) the dispersed droplets come together but do not fuse. *Coalescence*, the complete fusion of droplets, leads to a decrease in the number of droplets and the ultimate separation of the two immiscible phases. Aggregation precedes coalescence in emulsions; however, coalescence does not necessarily follow from aggregation. Aggregation is, to some extent, reversible. Although it is not as serious as coalescence, it will accelerate creaming or sedimentation, because the aggregate behaves as a single drop.

Aggregation is related to the electrical potential on the droplets, but coalescence depends on the structural properties of the interfacial film. As discussed previously, it has been recognized that combinations of emulsifiers produce more stable emulsions than a single emulsifier alone. One reason for this synergy, as suggested by Shulman and Cockbain, is that appropriate combinations of surfactants form densely packed complex films at the oil-water interface. Additional beneficial effects of mixed emulsifier films could result from an increase in viscosity of the interfacial emulsifier film. A viscous interfacial film could enhance emulsion stability because thinning of the film at the points of droplet to droplet contact would be inhibited. An additional explanation for the beneficial effect of mixed-film emulsifiers suggests that appropriate mixtures of surfactants provide a more elastic interfacial film. A more elastic interfacial film would resist rupture upon collision of emulsion droplets.

It has also been observed that when emulsifiers are combined in certain concentrations and proportions, liquid crystalline phases can be formed. The preparation of emulsions with surfactants that form liquid crystalline states can have greater stability against coalescence compared to emulsions that are formulated in the absence of liquid crystalline states. Friberg and Larson<sup>27</sup> have explained the enhanced stability of emulsions due to liquid crystals in terms of a reduced van der Waals attraction between emulsion droplets. Such an effect depends upon the formation of layers or lamellae around the emulsion droplets. Each layer of liquid crystal contributes to a further reduction in the van der Waals attractive force.

An additional effect of liquid crystals may be related to the high viscosity that often is observed upon their formation. Liquid crystals possess a viscosity that is on the order of 100-fold greater than most oil-water interfaces. The high viscosity may result in reduced rates of coalescence. A key factor that may be important for the stabilizing effect of liquid crystals is the location of the liquid crystalline phase in relation to the dispersed droplets. To effectively inhibit coalescence, the liquid crystals should concentrate at the interface between the droplet and the continuous phase. This may not occur with all oil-water-surfactant combinations.

Particle-size analysis can reveal the tendency of an emulsion to aggregate and coalesce long before any visible signs of

instability are apparent. The methods available have been reviewed by Groves and Freshwater.<sup>28</sup>

### INVERSION

An emulsion is said to *invert* when it changes from an O/W to a W/O emulsion, or *vice versa*. Inversion sometimes can be brought about by the addition of an electrolyte or by changing the phase-volume ratio. For example, an O/W emulsion having sodium stearate as the emulsifier can be inverted by the addition of calcium chloride, because the calcium stearate formed is a lipophilic emulsifier and favors the formation of a W/O product.

Inversion often can be seen when an emulsion, prepared by heating and mixing the two phases, is being cooled. This takes place presumably because of the temperature-dependent changes in the solubilities of the emulsifying agents. The phase inversion temperature (PIT) of nonionic surfactants has been shown by Shinoda and Kunieda<sup>29</sup> to be influenced by the HLB number of the surfactant—the higher the PIT value, the greater the resistance to inversion.

Apart from work on PIT values, little quantitative work has been carried out on the process of inversion; nevertheless, it would appear that the effect can be minimized by using the proper emulsifying agent in an adequate concentration. Whenever possible, the volume of the dispersed phase should not exceed 50% of the total volume of the emulsion.

## BIOAVAILABILITY FROM COARSE DISPERSIONS

All dosage forms must be capable of releasing the drug in a known and consistent manner following administration to the patient. Both the rate and extent of release are important. Ideally, the extent of release should approach 100%, while the rate of release should reflect the desired properties of the dosage form. For example, with products designed to have a rapid onset of activity, the release of drug should be immediate. With a long-acting product, the release should take place over several hours or days, depending on the type of product used. The rate and extent of drug release should be reproducible from batch to batch of the product, and should not change during shelf-life.

The principles on which biopharmaceutics is based are dealt with in some detail in Chapters 38 to 39. Although most published work in this area has been concerned with the bioavailability of solid dosage forms administered by the oral route, the rate and extent of release from both suspensions and emulsions are also important and so must be considered in some detail.

### BIOAVAILABILITY FROM SUSPENSIONS

Suspensions of a drug may be expected to demonstrate improved bioavailability compared to the same drug formulated as a tablet or capsule. This is because the suspension already contains discrete drug particles, whereas tablet dosage forms must invariably undergo disintegration in order to maximize the necessary dissolution process. Frequently, antacid suspensions are perceived as being more rapid in action and therefore more effective than an equivalent dose in the form of tablets. Bates *et al.*<sup>30</sup> observed that a suspension of salicylamide was more rapidly bioavailable, at least during the first hour following administration, than two different tablet forms of the drug; this study was also able to demonstrate a correlation between the initial *in vitro* dissolution rates for the several dosage forms studied and the initial rates of *in vivo* absorption. A similar argument can be developed for hard gelatin capsules, where the shell must rupture or dissolve before drug particles are released and can begin the dissolution process. Such was observed by Antal *et al.*<sup>31</sup> in a study of the bioavailability of several doxycycline products, including a suspension and hard gelatin capsules. Sansom *et al.*<sup>32</sup> found that mean plasma phenytoin levels were higher after the administration of a suspension than when an equivalent dose was given as either tablets or capsules. It

was suggested that this might have been due to the suspension having a smaller particle size.

In common with other products in which the drug is present in the form of solid particles, the rate of dissolution, and thus potentially the bioavailability of the drug in a suspension, can be affected by such factors as particle size and shape, surface characteristics, and polymorphism. Strum *et al.*<sup>33</sup> conducted a comparative bioavailability study involving two commercial brands of sulfamethiazole suspension (Product A and Product B). Following administration of the products to 12 normal individuals and blood samples taken at predetermined times over a period of 10 h, the Strum study found no statistically significant difference in the extent of drug absorption from the two suspensions. The absorption rate, however, differed, and from *in vitro* studies it was concluded that product A dissolved faster than Product B, and that the former contained more particles of smaller size than the latter, differences that may be responsible for the more rapid dissolution of particles in Product A. Product A also provided higher serum levels during *in vivo* tests 0.5 h after administration. The results showed that the rate of absorption of sulfamethiazole from a suspension depended on the rate of dissolution of the suspended particles, which in turn was related to particle size. Previous studies<sup>34,35</sup> had shown the need to determine the dissolution rate of suspensions to gain information as to the bioavailability of drugs from this type of dosage form.

The viscosity of the vehicle used to suspend the particles has been found to have an effect on the rate of absorption of nitrofurantoin but not the total bioavailability. Thus Soci and Parrott<sup>36</sup> were able to maintain a clinically acceptable urinary nitrofurantoin concentration for an additional 2 h by increasing the viscosity of the vehicle.

### BIOAVAILABILITY FROM EMULSIONS

There are indications that improved bioavailability may result when a poorly absorbed drug is formulated as an orally administered emulsion. However, little research appears to have been done to directly compare emulsions and other dosage forms such as suspensions, tablets, and capsules; thus, it is not possible to draw unequivocal conclusions as to advantages of emulsions. If a drug with low aqueous solubility can be formulated so as to be in solution in the oil phase of an emulsion, its bioavailability may be enhanced. It must be recognized, however, that the drug in such a system has several barriers to pass before it arrives at the mucosal surface of the GI tract.

For example, with an O/W emulsion, the drug must diffuse through the oil globule and then pass across the oil-water interface. This may be a difficult process, depending on the characteristics of the interfacial film formed by the emulsifying agent. In spite of this potential drawback, Wagner *et al.*<sup>37</sup> found that indoxole, a nonsteroidal anti-inflammatory agent, was significantly more bioavailable in an O/W emulsion than in either a suspension or a hard gelatin capsule. Bates and Sequeira<sup>38</sup> found significant increases in maximum plasma levels and total bioavailability of micronized griseofulvin when formulated in a corn O/W emulsion. In this case, however, the enhanced effect was not due to emulsification of the drug in the oil phase *per se*, but more probably because of the linoleic and oleic acids present having a specific effect on GI motility.

### QUALITY CONTROL TESTING FOR SUSPENSIONS AND EMULSIONS

Most dosage forms containing active pharmaceutical ingredients require chemical and physical tests to ensure potency, purity and stability of the active pharmaceutical ingredient. Suspension and emulsion dosage forms typically require various physical tests to ensure consistent particle size and distribution as well as in-use tests to ensure that patients will be able to use the drug product effectively over the shelf-life of the product. Suspensions and fluid emulsions are generally tested for average particle size as well as some measure of particle size distribution. The latter could be a statistical parameter, such as standard deviation, but may also

be a limit on the upper or lower particle size, such as "99% of particles must be less than X micrometers." Rheological properties such as viscosity are also useful because they indicate ease of use, such as spreadability for a topical emulsion or suspension. For a parenteral suspension or emulsion, ease of injectability may also be a valuable test because the product may need to consistently be injected through a 21–27 Ga needle. Changes in viscosity, particle size or floccule size may alter the ability to effectively use the product. Other physical tests may include sedimentation rate/volume, zeta potential, redispersibility, pH, color, and possibly microscopic appearance. Microbiological testing may also be conducted, not only for sterile suspensions and emulsions, but whenever the product is capable of supporting microbial growth. When an antimicrobial preservative is required for the product, preservative effectiveness testing should be conducted and the product must be tested to be sure adequate concentrations of the preservative are present throughout the product shelf-life. It is also important to demonstrate dose uniformity of the suspension or emulsion by testing the drug content of aliquots of product that simulate dose volumes used by the patient. For suspension dosage forms, a dissolution test will most likely need to be performed because dissolution rate is an important step controlling rate and extent of absorption for poorly water soluble drugs.

As with other pharmaceutical dosage forms, chemical, physical and microbiological tests are performed at initial release of the product and during product stability studies. Key physical tests, such as particle size and viscosity, can also be conducted during manufacture of the product to ensure that the manufacturing process is producing product with acceptable physical characteristics.

### INTRODUCTION

Rheology is the branch of physics that deals with deformation, including flow, of matter. Although this definition was proposed in 1929, the recognition of rheological phenomena dates back to antiquity.<sup>1</sup> The earliest application of rheology (ca. 1600 BCE) is associated with the Egyptian Amenemhet, who made a 7° correction to the drainage angle of a water clock in order to account for the temperature-dependent variation in water flow during the course of a day. Archimedes's claim (ca. 250 BCE)—“Give me but one firm spot on which to stand, and I will move the earth.”—was based on the application of solid mechanics, the oldest branch of the physical sciences.<sup>1</sup>

Reiner<sup>2</sup> describes a simple mechanical experiment in which he lets three different materials—a pencil, a ball of plasticine, and a known mass of water—fall from some height onto the surface of a table. Newton's second law tells us that  $F = ma$ , where  $F$  is the force acting upon each of these materials of mass  $m$ , and  $a$  is the acceleration of the center of mass of each material. Since  $F$  is proportional to  $m$ ,  $a$  is the same for each of these materials. Consequently, these three bodies fall toward the table in exactly the same manner. Their material differences do not become apparent until they reach the tabletop. At that point, the pencil rebounds somewhat, the plasticine stays put, and the water spreads over the tabletop and, on reaching the edge, flows off. These very different outcomes—which mechanics is unable to explain—are the focus of rheology.

The ubiquity of rheological phenomena in pharmacy is evident in the levigation or mixing of ointments on slabs, the use of a mortar and pestle to prepare suspensions and emulsions, the flow of emulsions through colloid mills and pumps, the use of roller mills for compacting powders or processing ointments, and the mechanical properties of glass or plastic containers and of rubber or polymeric closures. Squeezing ointments, creams, or toothpaste from a collapsible tube, spreading lotion on the skin, or spraying liquids from atomizers or aerosol cans all involve rheological phenomena. The fluidity of solutions to be injected by syringe or infused intravenously, the flexibility of tubing used in catheters, and the strength of sutures and ligatures are important rheological properties. Drug release from dosage forms and delivery systems is often controlled or modulated by the rheological properties of the formulation matrix. Diffusion—a process occurring at the molecular level—is governed, in part, by the rheological behavior of the molecule's environment. Rheological principles govern the circulation of blood and lymph through capillaries and large vessels, the flow of mucus, the transit of the luminal contents through the gastrointestinal

tract, the bending of bones, the stretching of cartilage, and the contraction of muscles.

The centrality of rheological behavior to many unit operations in pharmaceutical manufacturing, to drug product functionality and stability, and to patient or consumer use of dosage forms and delivery systems necessitates a thorough understanding of rheology and the measurement of rheological behavior. The fundamentals of rheology are presented in the following section in the sequence that underscores their temporal recognition and application in pharmacy rather than their historic development in physics.

### FUNDAMENTALS

The jargon of rheology can be problematic for the uninitiated. For example, as Scott Blair<sup>3</sup> notes, stress and strain, in everyday English, have virtually the same meaning. Rheologists, however, use the word *stress* to refer to a system of forces, whether applied in a compressive, extensional, or shear mode, and use *strain* to refer to a change in size or shape.

Rheological principles stem from two fundamental laws derived in the late seventeenth century: Robert Hooke's law of elasticity (ca. 1676) and Isaac Newton's law of flow (1687). The corresponding equations, which embody these laws, characterize Hookean and Newtonian materials, respectively. When a force is applied to a body, the two rheological extremes of behavior are the pure elastic deformation of a Hookean solid and the pure, viscous flow of a Newtonian liquid. Pure (ideal) elasticity means that the body returns to its original form once the stress is removed, while pure (ideal) viscosity means that the liquid flows even under the smallest stress and does not return to its original shape or form once the stress is removed.<sup>4</sup> The resistance to deformation, or flow, is described by the modulus of elasticity or Young's modulus,  $E$ , for an elastic body undergoing extension, and by  $\eta$ , the coefficient of viscosity for a liquid.

Elastic deformation of solids is described by Hooke's law:

$$dl = \frac{\sigma}{E} \quad (1)$$

where  $dl$  is the elastic deformation or extension in length  $l$  caused by the application of stress  $\sigma$ . This is illustrated in Figure 22-1.

Viscous deformation, i.e., viscous flow, occurs in accordance with Newton's law,

$$\sigma = \eta \dot{\gamma} \quad (2)$$

wherein the applied stress  $\sigma$  results in flow with a velocity gradient  $\dot{\gamma}$ , or rate of shear. The proportionality constant  $\eta$  is

Figure 22-1. Elastic deformation in accordance with Hooke's law.

termed viscosity, while its reciprocal is called fluidity. Viscosity has also been described as the internal friction in the fluid as it corresponds to the resistance of the fluid to the relative motion of adjacent layers of liquid. This is illustrated in Figure 22-2.

Imagine a liquid contained between two very large, parallel plates as being divided into a stack of very thin, parallel layers, much like a deck of cards, as shown in Figure 22-2. Shear is applied to the liquid by pulling or pushing the top plate with a constant force  $F$  per unit area  $A$ , i.e.,  $F/A$ , or  $\sigma$ , while holding the bottom plate stationary. The top liquid layer, in contact with the moving plate, adheres to it and moves with the same velocity as the plate. The second layer, adjacent to the top one, is dragged along by friction, but its velocity is reduced somewhat by the resistance of the layers beneath it. Each layer is pulled forward by the layer moving above it but is held back by the layer underneath it, over which it moves and which it drags along. The farther the liquid layers are from the moving plate, the smaller their velocities. The bottom layer adheres to the stationary plate and has zero velocity. Thus, the velocity of the liquid layers increases in the direction  $x$  perpendicular to the direction of flow  $y$ . The shear strain or deformation in shear,  $\gamma$ , is the displacement  $y$  divided by the height,  $x$ , of the sheared or deformed portion of the liquid, as shown in Figure 22-2. It equals the tangent of the displacement angle  $\theta$  in radians that, at low values, is approximately equal to 0, i.e.,

$$\tan\theta = \gamma = \frac{y}{x} \cong 0$$

In due time, all layers except the bottom one undergo infinite deformation. What distinguishes one liquid from another is the rate at which the deformation increases with time. This is called the rate of (deformation in) shear,  $\dot{\gamma}$  or  $d\gamma/dt$ , the derivative of  $\gamma$  with respect to time,  $t$ . An equivalent definition for  $\dot{\gamma}$  is the velocity gradient, i.e., the rate at which the velocity,  $v$ , changes with the distance,  $x$ , perpendicular to the direction of flow:

$$\dot{\gamma} = \frac{dv}{dx} = \frac{d\gamma}{dt} \quad (3)$$

The rate of shear or velocity gradient,  $\dot{\gamma}$ , indicates how fast the liquid flows when a shear stress is applied to it. Its unit according to both definitions is  $s^{-1}$ , since  $\gamma$  is dimensionless, velocity is expressed in m/sec, and  $x$  in m.

Figure 22-2. Laminar flow of a liquid contained between two parallel plates.

It should be noted that the symbols often used in the past in the pharmaceutical literature for the rate of shear,  $D$ , and for the shearing stress,  $\tau$ , have been replaced by  $\dot{\gamma}$  and  $\sigma$ , respectively, in accordance with more widely accepted nomenclature recommendations.<sup>5,6</sup>

Characteristic shear rates for pharmacy-related activities are listed in Table 22-1. Even for a given process, the shear rate can vary within wide limits, depending upon the scale of the process and the processing rate. Thus, when a lotion is rubbed into the skin, if the hand (moving surface) slides across the skin (stationary surface) with a velocity  $v = 45$  cm/s and if the thickness of the lotion film is  $x = 0.05$  cm, then, according to Equation 3, the rate of shear is  $\dot{\gamma} = (45 \text{ cm/s}) / (0.05 \text{ cm}) = 900 \text{ s}^{-1}$ . For a given force and a constant viscosity, the rate of shear is uniform throughout the layer of lotion.

The flow of liquids by parallel layers, moving past each other and dragging adjacent layers along (as in Figure 22-2), is called *laminar* or *streamline* flow. At higher velocities and/or if the plates have rough surfaces, eddies or swirls develop, whereby mass transfer occurs from one layer or lamina to another. Theoretically, this complex phenomenon—referred to as turbulent flow—may be described by a set of partial differential equations, known as the Navier-Stokes equations, which govern fluids in motion. However, explicit solutions of these nonlinear equations, originally derived in the 1840s on the basis of laws of conservation of mass, momentum, and energy, remain elusive.

From a historic rheological viewpoint, deformation of matter was first described in ideal terms. Precise differentiations were made among perfect, rigid *Euclidean* bodies (solids), ideal

Table 22-1. Approximate Shear Rates for Pharmaceutical Operations

Operation	Rate of Shear, $s^{-1}$
Particle sedimentation in a suspension	$10^{-3}$
Film drainage	$10^{-1}$ – $10^1$
Pouring liquid from a bottle	50
Extrusion	1–100
Pumping fluids	1–3,000
Mixing or stirring	10–1,000
Spreading lotion or cream on skin	400–1,000
Levigating ointment on a slab with spatula	400–1,000
Injection via syringe	4,000
Dispensing nasal spray from plastic squeeze bottle	20,000
Processing in colloid mill	$10^5$ – $10^6$
Film-coating	$10^4$ – $10^6$
Spray drying	$10^5$ – $10^6$

*Hookean* elastic solids, *Pascalian*, or inviscid fluids, and *Newtonian* liquids. For ideal Euclidean solids, only mass (or density) is relevant; rigid bodies do not undergo deformation under stress, irrespective of the amount of force applied. When stress is applied to an ideal Hookean elastic solid, the deformation induced is fully recovered when the stress is removed. Inviscid fluids (e.g., gases at low pressure) exhibit no resistance to flow when stressed, whereas Newtonian liquids undergo flow at a rate that is proportional to the stress applied.

Unfortunately, most solids and fluids encountered in pharmacy do not exhibit ideal behavior consistent with the classical models that evolved with Hooke, Pascal, or Newton. By the nineteenth century, evidence for more complex, nonideal rheological behavior began to accumulate, and the clear-cut dividing line between *Hookean elastic solids* and Newtonian or viscous liquids became increasingly blurred. Some systems that behave as elastic solids when subjected to small stresses or to moderate stresses of short duration will undergo permanent deformation, resembling very viscous liquids if the stresses are larger and/or applied for longer periods of time. For many materials, the temporal dependence of their rheological properties necessitates careful consideration of their handling prior to and during the process of rheological evaluation. Nonetheless, an understanding of ideal rheological behavior is necessary before deviations from ideality can be considered.

## ELASTIC SOLIDS

In the stretching or extension of an elastic solid, the deformation is said to be in tension. The deformation or strain of the stretched body, or its elongation, is the difference between its length while under tension,  $l_s$ , and its original length,  $l$ , which is equal to the length after the stress is released, expressed as a fraction of the original length, namely,  $(l_s - l)/l$ . Other modes of deformation are by bending or flexure, torsion, compression, and shear.

For an ideal elastic solid, Hooke's law (Equation 1) states that the stress is directly proportional to the strain. This relationship is obeyed by real solids at moderate stresses and strains sustained for short periods of time. The *modulus of elasticity* or *Young's modulus*,  $E$ , is a measure of the stiffness, hardness, or resistance to elongation. There is also a modulus of shear or rigidity and a compression or bulk modulus. *Tensile compliance* is the reciprocal of Young's modulus, or the ratio of strain to stress.

In the CGS system, the units of stress are dynes/cm<sup>2</sup> or, since force = mass  $\times$  acceleration,  $(g\text{-cm/sec}^2)/\text{cm}^2 = g/(\text{cm sec}^2)$ . To convert dynes/cm<sup>2</sup> to the SI unit, Newton/m<sup>2</sup> or Pascal, divide by 10. Since strain is dimensionless, Young's modulus has the same dimensions as stress. Modulus values for a range of solids of pharmaceutical or biomedical interest are listed in Table 22-2.

Figure 22-1. shows representative stress-strain curves in tension, also called load-elongation curves. The cross-sectional area  $A$  of the solid becomes smaller as it is stretched. Therefore, to calculate the actual or true tensile stresses, the forces are divided by  $A_s$ , the cross-sectional area at each appropriate elongation. Stress-strain curves often are plotted with the strain or extension, the dependent variable, on the abscissa, while consistency or flow curves (see below) usually are plotted with stress, the independent variable, on the abscissa. The practice followed here is to plot stress on the ordinate for both stress-strain and consistency curves in order to make modulus and viscosity, respectively, the slopes of these curves.

The characteristic portions in the representative stress-strain curve *OLYAHB* in Figure 22-1 are as follows. Hooke's law of proportionality between stress and strain is obeyed throughout the linear portion *OL*. The elastic modulus of the solid is the slope of *OL* or the tangent of the angle *LOC*. The material behaves elastically up to the yield point *Y*, where the stress is called yield stress. When stresses below the yield stress are applied to

**Table 22-2. Modulus of Elasticity<sup>a</sup> of Representative Solids of Pharmaceutical or Biomedical Interest**

Material	Young's Modulus, Pa
Steel	$2.2 \times 10^{11}$
Glass	$6 \times 10^{10}$
Potassium chloride	$2.3 \times 10^{10}$
Silk, viscose rayon	$1.5 \times 10^{10}$
Microcrystalline cellulose	$1.3 \times 10^{10}$
Polyethylene, low density	$2.4 \times 10^8$
Rubber, vulcanized	$2 \times 10^6$
Tooth enamel	$4.7 \times 10^{10}$
Bone	$2.2 \times 10^{10}$
Tendon	$1.3 \times 10^9$
Muscle	$6 \times 10^5$
Soft tissue	$7.5 \times 10^3$
Gelatin gels – 10% solids	$2.4 \times 10^4$
Gelatin gels – 20% solids	$1.0 \times 10^5$
Gelatin gels – 30% solids	$1.5 \times 10^5$

the sample and then released, it stretches and contracts along the same curve *OLY*.

Beyond *Y*, the material behaves as a plastic rather than as an elastic solid. Along the (nearly) horizontal portion *YAH*, the material is ductile; it flows or creeps under practically constant stress like a viscous liquid. If the stress is released at *A*, the sample retracts along *AC*. The nonrecoverable deformation *OC* is called *permanent set*. Many materials undergoing such "cold flow" are strengthened by some change in structure, causing an upturn *HB* in the stress-strain curve. This is called *work (or strain) hardening*. It may result from the elimination of flaws, from a reduction in crystal size (as in the case of metals), or from reversible crystallization on stretching (as in the case of homopolymer elastomers).

At *B*, the sample ruptures; *R* is the elongation at the break or the ultimate elongation, and the stress corresponding to *B* is the *ultimate strength* or *tensile strength*. These values, as well as the load-elongation curve beyond *Y*, depend on the rate at which the sample is stretched.

The area *OLYAHBRCO* under the stress-strain curve is the energy or work required to break or rupture the material. It measures the material's toughness or brittleness. Glass is hard because of its high elastic modulus. Owing to the absence of a yield point and to a very low elongation to break, it is brittle, as opposed to steel, which undergoes work hardening, has a high elongation to break, and is tough. Plastics are medium-hard or soft. Those that exhibit comparatively high elongations at break, like polyethylene but unlike polystyrene, are tough. Vulcanized rubbers are tough even though they are soft (low elastic modulus) because their elongation to break is very high, namely, 600 to 800 percent.

## NEWTONIAN FLUIDS

The viscosity of simple liquids (i.e., pure liquids consisting of small molecules and solutions where solute and solvent are small molecules) depends only on composition, temperature, and pressure. It increases moderately with increasing pressure and markedly with decreasing temperature. For solutions of solid solutes, the viscosity usually increases with concentration. Simple liquids follow Newton's law (Equation 2) of direct proportionality between shear stress and rate of shear, so that their viscosity is independent of the shear stress or the rate of shear. Their flow behavior is thus referred to as Newtonian. Representative Newtonian viscosities are listed in Table 22-3. Fluid flow through cylindrical pipes or capillaries is laminar,

**Table 22-3. Newtonian Viscosities and "Activation Energies",  $E_a$ , for Viscous Flow**

Material	Temperature, °C.	Viscosity, mPa•s	$E_a$ for Viscous Flow, Kcal/mole
Water	20	1.0	4.2
	50	0.55	3.4
	99	0.28	2.8
Ethanol, absolute	20	1.2	3.3
	50	0.7	3.3
40% w/w	20	2.9	6.8
	50	1.13	5.3
Ethyl ether	20	0.24	1.65
Glycerin			
anhydrous	20	1,500	12.5
95% w/w	20	545	10.6

i.e., Newtonian, at low velocities, for small tube radii or for liquids of high viscosity. The liquid layers are very thin cylinders concentric with the duct.<sup>2</sup> During flow they telescope past one another, as shown in Figure 22-3A. The arrows in Figure 22-3B represent the velocity  $v$  of the individual cylindrical layers of radius  $r$ ;  $v$  is maximal in the center of the tube and decreases in the radial direction, i.e., in the direction  $r$  (previously  $x$ ) perpendicular to the direction of flow  $y$ . The velocity is zero in the outermost liquid layer adjacent to and adhering to the wall, whose radius is equal to the inside radius of the tube  $R$ . In the center of the tube, where  $v$  is maximum, the velocity gradient  $dv/dr = \gamma$  is zero. This is shown in Figure 22-3C, where the arrows represent  $\gamma$  and the velocity gradient is maximum at the wall.

If  $V$  is the volume of liquid flowing through a cylindrical tube of radius  $R$  in time  $t$ , the volumetric flow rate is  $V/t$ , and the shear rate at the wall is

$$\dot{\gamma}_{\text{wall}} = \frac{4}{\pi R^3} (V/t) \quad (4)$$

The shear stress is zero in the center of the tube and maximum at the wall:

$$\sigma_{\text{wall}} = \frac{R\Delta P}{2l} \quad (5)$$

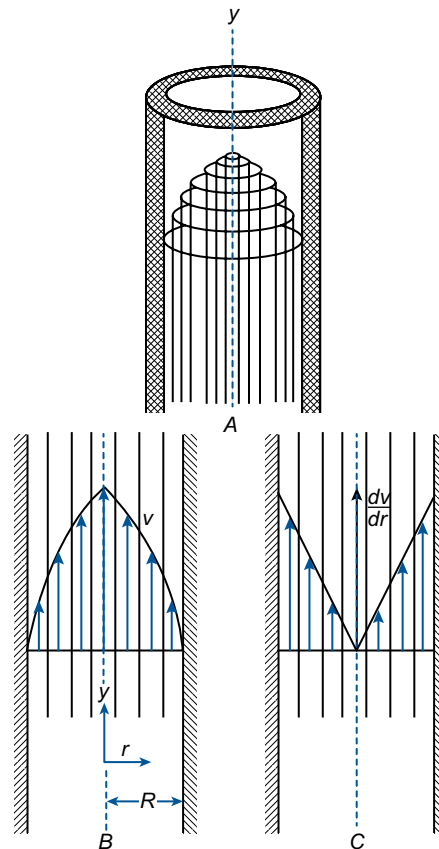

The liquid flows through the tube due to pressure, either caused by its own weight (hydrostatic) or produced by a pump. This pressure exceeds the innate viscous friction of the liquid and is converted into heat. The pressure drop,  $\Delta P$ , along a length  $l$  of the tube is the difference between the pressure at the beginning and at the end of the tube.

As viscosity is shear stress divided by rate of shear, and as both vary in the  $x$ -direction perpendicular to the direction of flow, both must be evaluated at the same location. Using the values at the wall of a cylindrical tube, dividing Equation 5 by Equation 4, and rearranging gives

$$\left(\frac{V}{t}\right) = \frac{R^4 \Delta P}{81\eta} \quad (6)$$

This is Poiseuille's law, found experimentally by this French physician while studying the flow of liquids through capillary tubes representative of blood vessels. (The poise is also named in his honor.)

In the human body, the pumping action of the heart supplies the driving pressure for the flow of blood, which is the difference between the arterial and venous pressures. Digitalis

**Figure 22-3.** Laminar flow of a liquid through a cylindrical duct. A, Three-dimensional view of telescoping layers; B, cross-section showing radial distribution of velocity; C, cross-section showing radial distribution of velocity gradient.

glycosides increase the force of contraction of the heart muscle and make the heart a more efficient pump. This increases  $\Delta P$  and, hence, the rate of flow of blood  $V/t$ . Vasodilator drugs like nitroglycerin or hydralazine hydrochloride increase the radius of blood vessels by relaxing the vascular smooth muscles. Since the flow rate varies with the fourth power of the radius of the blood vessel, a mere 5 percent increase in radius causes a 22 percent increase in the flow rate at constant blood pressure because  $(1.05)^4 = 1.22$ .

Plots of shear stress (on the  $y$  axis) as a function of the rate of shear (on the  $x$  axis) are referred to as flow curves or *rheograms*. The *rheograms* of typical Newtonian liquids, like those of Figure 22-4, are straight lines going through the origin. Viscosity is the slope of such a line or the tangent of the angle it makes with the horizontal axis. Of the two liquids shown in Figure 22-4, A has a higher viscosity than B because  $\alpha > \beta$ , so that  $\eta_A (= \tan \alpha) > \eta_B (= \tan \beta)$ ;  $\eta_A = \sigma_2/\gamma_2 = \sigma_1/\gamma_1$  and  $\eta_B = \sigma_1/\gamma_3 = \sigma_3/\gamma_2$ . A given shear stress,  $\sigma_1$ , produces a greater rate of shear,  $\gamma_3$ , in the more fluid Liquid B than  $\gamma_1$  in the more viscous Liquid A. Alternatively, to produce a given rate of shear,  $\gamma_2$ , in the two liquids requires a higher shear stress,  $\sigma_2$ , for the more viscous Liquid A than  $\sigma_3$  for the more fluid Liquid B.

In the CGS system, viscosity is defined as the tangential force per unit area, in dynes/cm<sup>2</sup>, required to maintain a difference in velocity of 1 cm/s between two parallel layers of liquid 1 cm apart. Its unit is, therefore, dynes/cm<sup>2</sup>-sec<sup>-1</sup> or g/cm-s, which is called a *poise*. Because many common liquids, including water, have viscosities on the order of 1/100 of a poise, their viscosity is often expressed in *centipoise*. In the SI system, the unit of viscosity is Newton/m<sup>2</sup>-s<sup>-1</sup> or Pascal-s, which equals 10 poise. Typical Newtonian viscosities are listed in Table 22-3.

**Figure 22-4.** Rheograms or flow curves of two Newtonian liquids.

The variation of viscosity with temperature often is described by an Arrhenius equation:

$$\eta = Ae^{E_a/RT}$$

$$\ln \eta = \ln A + \left( \frac{E_a}{RT} \right) \quad (7)$$

where  $A$  and  $E_a$  are constants,  $T$  is the absolute temperature, and  $R$  is the molar gas constant. Values of  $E_a$ , the activation energy for viscous flow, are listed in Table 22-3. Large values of  $E_a$  indicate that the viscosity decreases substantially with rising temperature. According to Equation 7, plots of  $\ln \eta$  as a function of the reciprocal of the absolute temperature should be straight lines with slopes of  $E_a/R$ . For associated, e.g., hydrogen-bonded, liquids, such plots are often somewhat curved. According to Eyring's "hole theory," liquids contain vacancies or holes that are essential to flow; the activation energy is used largely to form these holes.<sup>7a</sup>  $E_a$  is about 1/3 to 1/4 of the latent heat of vaporization for nonassociated liquids. Even though the viscosity of liquids often shows an inverse dependence on temperature, the concept of an activation energy and barrier associated with viscous flow (and diffusion), at least in simple liquids, has been disputed.<sup>7b</sup>

## NON-NEWTONIAN FLUIDS

Fluids that do not obey Newton's law (Equation 2) are described as non-Newtonian fluids. The rheological behavior of non-Newtonian fluids may be characterized either as time-independent or time-dependent non-Newtonian fluids.

### TIME-INDEPENDENT NON-NEWTONIAN FLUIDS

**Shear-thinning Fluids.** Many colloidal systems, especially polymer solutions and flocculated solid/liquid dispersions, become more fluid the faster they are stirred. This shear-thinning behavior is often referred to as *pseudoplasticity*, but the latter term is outdated and potentially misleading. Shear-thinning behavior is an example of non-Newtonian flow because the viscosity, at constant temperature and composition, is not constant, as required by Newton's law of viscous flow (Equation 2), but decreases with increasing shear. As the increase in shear rate is greater than the increase in the corresponding shear stress, the flow curve of Figure 22-5 is concave toward the shear-rate axis.

There is an apparent viscosity for each value of shear rate or shear stress, which can be expressed in two different ways. At point  $P$  in Figure 22-5, the apparent viscosity can be taken as the slope of the secant to the flow curve at  $P$ , or  $\tan \theta$ , which is the viscosity of a Newtonian liquid whose flow curve passes

**Figure 22-5.** Flow curve of a shear-thinning liquid.

through  $P$ . This is equal to the ratio  $\sigma_p/\gamma_p$ . The second method defines the apparent viscosity as the slope of the tangent to the flow curve at  $P$ , i.e.,  $d\sigma_p/d\gamma_p = \tan \phi$ . Since both  $\theta$  and  $\phi$  decrease with increasing shear stress or shear rate, so does the viscosity.

The shear-thinning behavior of polymer or macromolecule solutions arises from the alignment of neighboring macromolecules and the degree of their entanglement and concomitant immobilization of solvent. In aqueous solution, for example, the flexible, thread-like macromolecules are buffeted constantly by the surrounding water molecules in thermal agitation. This causes continuous random motion of chain segments by translation and by rotation around bonds between the atoms that make up the macromolecular backbone. These thermal fluctuations result in the formation of loose, roughly spherical coils that are permeated by water. The macromolecule chains are encased in sheaths of water of hydration. Additional water is mechanically trapped inside the open coils. The coiled macromolecules, in constant segmental motion, become entangled (Figure 22-6A). Upon the application of shear, a unidirectional laminar motion is superimposed on the random thermal motion of the water molecules and chain segments. The randomly coiled, entangled macromolecules tend to disentangle themselves and to align themselves in the direction of flow, as shown in Figure 22-6B. The viscosity of the solution—its resistance to flow—depends on the size and shape of the flow units. The imposition of increasing shear in these systems enables the macromolecule "chains" to uncoil progressively and become streamlined or elongated, thereby offering less resistance to flow than the original, approximately spherical, shapes. At the same time, the amount of water trapped inside the coils and dragged along decreases. Furthermore, the chains become gradually more disentangled. Reduced entrapment of water and decreased entanglement of the macromolecules reduce the size of the flow unit, thereby reducing the viscosity. A further reduction in viscosity results from shear-induced uncoiling of the macromolecules. Thus, the apparent viscosity at a given rate of shear reflects the degree of randomization, coiling, entanglement, and alignment of the macromolecules, and the extent to which solvent molecules are associated with the macromolecules.

Dispersions of flocculated solid particles exhibit shear-thinning if the particle-particle bonds are too weak to withstand the applied shear stresses. Examples of weak interparticle bonds include weakly flocculated particles, in a secondary minimum, or electrostatically attracted lamellar clay platelets with positively charged edges and negatively charged faces, which produce a "house-of-cards" structure in an aqueous suspension.

Shear progressively breaks up these aggregates at a rate that increases with increasing shear stress, releasing increasing amounts of trapped water. Brownian motion tends to rebuild the aggregates at a rate that is independent of shear. There is an

**Figure 22-6.** Three randomly coiled polymer chains in solution. (A) At rest; (B) In shear field.

average equilibrium size for the aggregates at each rate of shear that decreases with increasing shear, resulting in a decrease in the resistance to flow, or viscosity, as the shear increases.

At extremely low shear rates, well below  $1 \text{ s}^{-1}$ , the rate of disentanglement and alignment of polymer chains and the rate of breaking up of aggregates of particles under the influence of shear are negligible, compared to the rate of entanglement and randomization of polymer chains and to the rate of aggregation of particles produced by Brownian motion, respectively. Hence, the flow units are neither noticeably deformed nor reduced in size by shear, and the systems exhibit Newtonian flow, with a constant and high viscosity designated as the lower Newtonian or zero-shear viscosity,  $\eta_0$ .

At very high shear rates, the dissolved polymer chains are wholly disentangled and well aligned in the direction of flow, and the aggregates of particles are broken up as far as possible. There is no residual structure left that can be broken up by further increments in shear rate: The viscosity levels off at a constant value called the upper Newtonian viscosity,  $\eta_\infty$ . Turbulent flow and shear-induced rupture of polymer chains may set in before the upper Newtonian regime is reached. As can be seen in Figure 22-7,  $\eta_\infty$  is considerably lower than  $\eta_0$ . The value of the non-Newtonian viscosity observed at intermediate shear rates, including those encountered in most practical situations, depends on the amount of residual structure. It is, therefore, called *structural viscosity*.

**Dilatancy.** In contrast to shear-thinning, *shear-thickening* or *dilatancy*, i.e., an increase in viscosity with increasing shear, is rare. It is shown by concentrated dispersions of particles that do not tend to aggregate or stick together, provided the amount of liquid present is not much larger than that needed to fill the voids between the particles. Sediments of suspensions from which the supernatant liquid has been decanted are sometimes dilatant. When such a concentrated suspension is poured or stirred slowly, there is just enough liquid to lubricate the slipping of one particle past another, and the viscosity is low. When stirred fast, the particles get into each other's way, block each other, and bunch up rather than slipping past each other. Large voids form between the unevenly clustered particles, and as the liquid seeps into these, the suspension appears dry—as if the suspended solids had expanded or become dilated. This phenomenon, which results in progressive viscosity increases, becomes more severe with increasing shear. When high shear is followed by low shear or rest, the particles that had been crowded together separate again, the interparticle void volume decreases, and the viscosity drops as the suspension appears

**Figure 22-7.** The three flow regions of a shear-thinning liquid. Shaded areas refer to lower (*left*) and upper (*right*) Newtonian regions; center area represents shear-thinning behavior.

wet again. Wet sand offers small resistance to slow flow or penetration but stiffens and appears dry when deformed fast.

Among the few systems reported<sup>8</sup> to exhibit dilatant flow are suspensions of starch in water, aqueous glycerin, or ethylene glycol containing about 40 to 50 percent v/v starch, and concentrated suspensions of inorganic pigments in water and in nonpolar liquids with enough surfactant added to deflocculate the disperse phase completely, e.g., red iron oxide (12 percent v/v in water), zinc oxide (30 percent v/v in water), barium sulfate (39 percent v/v in water), and titanium dioxide (30–50 percent v/v in water).

**Plasticity.** Semisolids that do not flow at low shear stresses (exhibiting reversible deformation like elastic solids) but flow like liquids above their yield value (i.e., yield stress) are termed *plastics* or *Bingham bodies*. This type of rheological behavior is called *plasticity*. Plasticity is often exhibited by semisolids characterized as structured media, i.e., semisolids that have a cross-linked three-dimensional network of polymers, macromolecules, or particulates extending throughout the system.

Figure 22-8 shows the flow curves for two plastic systems. System *B* has a lower yield value than System *A* and Newtonian behavior at stresses above the yield value;  $BC\sigma_{\text{yield}}$  is a straight line of inclination  $\theta$ , so that the *plastic viscosity* of *B*, i.e., its viscosity above the yield value, is the slope of this line or  $\tan \theta$ :

$$\eta_{\text{plastic}} = \frac{\sigma - \sigma_{\text{yield}}}{\dot{\gamma}} \quad (8)$$

This is equivalent to moving the origin of the flow curve from zero stress to the yield stress and treating System *B* as a Newtonian liquid at stresses beyond. Semisolids with high yield values are described as “hard.” When their plastic viscosity is high, they are described as “stiff.”

Some Bingham bodies have flow curves that deviate from straight lines at stresses close to the yield stress, such as the portion *CD* in the flow curve of System *B*, where flow occurs even below the yield stress. This phenomenon is called *plug flow* because the material moves in chunks or as a plug rather than by laminar motion, often through slippage at the wall of the duct. In such cases, the yield value usually is obtained by extrapolating the linear portion *BC* to the stress axis. System *A* is shear-thinning above its yield stress. This type of flow behavior is observed frequently with suspensions thickened with dissolved polymers, where the vehicle itself is shear-thinning.

## TIME-DEPENDENT NON-NEWTONIAN FLUIDS

In the previous discussion, shear-thinning and plastic behavior were seen to arise from competition between the detachment

Figure 22-8. Flow curves of two plastic systems.

of entangled dissolved macromolecules, or the rupturing of van der Waals links among dispersed particles by shear, and the re-establishment of such links by Brownian motion. The balance between breakdown and restoration of links shifts more and more toward breakdown as the shear increases. Reduction in interchain or interparticle links results in smaller flow units and lower apparent viscosity. It was assumed tacitly that the system adapts itself to changing shear “instantaneously,” i.e., so fast that by the time the instrumental conditions had been changed to higher or lower shear and readings then taken, the equilibrium between breakdown and restoration of links at the new shear already had been reached, producing flow units of the new average equilibrium size and the corresponding new apparent viscosity. Points representing pairs of  $\dot{\gamma}$ ,  $\sigma$  values, determined at increasing and at decreasing shear rates or shear stresses in Figures 22-4, 22-5, and 22-8, fall on the same single curves. It is immaterial whether a given shear rate was reached by increasing or decreasing the speed of the viscometer. This is the meaning of the double arrows on these curves.

**Thixotropy.** If the suspension is viscous and/or the particles are large and heavy, their Brownian motion is too slow to restore the broken interparticle links “instantaneously.” Likewise, the entanglements of polymer chains are slow to be reestablished by Brownian motion if their solution is viscous. If the rate of link restoration by Brownian motion is lower than the rate of link breakdown by shear, the apparent viscosity decreases even while the system is under constant shear, as the size of the particle aggregates or the extent of macromolecular entanglement is progressively reduced. Furthermore, the apparent viscosity at a given shear rate is lower if the system was stirred recently at high speeds than if that shear rate was approached from low speeds or from rest.

Materials whose consistency depends on the duration of shear as well as on the rate of shear are said to be *thixotropic* or to exhibit *thixotropy*. Their apparent viscosity depends not only on temperature, composition, and rate of shear or shear stress, but on the previous shear history and time under shear.

The extreme behavior is an isothermal, reversible sol-gel transformation produced by rest and by shear, respectively. For example, an aqueous dispersion of 8% w/w sodium bentonite sets to a gel within an hour or two after preparation when undisturbed, but flows and can be poured within many minutes after it had been stirred above the yield value. After prolonged rest it reverts to a gel as Brownian motion rebuilds the “house-of-cards” structure throughout the material.

Thixotropy in a shear-thinning liquid is shown in Figure 22-9. Starting with the system at rest (at the origin  $O$ ) and gradually increasing the speed of the viscometer produces the “up”

Figure 22-9. Flow curves of a shear-thinning liquid exhibiting thixotropy.

branch  $ODAB$  of the flow curve. After the maximum shear rate  $\dot{\gamma}_1$  and shear stress  $\sigma_3$  corresponding to point  $B$  have been reached, the speed of the instrument is reduced. If there is not enough time for Brownian motion to regenerate completely the structure torn down at high speed, the liquid will be less viscous, and the “down” branch of the flow curve,  $BCO$ , will be lower than the “up” branch. Thus, the shear stress required to maintain the rate of shear  $\dot{\gamma}_2$  has been reduced from  $\sigma_1$  to  $\sigma_2$ , and the apparent viscosity has dropped from  $\sigma_1/\dot{\gamma}_2$  to  $\sigma_2/\dot{\gamma}_2$ . This contrasts with the flow curve of Figure 22-6, where the “up” and “down” branches coincide.

When starting from rest, if the speed is not increased all the way up to  $\dot{\gamma}_1$  but only to  $\dot{\gamma}_2$ , corresponding to point  $A$  in Figure 22-9, and then decreased, the “down” branch is  $AEO$ . Since the maximum speed is lower than previously, less structure is broken down, and the apparent viscosity is not reduced by as much.

If the liquid in the instrument is kept at rest for a sufficient time period after it was subjected to the shear cycle  $ODABCO$ , Brownian motion rebuilds its structure, restoring its original high consistency. Starting from rest, the flow curve is again  $ODABCO$ . If no rest period is allowed and the shear cycle is repeated as soon as the “down” branch is completed, the next “up” branch is below  $ODAB$ , say,  $OFB$  in Figure 22-10. A third shear cycle following immediately after the second may give the “up” branch  $OGB$ . The “down” branch  $BCO$  may be curved, as in Figure 22-9, or straight, as in Figure 22-10. If the buildup of structure is very slow, there may be no structure left after the third shear cycle. In that case, the “up” branch coincides with the straight “down” branch  $BCO$ , and the liquid has become Newtonian. This is only temporary because the flow curve reverts to  $OABCO$  of Figure 22-10 after a prolonged rest period.

Thixotropy frequently is superimposed on plastic flow behavior. The yield value may disappear after one or more shear cycles, as in curve  $C$  of Figure 22-11; it may be reduced, as in curve  $B$  (sometimes called false body behavior), or it may remain unaltered, as in curve  $A$ .

The difference between the up and down branches of a flow curve illustrates a common phenomenon called *hysteresis*. The area enclosed by the two branches (e.g., areas  $ODAEO$  and  $ODABCO$  in Figure 22-9) or by the two branches and the stress axis (as in Figure 22-11B and C) is called the hysteresis loop. Its size is a measure of the extent of thixotropic breakdown in the structure of the system. In Figure 22-10, the areas enclosed by the two branches of the flow curves representing successive shear cycles become progressively smaller:  $OABCO > OFBCO > OGBCO$ . This parallels a decrease in the amount of structural

**Figure 22-10.** Flow curves representing successive shear cycles for a thixotropic, shear-thinning liquid.

**Figure 22-11.** Flow curves of plastic systems exhibiting thixotropy (see text).

breakdown of the system as each cycle leaves intact less residual structure to be broken down in the next cycle. When no structure remains, the Newtonian flow curve *OCBCO* of Figure 22-10 results. The absence of hysteresis in the flow curves of Figures 22-5 and 22-8 is due to another cause: The rebuilding of structure by Brownian motion is as fast as, or faster than, the shear-induced structural breakdown or the response time of the viscometer.

Thixotropy may be represented quantitatively by the area of the hysteresis loop, by a thixotropic coefficient, or by index (*T.I.*) at a specific  $\dot{\gamma}$  for a set period of time, e.g.,

$$T.I. = \frac{\sigma_{\text{before shearing}}}{\sigma_{\text{after shearing at } 0.01\text{s}^{-1}}} \quad (9)$$

or by shearing samples at various  $\dot{\gamma}$  as a function of time and fitting all of the data to an equation of the form

$$\eta = A\dot{\gamma}^B t^C \quad (10)$$

where *A* is a proportionality constant, and the exponents *B* and *C* are indices of shear-thinning and thixotropy, respectively. As *B* increases, the fluid becomes more shear-sensitive; as *C* increases, the fluid becomes more time-dependent.<sup>9</sup> A simple alternative method involves the measurement of the decay of shear stress or apparent viscosity as a function of time at a constant rate of shear. This method is illustrated in Figure 22-12. When a system is stirred at a constant shear rate, it eventually reaches constant or equilibrium values for shear stress and apparent viscosity. This is shown by the leveling off of the curve. Equilibration times at a given shear rate may range from minutes to hours, or longer, depending upon the nature of the structured system.

Thixotropy is particularly useful in the formulation of pharmaceutical suspensions and emulsions. These must be poured easily from containers, indicating low viscosity. Low viscosity, however, causes rapid settling of solid particles in suspensions and rapid creaming of emulsions. Solid particles that have settled out frequently stick together, producing a sediment difficult to redisperse (“caking” or “claying”). Creaming in emulsions is a first step toward coalescence. Thixotropy can be used to resolve this dilemma. A thixotropic agent, such as sodium bentonite magma, other colloidal clays (magnesium bentonite, attapulgite), colloidal silicon dioxide, or microcrystalline cellulose, is incorporated into the suspensions or emulsions to confer a high apparent viscosity or even a yield value. High viscosities retard sedimentation and creaming since, according to Stokes’ law, the rate of sedimentation or creaming is inversely proportional to the viscosity of the medium. If the system possesses a yield value, sedimentation or creaming is prevented altogether since there is no flow below the yield stress, i.e., the apparent viscosity at low shear becomes infinite. When it is desired to pour some of the suspension or emulsion from its container, it is shaken well, at shear stresses considerably above the yield value. The agitation temporarily breaks down the thixotropic structure, such as the house-of-cards scaffold of bentonite, reducing the yield value to zero and lowering the apparent viscosity. This makes for easy pouring. Back on the shelf, the viscosity slowly increases again, and the yield value is restored as Brownian motion rebuilds the house-of-cards structure of bentonite. This prevents sedimentation and caking of the suspended particles and creaming of the emulsion droplets; the dispersed particles again become trapped in the plastic matrix. The optimum flow curve for such formulations is that of Figure 22-11C.

*Rheopexy and Negative Thixotropy.* Once the links among suspended particles or the entanglements among dissolved polymer chains have been broken by shear, their restoration by Brownian motion is slow if the suspensions or solutions are viscous. In such cases slow flow, gentle agitation, or moderate

**Figure 22-12.** Time dependence of shear stress or of apparent viscosity of a thixotropic system.

and rhythmic vibration may accelerate the rebuilding of the structure, i.e., the restoration of the links between particles or macromolecules by Brownian motion. Low shear rates thus hasten the reappearance of high apparent viscosities or onset of gelation in thixotropic sols. In the case of sheared dispersions of bentonite, gentle vibration or rotation of the beaker speeds up the rebuilding of the house-of-cards structure. The material's recovery of some of its presheared viscosity at a faster rate when it is gently sheared, compared to when it is allowed to stand, is called *rheopexy*. Synovial fluid—responsible for lubricating and cushioning the joints—has been shown to exhibit considerable rheopectic behavior, apparently as a result of the interaction between hyaluronic acid and proteins (primarily albumin). Rheopexy is not to be confused with negative thixotropy (i.e., *antithixotropy*), which is defined as a reversible time-dependent increase in viscosity at a particular shear rate as a result of shear-induced buildup of structure over time.

## VISCOELASTICITY

Normal condensed matter is either solid or liquid. The molecules of an ideal solid are fixed in place while those of an ideal liquid are mobile. Soft condensed matter occupies a middle ground between the solid and liquid states as it typically possesses a structure that is on a substantially larger scale than atomic or molecular dimensions, i.e., the mesoscopic scale. (Soft condensed matter, soft matter, and nanostructured systems are, in effect, colloids or colloidal dispersions, but the latter terms are being increasingly supplanted in the scientific literature by the former terms.) As a result, the macroscopic rheological behavior of soft condensed matter is determined by the structure and dynamics at the mesoscopic scale and is often described as viscoelastic in nature. When stressed, viscoelastic materials simultaneously exhibit some of the properties of elastic solids and some of the properties of viscous liquids: some deformation occurs instantaneously upon the application of stress and continues as long as the stress is applied. Upon removal of the stress, there is partial recovery of the original shape. In effect, viscoelastic systems are capable of storing part of the deformation energy elastically and reversibly. The relative proportions of elastic deformation and viscous flow are dependent upon the duration of time that stress is applied. In general, over short periods of time, a viscoelastic material will exhibit predominantly elastic behavior while, over longer periods of time, viscous flow will predominate. In effect, the rheological characterization of viscoelastic materials depends, in part, on the experimental methodology employed. One useful parameter is the dimensionless Deborah number,  $N_{De}$ , defined by Reiner<sup>10</sup> as

$$N_{De} = \frac{\lambda}{t_p} \quad (11)$$

where  $\lambda$  is the stress relaxation time (defined as the time required for the stress to decay to  $1/e \cong 36.8$  percent of its initial value) and  $t_p$  is the process or observation time. When material is instantaneously deformed, the structure is perturbed as viscous flow occurs, and its microstructural elements, whether molecules or particles, are in a higher energy state. It takes some time for these molecules or particles to diffuse to a location where their energy state is equivalent to the pre-stress level.<sup>11</sup> The relaxation time for viscoelastic materials is of the same order of magnitude as the observation time ( $N_{De} \cong 1$ ), while the relaxation time for a Newtonian fluid would be 0 (i.e., relaxation time is instantaneous) and that for a Hookean solid would be  $\infty$  (i.e., no relaxation occurs). For nonideal materials, then,  $N_{De} \ll 1$  indicative of liquids and  $N_{De} \gg 1$ , of solids.

Oscillatory test methods have been particularly useful for characterizing viscoelastic materials and separating the elastic from the viscous components of their rheological behavior. In typical small amplitude oscillatory testing, stress is measured as a cone or plate, in contact with the sample, and is made to oscillate with low amplitude at a sinusoidal angular velocity. For elastic solids,

shear stress will be in phase with shear strain; for Newtonian fluids, shear stress will be  $90^\circ$  out of phase with shear strain. Viscoelastic materials will exhibit a shear stress that lags behind the shear strain by an angle—the phase angle or phase shift,  $\Delta$ —that ranges between  $0^\circ$  and  $90^\circ$ . The tangent of  $\Delta$  is a measure of the energy lost per oscillatory cycle to the energy stored per cycle, i.e.,  $\tan \Delta = G''/G'$ , the ratio of the loss (viscous) modulus to the storage (elastic) modulus. At the “crossover” point, when these moduli are equal, i.e., when  $G'' = G'$  or  $\tan \Delta = 1$ , the material is equally viscous and elastic.  $\tan \Delta$  values  $< 1$  are associated with gels or semisolids;  $\tan \Delta > 1$  are associated with fluids.

Large amplitude oscillatory testing methods—wherein oscillation with increasing peak strain is employed—are gaining some traction. These approaches allow the determination of the yield strain associated with structured systems.

Silicone putty (*Silly Putty*) is an example of a viscoelastic material. It has a comparatively short mean relaxation time ( $\sim 1$  s) at room temperature. It bounces, behaving like an elastic solid when the time of observation or of application of stress is short, but flows and shows little elasticity when slowly stretched. However, viscoelasticity is widespread even among liquids and plastic materials that seem to lack elasticity or stringiness to the touch, especially if they are tested at small deformations. Higher deformations or rates of shear approaching use conditions frequently rupture the elastic network in these materials, causing the loss of the elastic components of their rheological properties. For instance, fluid emulsions are often slightly viscoelastic at very low shear due to flocculation of the disperse droplets and interlinking of the flocs; they flow readily and lose all recovery properties under slightly higher shear.<sup>12</sup> Davis<sup>13</sup> determined the viscoelastic properties of oleaginous, emulsion, and absorption-type ointment bases by creep measurements. Radebaugh and Simonelli<sup>14</sup> evaluated the viscoelastic properties of powder-filled semisolids, using starch dispersions in lanolin as their model. As gels, pastes, and polymer or macromolecule solutions often exhibit substantial viscoelasticity, this aspect of rheological behavior should not be ignored.

Most biological fluids (e.g., blood, mucus, saliva, cervical fluid) exhibit substantial viscoelastic behavior, due to their multicomponent nature. Early investigators conceptualized blood as a viscous fluid ( $\eta \cong 4 \text{ mPa} \cdot \text{s}$ ), assuming that the viscosity controls its flow properties.<sup>15</sup> However, blood—as a fluidized suspension of elastic cells—is a non-Newtonian fluid with viscoelastic properties. At low shear rates, blood viscosity is higher because of the tendency of erythrocytes to aggregate. At high shear rates, which are typical for the arterial side and capillaries, blood viscosity is lower and constant because of erythrocyte deformation.<sup>16–18</sup> Comprehensive studies show that the shear dependence of the viscosity of blood may be attributed exclusively to the reversible formation or disintegration of erythrocyte aggregates, which increases at decreasing shear rates.<sup>19–21</sup> In the circulation, the rheological behavior of blood is determined by the interactions of the erythrocyte cells with the vessel walls.<sup>16,22</sup> Below a critical vessel caliber of 1 mm, blood viscosity becomes dependent upon vessel radius. Viscosity drastically decreases when the vessel caliber is approximately 12 to 15  $\mu\text{m}$ , the result, in part, of blood's lower hematocrit in capillaries and the biconcavity of red blood cells, the average diameter ( $d$ ) of which is 7.5  $\mu\text{m}$ . Their size is by no means negligible, compared to the radius ( $R$ ) of the capillaries. This leads to a reduction in the apparent viscosity by a factor of  $(1 + d/R^2)$ .<sup>23</sup> In addition, blood viscosity is affected by the tubular pinch effect, which consists of an accumulation of red cells in an annular region of cylindrical capillaries, located at a distance of about 60 percent of the capillary radius from the capillary axis during laminar flow of blood. Almost colorless plasma flows in the vicinity of the capillary wall. Blood flowing in the center of the capillary is also deficient in red cells. This phenomenon commonly is observed when suspensions of spherical or asymmetric particles flow through ducts whose diameter is only a low multiple of the particle size.<sup>23</sup>

The flow properties of blood are determined by the hematocrit (*Hct*) value, plasma viscosity, red cell aggregation, and deformability.<sup>16,22</sup> The studies of blood viscosity factors present an important mechanism to better understand the pathways of cardiovascular disorders. It also allows utilization of blood viscosity tests in diagnostic, prognostic, and preventive medicine.<sup>19</sup> Elevated *Hct* levels have been associated with adverse cardiovascular outcomes, including arteriosclerosis, coronary heart disease, angina pectoris, myocardial infarction, and CHD incidence.<sup>24–26</sup> Individuals who exercise regularly have been found to have reduced blood and plasma viscosity compared with nonexercisers.<sup>25</sup> On the other hand, after heavy exercise or during severe asthma attacks, serum mean lactate levels increase. In high concentrations, lactic acidosis produces erythrocyte swelling, increasing the *Hct* level and increasing whole-blood viscosity at both high and low shear rates.<sup>17</sup>

Unusual rheological phenomena associated with viscoelastic flow include the *Weissenberg effect*, in which fluid climbs up a shaft or impeller rotating in the fluid, and the *die swell effect*, wherein fluid exiting from a tube or capillary expands to two or more times the diameter of the tube. The Weissenberg effect is occasionally encountered in mixing operations, while the die swell effect may be experienced during extrusion processes. Both phenomena result from the so-called normal stress effect in viscoelastic flow, i.e., the tendency of some viscoelastic fluids to flow in a direction normal to the direction of shear. Experimentally observable stresses normal to the direction of shear arise from fluid motion and the isotropic hydrostatic pressure in the system. In Newtonian fluids, the stresses generated by the flow act parallel to the direction of shear; Figure 22-13 presents a schematic view in *x*, *y*, and *z* coordinates of the stresses operating within a system subjected to shear.

The stresses in the system are denoted by  $\sigma_{xx}$ ,  $\sigma_{yy}$ ,  $\sigma_{zz}$ ,  $\sigma_{yx}$ ,  $\sigma_{xy}$ ,  $\sigma_{zy}$ ,  $\sigma_{yz}$ ,  $\sigma_{zx}$ ,  $\sigma_{xz}$ , and  $\sigma_{zx}$ , where the first subscript letter indicates the direction of the plane in which the shear stress lies and the second gives the direction in which it acts. The stresses  $\sigma_{xx}$ ,  $\sigma_{yy}$ , and  $\sigma_{zz}$  are the normal stresses in the system. In a Newtonian system in simple shear in the *x*-direction, there are only six independent stresses in the system.<sup>27</sup> It is customary to eliminate the isotropic pressure in the system by taking the differences between normal stresses<sup>28</sup>:

$$\begin{aligned} \sigma_{xx} - \sigma_{yy} &= N_1 \\ \text{and} \\ \sigma_{yy} - \sigma_{zz} &= N_2 \end{aligned} \quad (12)$$

**Figure 22-13.** Schematic representation in *x*, *y*, and *z* coordinates of stresses operating within a system subjected to shear.

where  $N_1$  and  $N_2$  are the first and second normal stress differences, respectively.

In effect, stresses normal to the direction of shear are different from those in the parallel direction. Fluids that exhibit no normal stress effects but only time-independent non-Newtonian viscous flow are sometimes characterized as generalized Newtonian fluids. However, when normal stress effects are evident, the fluids are viscoelastic in nature. Another indicator of viscoelasticity related to the Deborah number,  $N_{De}$ , is the dimensionless Weissenberg number,  $N_{Wi}$ , that characterizes the importance of elasticity in the flow by expressing the ratio of the first elastic normal stress difference to the shear stress:

$$N_{wi} = \frac{N_1}{\sigma} \quad (13)$$

For Newtonian fluids  $N_{Wi} \equiv 0$ ; for viscoelastic fluids  $N_{Wi} > 0$ . In the course of addressing scale-up issues in biotechnology, Zlokarnik<sup>29</sup> has estimated  $N_{Wi}$  for various aqueous hydrocolloid solutions (carboxymethylcellulose sodium, 1–2% w/v; xanthan gum, 0.05–0.2% w/v) used as model fluids in cell culture studies; typical  $N_{Wi}$  values range from 1 to 10. In effect, the substantial viscoelastic nature of these systems must not be ignored if scale-up is to be successful.

In the realm of pharmaceutical solids, plasticity and viscoelasticity are observed during the course of tableting. This is not unexpected, given the conditions of extreme stress used in the compaction of compressed tablets. The viscoelastic parameters of a number of drugs and excipients have been measured under various conditions during the stress-unloading phase of the tablet compaction cycle in a rotary tablet press.<sup>30,31</sup>

## RHEOLOGICAL MODELS

### Liquids

Many liquids of pharmaceutical interest follow the empirical power law, or Ostwald-de Waele equation, over a wide range of shear rates, where

$$\begin{aligned} \dot{\gamma} &= K\sigma^n \\ \text{or} \\ \ln \dot{\gamma} &= \ln K + n \cdot \ln \sigma \end{aligned} \quad (14)$$

In many references in the literature, the power law is given as  $\sigma = k\dot{\gamma}^n$ , so that values of  $n > 1$  correspond to dilatant or shear-thickening behavior and values of  $n < 1$  to shear-thinning behavior. Of course, for Newtonian liquids  $n = 1$ .

For so-called *power-law liquids*, a log-log plot of  $\dot{\gamma}$  as a function of  $\sigma$  yields a straight line of slope  $n$ . The power law equation has the advantage of representing flow behavior in terms of only two constants,  $K$  and  $n$ . On the other hand, it has the disadvantage of all power laws, namely, the dimensions of the intercept  $K$  depend on the value of  $n$ , the specific shear rate at which  $K$  is evaluated, and the nature of the rheometer.<sup>2</sup>

For  $n = 1$ ,  $K = 1/\eta$ , and Newton's law (Equation 2) results. Thus, the exponent,  $n$ , is an index of the deviation from Newtonian flow behavior. The more  $n$  differs from unity, the more non-Newtonian is the flow behavior, i.e., the more substantial the viscosity decrease or increase with increasing shear. Among pharmaceutical liquids, the most commonly encountered deviants from time-independent Newtonian behavior are those described as shear-thinning fluids for which the power law exponent  $n > 1$ ; less commonly encountered are dilatant fluids for which  $n < 1$ . Shear-thinning and dilatant liquids frequently follow this empirical power law (or Equation 8) over a wide range of shear rates.

## OTHER EMPIRICAL EQUATIONS AND MODELS

Many empirical equations and models have been developed over the years in an effort to describe the flow behavior of non-

Newtonian systems. One of the more successful relationships is the Herschel-Bulkley model:

$$\sigma = k\dot{\gamma}^n + \sigma_0 \tag{15}$$

in which  $\sigma$  is the yield stress, and  $k$  is a consistency coefficient. For dilatant or shear-thickening systems,  $k > 0$ ,  $1 < n < \infty$ , and  $\sigma_0 = 0$ ; for shear-thinning systems,  $k > 0$ ,  $0 < n < 1$ , and  $\sigma_0 = 0$ ; and, for Bingham plastics,  $k > 0$ ,  $n = 1$ , and  $\sigma_0 > 0$ .

**Viscoelastic Materials.** Viscoelastic behavior is often represented in terms of a mechanical model. Two of the basic elements used in such a model are a helical spring (which obeys Hooke's law and is characterized by a modulus  $E$ ) and a dashpot (i.e., a cylindrical container with a loosely fitting piston filled with a Newtonian liquid, characterized by its viscosity,  $\eta$ ). When the deformation is in shear rather than in tension, Young's modulus  $E$  is replaced with the rigidity or shear modulus  $G$ . When a spring and a dashpot are connected in series, they form a Maxwell element (Figure 22-14A); when they are connected in parallel, they form a Voigt-Kelvin element (Figure 22-14B). Several Maxwell and/or Voigt-Kelvin elements can be combined in parallel and/or in series to represent the complex viscoelastic behavior of solutions and semisolids. A simple combination is Burgers' model, which consists of a Maxwell and a Voigt-Kelvin element in series (Figure 22-14C) and is characterized by two elastic moduli and two viscosities.

When a constant load or stress,  $\sigma_0$ , is applied to a Maxwell element, the elastic spring extends immediately to the recoverable strain or elongation,  $\gamma_{el} = \sigma_0/E$  (Figure 22-15A). The piston in the dashpot pulls upward gradually; this permanent deformation,  $\gamma_{vis}$ , is directly proportional to time,  $t$ . The two deformations are additive:  $\gamma = \gamma_{el} + \gamma_{vis}$ . At time  $D$ ,  $\gamma = BD = BC + CD = OA + CD$ . When the stress is removed at time  $D$  (Point  $B$ ), the spring retracts immediately and fully, and the specimen contracts from  $B$  to  $C$  by a length,  $\gamma_{el} = BC = OA$ . The permanent or nonrecoverable deformation, or creep, is

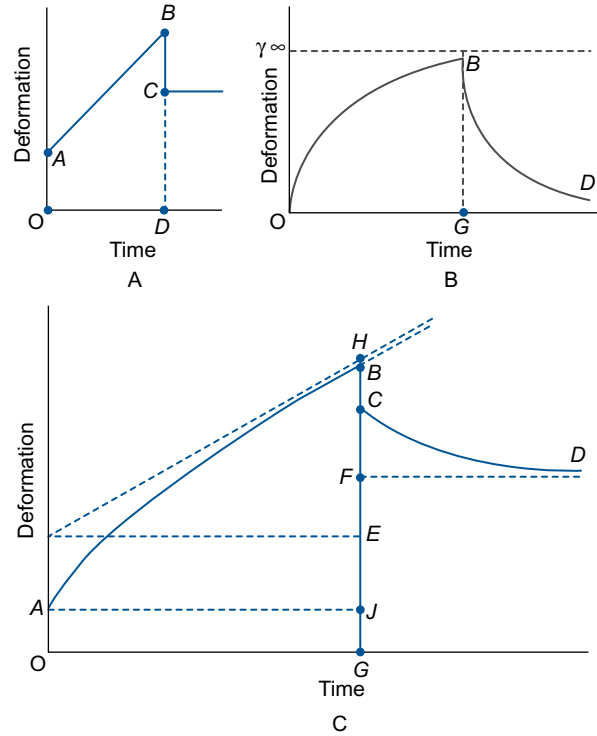

$$\gamma_{vis} = CD = \frac{\sigma_0 t}{\eta}$$

In plots like those of Figure 22-15, compliance (i.e., strain per unit stress) often is used instead of strain. Compliance (e.g., shear or tensile) is the reciprocal of modulus.

If the Maxwell element is stretched to a given  $\gamma_0$ , the stress required to maintain this deformation constant decreases gradually. As the piston of the dashpot is pulled gradually upward and the

**Figure 22-14.** Elements of mechanical models for viscoelastic behavior. A, Maxwell element; B, Voigt-Kelvin element; C, Burgers' model. Arrows show applied force or load.

**Figure 35-15.** Deformation of three rheological models at constant applied stress. A, Maxwell element; B, Voigt-Kelvin element; C, Burgers' body.

dashpot extended, it increasingly relieves the stress on the spring, which gradually contracts. After a long time, as  $\gamma \rightarrow \gamma_{vis}$ ,  $\sigma \rightarrow 0$ .

If the initial stress is  $\sigma_0$  and the stress at time,  $t$ , is  $\sigma$ , the stress relaxation is

$$\sigma = \sigma_0 e^{-(Et/\eta)} = \sigma_0 e^{-t/\theta} \tag{16}$$

The exponent  $Et/\eta$  is dimensionless, and the ratio  $\theta = \eta/E$  is the relaxation time.

When a constant stress  $\sigma_0$  is applied to a Voigt-Kelvin element (Figure 22-15B), the spring can stretch only as fast as the slow extension of the viscous dashpot permits. The greater the viscosity of the liquid in the dashpot, the greater is this retardation. The stress is shared by spring and dashpot, i.e.,  $\sigma_0 = E\gamma + \eta\dot{\gamma}$ . As  $\sigma_0$  stretches the spring-dashpot assembly, the retarded elastic deformation of the specimen increases with time until, at  $t = \infty$ , the spring reaches the full extension corresponding to the applied stress:  $\gamma_0 = \sigma_0/E$ . No additional deformation then takes place. When the stress is removed at time  $G$ , the specimen retracts fully to its original shape where  $\gamma = 0$ , because of the elasticity of the spring, but the motion is damped along the exponential curve  $BD$ , which is the mirror image of  $OB$ , because the plunger is pulled back only slowly to its original position through the viscous liquid in the dashpot. A retardation time,  $\theta_d$ , analogous to the relaxation time, is the time required for strain to relax to  $1/e$  of its initial value when stress is removed and is defined as  $\theta_d = E/\eta$ . Along the retarded elastic deformation branch  $OB$

$$\gamma = \left(\frac{\sigma_0}{E}\right)(1 - e^{-t/\theta_d}) = \gamma_{\infty}(1 - e^{-t/\theta_d}) \tag{17}$$

When the stress is removed, the exponential curve  $CD$  is described by

$$\gamma = \left(\frac{\sigma_0}{E}\right)e^{-t/\theta_d} = \gamma_{\infty}e^{-t/\theta_d} \tag{18}$$

Under constant load, Voigt-Kelvin elements reach a constant deformation; Maxwell elements continue to deform in creep as long as the load is applied. Upon removal of the load, Maxwell elements recover instantly, but not completely, while Voigt-Kelvin elements recover gradually, but completely. Most materials require more than one Maxwell or Voigt-Kelvin element to characterize their rheological behavior and to describe their load-deformation curves. The most suitable models frequently have a range or spectrum of relaxation or retardation times.

The creep deformation-time curve of Burgers' body (see Figures 22-14C and 22-15C) approximates the behavior of many viscoelastic materials, such as disperse and polymeric systems. In Figure 22-15C, the *OAB* portion of the curve, corresponding to the period when the model is under a constant stress,  $\sigma_0$ , consists of two segments. When the load is applied, *spring 2* stretches instantly and the specimen is elongated from *O* to *A*. On a molecular level, this corresponds to the elastic stretching of bonds between primary structural units, such as primary particles aggregated into flocs or crystallites in a semicrystalline polymer above its glass transition temperature. If the stress is removed at *A*, the specimen would recover its original structure completely.

The second segment, *AB*, results from the combination of the recoverable deformation of *spring 3*, retarded by *dashpot 3*, which is connected in parallel, and the non-recoverable creep of *dashpot 1*. The recoverable deformation predominates in the initial, strongly curved region of *AB*. In this region, interparticle bonds break and reform. The remainder of *AB*, which approaches a straight line, represents mainly the creep of *dashpot 1*. Here, some of the bonds that break are too slow to reform within the test period. The rupture of such interparticle bonds releases some structural units, which flow past one another to produce the permanent deformation.

At time *G*, the overall deformation is the sum of the instantaneous deformation of *spring 2* (*BC* or *AO* or *JG*), of *spring 3* damped by *dashpot 3* (*CF*), and of *dashpot 1* (*HE*). The first two deformations are completely recoverable; the third is not recovered at all:

$$\gamma = BG = JG + EJ + BE = \frac{\sigma_0}{E_2} + \left( \frac{\sigma_0}{E_2} (1 - e^{-t/\theta_d}) \right) + \frac{\sigma_0}{\eta_1} t \quad (19)$$

where the retardation time  $\theta_d = \eta_3/E_3$ .

The recovery, *BCD*, follows a pattern similar to the deformation. When the stress is removed at time *G*, *spring 2* retracts instantly, and the specimen contracts along *BC* = *OA*. The retraction of *spring 3* is retarded by *dashpot 3* along *CD*. The non-recoverable part of the deformation, due to *dashpot 1*, is represented by *FG* = *HE*.

**Disperse Systems.** Many pharmaceutical preparations are dispersions of solids or liquids in liquid or semisolid vehicles, and their usefulness often depends on their flow properties. Few disperse systems are Newtonian. Most exhibit non-Newtonian flow behavior, some of it time-dependent, often in conjunction with elastic deformation.

$$\text{Einstein's law of viscosity } \eta_{sp} = \left( \frac{\eta_{12}}{\eta_1} \right) - 1 = \frac{\eta_{12} - \eta_1}{\eta_1} = 2.5\phi \quad (20)$$

is the simplest equation derived to describe the flow behavior of dispersions. Unfortunately, it applies only to Newtonian and idealized systems. The Newtonian viscosities  $\eta_{12}$  and  $\eta_1$  are those of the dispersion and of the liquid vehicle or solvent, respectively;  $\eta_{sp}$  represents the specific viscosity of the dispersion, i.e., the increase in viscosity of the dispersion over that of the solvent, expressed as a multiple of the viscosity of the solvent;  $\phi$  is the volume fraction of the disperse phase. The viscosity of a dispersion obeying Einstein's law depends only on the viscosity of the solvent and on the volume of solvent replaced by the disperse phase, not on the size of its particles.

Assumptions operative in Einstein's law of viscosity include negligible gravitational and inertial effects and the absence of turbulence. Particles of the dispersion are large compared to the solvent molecules (i.e., the discontinuities between the solvent molecules are negligible, compared to the size of the dispersed particles) but small compared to the dimensions of the viscometer (e.g., the diameter of the capillary or the gap between the coaxial cylinders). The particles of the dispersion neither attract nor repel one another. (In reality, as most dispersions consist of particles of like charge, the viscosity of such dispersions increases due to interparticle electrostatic repulsion [the *electroviscous effect*]. In aqueous dispersions, viscosity increases can be minimized by adding electrolytes.) In addition, Einstein's law assumes that the solvent is continuous and that the particles are unsolvated, smooth, and rigid spheres (e.g., glass beads, polymer latex particles, and many spores and fungi). However, emulsion droplets are deformable and the liquid inside them can circulate. This decreases the distortion of the flow pattern around the droplets and reduces the numerical constant in Equation 20 below 2.5. Rigid anisometric particles offer increased resistance to flow, raising the constant above 2.5. If the solvation layer of solvated spherical particles is included in  $\phi$ , their dispersions may obey Equation 20. Examples of the latter are solutions of globular proteins at their isoelectric point, where their net electrical charge is zero.

Furthermore, the "ideal" dispersions addressed by Einstein's law are considered to be so dilute that the distortion of the laminar streamlines of the solvent at the surface of one particle does not overlap and reinforce the distortions around its neighbors. However, at higher disperse phase concentrations, the perturbation of laminar flow produced by one particle reaches into the fields of other particles. This produces additional resistance to flow and increases  $\eta_{sp}$  and  $\eta_{12}$  above the values given by Equation 20.

Deviations from these conditions result in higher dispersion viscosities than those calculated by Einstein's law except that, when the disperse phase is fluid, the calculated viscosity is too high. An example of an extreme positive deviation is found in aqueous sodium bentonite dispersions. Their specific viscosity is about 70 times greater than that calculated from Equation 20. The particles are thin plates, deviating considerably from spherical shape. They are hydrated, and their negatively charged faces attract the positively charged edges but repel the negatively charged faces of other particles. Polymer solutions with their thread-like, highly solvated, entangled macromolecules also deviate considerably from Einstein's law. Several variations on Einstein's law express the specific viscosity as a polynomial in  $\phi$ , thereby broadening its applicability, for example, to more concentrated dispersions.

One of the more successful relationships applied to dispersions with a high solids content is the Casson model<sup>32</sup>:

$$\sigma^{1/2} = k_0 + k_1 \dot{\gamma}^{1/2} \quad (21)$$

where  $k_0$  and  $k_1$  are constants that depend on the properties of the dispersion medium and the disperse phase. Although the Casson equation has been used empirically in modeling the rheological properties of a wide range of concentrated dispersions, it was originally derived from basic principles with the assumption that the disperse phase behaved as rigid rods.

## COMPUTATIONAL RHEOLOGY

Empirical relationships aside, numerical methods for the characterization of non-Newtonian flow were developed in the 1960s, but computational rheology has emerged to address previously intractable problems, such as three-dimensional transient flows of polymeric liquids, non-isothermal non-Newtonian flows, or turbulent flow of generalized Newtonian and viscoelastic materials.<sup>33</sup> Computer software, in consort with modern rheometer design, has also facilitated the development

of more complex models of deformation and flow under flow regimes, ranging from the laminar to the turbulent, even encompassing the transitional flow regime, in which flow is neither completely laminar nor completely turbulent. In all likelihood, the net effect of these advances is to demystify rheological principles and allow the *a priori* estimation of the mechanical properties of the living and nonliving systems with which we contend.

## RHEOLOGICAL MEASUREMENTS

Many of the instruments designed to measure steady shear flow and the corresponding viscosity do not enable the precise delineation of sample dimensions, the forces exerted, or the resultant deformation or flow. These devices are referred to in this text as viscometers. Those instruments that enable a thorough, geometrically accurate analysis of deformation and flow to be made are referred to as rheometers. The term *viscometer* should be reserved for a subset of rheometers that measure only Newtonian viscosity. When flow or deformation is not well defined or is indeterminate, the resulting measurements are likely to correspond, at best, to approximations of the true rheological behavior of the sample.

A wide array of viscometers and rheometers is available commercially; they vary in regard to mode of generation of simple shear flow, measurement geometries, range of shear rate and shear stress, sample size, ease of operation, reproducibility, and cost. It is necessary to select an instrument that provides the information desired for a specific application. Information on selected suppliers along with websites is listed in Table 22-4. This section outlines the basic aspects of some of the types of viscometers and rheometers available.

All of the equations routinely used with viscometers yield viscosities, shear rates, and shear stresses based on the assumption that the fluid is Newtonian. The viscosity, in particular, is often an *apparent* viscosity because the corresponding shear stress and shear rate may not be precisely defined. For non-Newtonian fluids—and in order to compare data from one

viscometer to another—the pseudo-Newtonian data must be corrected for non-Newtonian behavior.

One very important potential problem is measuring the apparent viscosity of a material at a single rate of shear instead of covering a wide range of shear rates. A Newtonian, a shear-thinning, a plastic, and a dilatant fluid may all have the same apparent viscosity if their flow curves have a common intersection point since apparent viscosity is defined as shear stress/shear rate, whereas their flow curves may demonstrate very dissimilar behavior.

Measuring the apparent viscosity over a range of shear rates but maintaining the material for only short times at each shear rate also can give misleading results by missing thixotropic or time-dependent effects. The latter usually are detected by measuring the flow curve first at increasing shear rates and, after reaching the desired maximum value, at decreasing shear rates. An alternate technique is to keep the material at a constant shear rate for a given period of time and to observe the decay, if any, of the shear stress with time.

## GENERAL VISCOMETER AND RHEOMETER TYPES

At the outset it should be noted that simple shear flow can be generated by (a) *pressure flow*, in which a sample is forced through a channel, pipe, or slit; or (b) *drag flow*, in which motion is caused by moving one of the walls in contact with the sample to be evaluated. A third methodology, based on the velocity of an object rolling or falling through the liquid or rising through the liquid around the object, involves substantially more complex flow patterns. Viscometers or rheometers embodying these methods are exemplified by capillary or slit devices, rotational instruments, and falling or rolling ball units, respectively.

The apparent viscosity can be determined following calibration of the instrument with a standard Newtonian fluid:

$$\eta = K_{\eta}(\dot{\alpha}_\gamma, \alpha_\sigma) \quad (22)$$

**Table 22-4. Selected Viscometer and Rheometer Companies with Web Addresses**

Company	Instrumentation	Web Address
Anton Paar USA, Inc.	Rotational rheometers; rolling ball viscometers	<a href="http://www.anton-paar.com/">http://www.anton-paar.com/</a>
Brookfield Engineering Laboratories, Inc.	Brookfield viscometers/rheometers	<a href="http://www.brookfieldengineering.com">http://www.brookfieldengineering.com</a>
Cannon Instrument Co.	Capillary viscometers	<a href="http://www.cannoninstrument.com">http://www.cannoninstrument.com</a>
Grace Instrument Co.	Viscometers/rheometers, especially for high pressures & temperatures	<a href="http://www.graceinstrument.com">http://www.graceinstrument.com</a>
Malvern Instruments	Rosand capillary rheometers; Kinexus rheometers; Bohlin rheometers	<a href="http://www.malvern.com">http://www.malvern.com</a>
proRheo GmbH	Rheomat viscometers/rheometers	<a href="http://www.prorheo.de">http://www.prorheo.de</a>
RheoSense, Inc.	VROC viscometers/rheometers	<a href="http://www.rheosense.com">http://www.rheosense.com</a>
TA Instruments	ARES-G2 rheometers; Discovery Hybrid rheometers	<a href="http://www.tainstruments.com">http://www.tainstruments.com</a>
Texture Technologies	TA.HD Plus; TA.XT Plus, TA.XT Express texture analyzers	<a href="http://www.texturetechnologies.com">http://www.texturetechnologies.com</a>
Thermo Fisher Scientific, Inc.	Haake RheoStress, RotoVisco rotational rheometers; Höppler rolling ball viscometer	<a href="http://www.thermoscientific.com">http://www.thermoscientific.com</a>
Vilastic Scientific, Inc.	V-E System; Bioprofiler; Vilastic-3 viscoelasticity analyzers	<a href="http://www.vilastic.com">http://www.vilastic.com</a>

**Table 22-5. Viscometer/Rheometer Parameters**

Instrument Type	$\chi\gamma_s$	$\chi\sigma$
Pressure flow	Time of fluid flow	Fluid density
Drag flow	Rotational speed	Torque
Falling sphere or object	Velocity of falling sphere or object	Sphere or object diameter; density difference between sphere and fluid
Rolling sphere	Velocity of rolling sphere; angle of inclination	Sphere or object diameter; density difference between sphere and fluid

where  $K_\eta$  is the viscometer or rheometer constant for determining viscosity, and  $x_\gamma$  and  $x_\sigma$  are experimental parameters, related to shear rate and shear stress, respectively. Alternately, shear rate and shear stress can be determined separately as follows:

$$\dot{\gamma} = K_\gamma x_\gamma \quad (23)$$

and

$$\sigma = K_\sigma x_\sigma \quad (24)$$

where  $K_\gamma$  and  $K_\sigma$  are the viscometer constants for determining shear rate and shear stress, respectively.  $K_\gamma$  and  $K_\sigma$  are related to  $K_\eta$  as follows:

$$K_\eta = \frac{K_\gamma}{K_\sigma} \quad (25)$$

The experimental parameters  $x_\gamma$  and  $x_\sigma$  for three basic types of viscometers and rheometers are listed in Table 22-5.

In shear flow, the temperature of the sample rises progressively as the energy used to overcome its viscous resistance is transformed into heat. The higher the viscosity, the greater the heat buildup. Since the viscosity of liquids depends strongly on temperature, accurate temperature control is essential. Despite the minimal heat buildup in capillary viscometers, since only a small portion of the test liquid is sheared at any given moment and the measurements are intermittent, capillary viscometer use typically employs provisions for temperature control. Accurate temperature control can be accomplished through the use of a constant-temperature water or oil bath for immersion of a capillary instrument or the sample holder (e.g., cup) of a rotational device, or the incorporation of a Peltier plate or its concentric cylinder equivalent.

## CAPILLARY AND SLIT VISCOMETERS AND RHEOMETERS

### CAPILLARY INSTRUMENTS

The glass Ostwald, Cannon-Fenske, and Ubbelöhde capillary viscometers are among the most popular capillary instruments in use. The duct is a cylindrical capillary of length  $L$ , and the driving force causing the liquid to flow through it is its weight. Thus,  $\Delta P$  in Poiseuille's law (Equation 6) is replaced by the hydrostatic pressure  $h\rho g$  of a liquid column of height  $h$  and density  $\rho$ ;  $g$  is the acceleration of gravity:

$$\eta = \left( \frac{\pi R^4 h g}{8LV} \right) \rho t = K_\eta \rho t \quad (26)$$

A standard volume of the liquid is transferred into the viscometer. Liquid is then drawn into the upper reservoir bulb of the instrument by suction (Figure 22-16). The efflux time,  $t$ ,

**Figure 22-16.** Capillary viscometers: Ubbelöhde, Ostwald, and Cannon-Fenske.

required for the liquid level (meniscus) to fall from the upper to the lower mark (the height,  $h$ ), emptying the upper reservoir, is determined. The height decreases as liquid flows through the capillary, but its time-averaged value is constant for a given viscometer containing a constant volume of liquid.

Calibration of the viscometer consists of determining the constant  $K\eta$  experimentally with a liquid of known viscosity and density by measuring the efflux time  $t$  according to Equation 26. The viscosity for an unknown liquid is then determined from Equation 27:

$$\eta = K_\eta \rho t \quad (27)$$

The liquid used to calibrate the viscometer should have approximately the same flow time  $t$  as the unknown, in order to minimize the divergence from Equation 27. The major portion of the potential energy represented by the hydrostatic pressure head is dissipated (as heat) in overcoming the viscous resistance to flow in the capillary tube, i.e., the friction of layer slipping past concentric layer. A small portion of the potential energy is required to accelerate the liquid as it enters the capillary from the reservoir (*kinetic energy correction*). Another small amount is used up in the streamlines converging from the broad reservoir into the narrow capillary and in spreading the streamlines upon issuing from the capillary (the so-called *entrance* or *end effects*). These two corrections are included experimentally in the constant  $K\eta$ .

It is not necessary to evaluate  $K\eta$  if the viscosity of one liquid relative to a reference liquid is determined. It suffices to measure the flow time  $t_1$  for the reference liquid of known viscosity  $\eta_1$  and density  $\rho_1$  and to compare it with the flow time  $t_2$  for the liquid of density  $\rho_2$  whose viscosity  $\eta_2$  is to be determined. Thus, the viscosity of the unknown is

$$\eta_2 = \left( \frac{t_2 \rho_2}{t_1 \rho_1} \right) \eta_1 \quad (28)$$

If the viscosity of the reference liquid is not known, a *relative viscosity*  $\eta_r$  can be determined, as defined in the following equation:

$$\eta_r = \frac{\eta_2}{\eta_1} = \frac{t_2 \rho_2}{t_1 \rho_1} \quad (29)$$

If the density of the liquid is not known, a *kinematic viscosity*  $\nu$ , defined as the absolute viscosity divided by the fluid density, can be determined:

$$\nu = \frac{\eta}{\rho} \quad (30)$$

Kinematic viscosity has the units of stoke(s) or centistoke(s) and is not numerically or dimensionally equivalent to the viscosity in mPa·s.

Shear rate and shear stress can be determined explicitly from Equations 23 and 24 as they apply to capillary viscometers. It can be shown that Equation 26 can be separated into shear stress and shear rate as follows:

$$\dot{\gamma} = \frac{4VL}{\pi R^3 t} = K_{\dot{\gamma}} \left( \frac{L}{t} \right) \quad (31)$$

and

$$\sigma = \left( \frac{hgR}{2L} \right) \rho = K_{\sigma} \rho \quad (32)$$

Thus,  $K_{\dot{\gamma}}$  and  $K_{\sigma}$  in Equations 31 and 32 could be calculated directly since all of the parameters in their definition appear to be measurable. In reality, the length of the capillary,  $L$ , cannot be measured precisely because of the corrections discussed previously. Consequently, calibration of the capillary viscometer with a Newtonian standard is required.

A range of shear rates and shear stresses can be obtained for a given liquid by using a series of glass capillary viscometers of different capillary diameters since the usual glass capillary viscometer affords viscosity measurements at only one time-averaged value of shear rate. The efflux times should exceed 200 s to minimize the kinetic energy correction and possible errors in determining the efflux time. Given the small  $\Delta P$  attained with glass capillary viscometers, their use in measurements of high-viscosity fluids is impractical. Alternatively, then, various *capillary extrusion* instruments operating under pressure, using an external pressurized gas reservoir or other source of constant pressure, are commercially available. In addition, capillary extrusion viscometers may allow the operator to vary the shear rate or shear stress, thereby facilitating non-Newtonian fluid characterization.

## SLIT VISCOMETERS AND RHEOMETERS

Slit viscometers and rheometers, like capillary extrusion devices, involve external pressure-driven flow. However, flow typically occurs through a thin rectangular channel or slit. In one microfluidic embodiment of this design (employing a software-driven precision temperature-controlled microsyringe), developed by RheoSense, Inc., an array of pressure sensors embedded in the floor of a microchannel enable the direct determination of the pressure gradient  $dp/dx$ , which is proportional to the apparent viscosity. For Newtonian liquids, the following relationships can be employed:

$$\dot{\gamma}_{\text{app}} = \frac{6Q}{\varpi h^2} \quad (33)$$

$$\sigma = - \left( \frac{dp}{dx} \right) \left( \frac{\varpi h}{2\varpi + 2h} \right) \quad (34)$$

and

$$\eta = \frac{\sigma}{\dot{\gamma}_{\text{app}}} \quad (35)$$

where  $Q$  is the flow rate,  $\varpi$  is the width of the channel, and  $h$  is the depth of the channel. For non-Newtonian liquids, the true shear rate in rectangular slit flow is calculated by applying the Weissenberg-Rabinowitsch correction to the data:

$$\dot{\gamma} = \left( \frac{\dot{\gamma}_{\text{app}}}{3} \right) \left( 2 + \frac{d \ln \dot{\gamma}_{\text{app}}}{d \ln \sigma} \right) \quad (36)$$

The development of this *microfluidic* approach to rheometry confers advantages such as precise control of flow rates, use of low sample volumes (e.g., <50  $\mu\text{L}$ ) and flow rates, and the attainment of a wide range of shear rates (e.g.,  $10^{-1}$  to  $10^6$   $\text{s}^{-1}$ ).

## ROTATIONAL VISCOMETERS AND RHEOMETERS

These instruments depend on the fact that the rotation of a solid body in contact with a liquid is impeded by a retarding force as a result of the viscous drag, which is proportional to the viscosity of the liquid. The advantages of rotational viscometers and rheometers are that the shear rate or shear stress can be varied over a wide range of values, and that continuous measurements at a given shear rate or shear stress can be made for extended periods of time, affording measurements of the time dependency as well as of the shear dependency of the viscosity.

Classical rotational viscometers of the *MacMichael* type—with an outer sample-containing cup rotated at a constant, though adjustable speed—and the *Stormer* type—with a stationary cup and a bob or rotor driven by weights linked to the shaft of the bob—are passé, given the advances in instrument engineering and integrated software. In most modern rotational viscometers or rheometers, the cup, as with the Stormer viscometer, is fixed. The bob is rotated at a constant speed that can be varied over a wide range of rpm or shear rates. The torque on the rotating bob required to maintain a constant speed of rotation against the viscous drag of the liquid is detected and instantaneously converted to appropriate rheological parameters.

## INFINITE GAP VISCOMETERS

This is a type of concentric-cylinder viscometer in which the viscous traction is measured on a spindle or bob rotating in the liquid, which is contained in a beaker or similar container. The size of the container is such that  $R_c^2 \gg R_b^2$ . The viscometer spindle can be inserted not only into beakers in the laboratory but also into kettles, reactors, and mixing tanks in the plant. Thus, the viscometer can be adapted for continuous in-line viscosity measurements. A guard can be mounted around the spindle to prevent it from being deflected laterally, thereby causing misalignment of the shaft. The guard also ensures that the condition,  $R_c^2 \gg R_b^2$  is maintained. The apparent viscosity is given by

$$\eta_{\text{app}} = \frac{3M}{32R^3\Omega} \quad (37)$$

where  $M$  is the torque,  $R$  is the radius of the spindle or bob, and  $\Omega$  is the angular velocity of the spindle or bob in radians  $\text{s}^{-1}$ .

## COAXIAL-CYLINDER RHEOMETERS

The geometry of a coaxial-cylinder viscometer is shown in Figure 22-17. The viscosity is calculated by means of the *Margules* equation:

$$\eta = \left( \frac{R_c^2 - R_b^2}{4\pi h R_b^2 R_c^2} \right) \left( \frac{M}{\Omega} \right) = K'_{\eta} \left( \frac{M}{\Omega} \right) \quad (38)$$

where  $R_b$  and  $R_c$  are the radii of the bob and cup, respectively,  $h$  is the height of the bob immersed in the liquid,  $M$  is the torque, and  $\Omega$  is the angular velocity of the bob in radians  $\text{s}^{-1}$ . The angular velocity of the bob is usually expressed in terms of rpm ( $\Omega = 2\pi/60$  rpm). The calibration factor  $K_{\eta}$  can be determined experimentally for each combination of cup and bob by means of appropriate viscosity standards.

Equation 38 was derived for two coaxial cylinders of infinite length. The *end effect* is the traction on both end surfaces of the bob if it is completely immersed in the liquid, or on its bottom surface if it is only partly immersed. Thus,  $h$  in Equation 38 is the “effective” height of the bob. One way to correct for the end effect is by adding an increment  $\Delta h$  to the height  $h$  of the bob

**Figure 35-17.** Geometry of a coaxial-cylinder (cup and bob) viscometer.

to arrive at an “effective height.” For a partly immersed bob with a flat bottom,  $\Delta h$  is frequently on the order of  $0.1 h$ . The added height can be determined experimentally for each material by filling the annular gap to different depths of immersion of the bob. The ratio  $M/\Omega$  is plotted against the height or depth of immersion  $h$ . The negative intercept of this usually straight line with the  $h$  axis represents  $\Delta h$ . The end effect is more conveniently accounted for by calibrating the viscometer with a viscosity standard as for capillary viscometers.

Shear rate and shear stress can be determined explicitly from Equations 23 and 24 as they apply to a coaxial-cylinder viscometer. It can be shown that Equation 38 can be separated into shear stress and shear rate as follows:

$$\sigma = \frac{M}{2\pi R_b^2 h} \quad (39)$$

$$\dot{\gamma} = \left( \frac{2R_c^2 \Omega}{R_c^2 - R_b^2} \right) \quad (40)$$

### CONE-AND-PLATE VISCOMETERS AND RHEOMETERS

These instruments consist of a rotating cone with a very obtuse angle and a stationary lower flat plate. The plate is raised until the apex of the cone just touches its surface. The liquid fills the narrow triangular gap between cone and plate (Figure 22-18). Its surface tension prevents it from spreading on the plate. The cone is driven at controlled speeds that can be varied continuously. The viscous drag on the rotating cone exerts a torque that is proportional to the shear stress. The angle  $\theta$  formed by cone and plate is usually less than 3 degrees, the average gap width is less than 2 mm, and sample volumes smaller than 0.5 mL can be used.

For small values of  $\theta$  in radians, the viscosity is determined as

$$\eta = \left( \frac{3\theta}{2\pi R_b^2} \right) \left( \frac{M}{\Omega} \right) \quad (41)$$

**Figure 35-18.** Geometry of a cone-and-plate viscometer.

where  $R_b$  is the cone radius. Equation 41 can be expressed in terms of shear stress and shear rate as follows:

$$\sigma = \frac{3M}{2\pi R_b^2} \quad (42)$$

$$\dot{\gamma} = \frac{\Omega}{\theta} \quad (43)$$

Equation 43 is applicable when  $\theta < \sim 3^\circ$ , i.e., the rate of shear across the conical gap is relatively constant.

### PARALLEL PLATE VISCOMETERS AND RHEOMETERS

A parallel plate or parallel disk instrument is similar to a cone-and-plate instrument except that the upper plate or disk of radius  $R$  is rotated at a constant angular velocity parallel to a fixed plate. Sample introduction, especially for very viscous or soft semisolid materials, is far less problematic for a parallel plate instrument than for concentric cylinder or cone-and-plate devices. An additional advantage is that variations in the shear rate can be achieved not only by altering the rate of rotation but also by varying the size of the distance or gap between the plates. The equations, with  $h$  equal to the distance between the plates, are as follows:

$$\eta = \left( \frac{h}{\pi R^4} \right) \left( \frac{M}{\Omega} \right) \quad (44)$$

$$\sigma = \left( \frac{3M}{2\pi R^3} \right) \left( 3 + \frac{d \ln M}{d \ln \dot{\gamma}_R} \right) \quad (45)$$

$$\dot{\gamma} = \frac{R\Omega}{h} \quad (46)$$

One disadvantage is that the flow between parallel plates is not homogeneous so that strain varies from 0 at the center to a maximum at the edge of the rotating plate. Consequently, torque should be evaluated at various rotational speeds. Hence, the correction in Equation 45 is shown for the change in torque relative to change in the rate of shear at the edge of the plate.

### FALLING BALL AND ROLLING BALL VISCOMETERS AND RHEOMETERS

**Falling Ball Viscometers.** With these instruments, viscosities are determined by measuring the velocity of a ball falling in the liquid being studied. This method is best suited for Newtonian liquids because it measures viscosities at a single shear rate. When a sphere of radius  $R$  and density  $\rho_2$  descends vertically through a liquid of density  $\rho_1$ , the driving force is the effective weight of the sphere, i.e., the weight of the sphere minus the

weight of the liquid it displaces. It equals the volume of the sphere multiplied by the density difference ( $\rho_2 - \rho_1$ ) and by the acceleration of gravity  $g$ , i.e.,  $(4\pi R^3/3)(\rho_2 - \rho_1)g$ . The viscous resistance of the liquid is given by Stokes's law, namely,  $6\pi\eta Rv$ . When the sphere attains the terminal or constant velocity  $v$  (which occurs soon after it is dropped into the liquid column), the two opposing forces are equal, so that the viscosity is, in general, governed by Stokes's law:

$$\eta = \frac{2R^2(\rho_2 - \rho_1)g}{9v} \quad (47)$$

Stokes assumed that the velocity of sedimentation was very low and that the liquid medium extended an infinite distance from the sphere. Among the factors requiring correction, therefore, is the proximity of the wall. The viscosity can then be determined from the following:

$$\eta = \left( \frac{2R^2g}{9} \right) \left( \frac{\rho_2 - \rho_1}{v} \right) = K_\eta \left( \frac{\rho_2 - \rho_1}{v} \right) \quad (48)$$

where  $v$  is the velocity in cm/sec of the falling, rolling, or rising object. Most viscometers of this type have a known distance marked on the instrument so that one merely measures the time for the object to move between the marks. Equation 48 then becomes:

$$\eta = \left( \frac{2R^2g}{L9} \right) \left( \frac{\rho_2 - \rho_1}{v} \right) t = K_\eta(\rho_2 - \rho_1)t \quad (49)$$

where  $L$  is the distance between the two marks on the viscometer, and  $t$  is the time for the object to travel between the marks. Calibration of the viscometer involves determining  $K_\eta$  using a viscosity standard for each ball or object.

For very viscous liquids, values of the Newtonian or the apparent viscosity at a single shear rate can be measured with a metal rod plunger immersed concentrically in a vertical cylindrical glass tube filled with the liquid. The tube is closed at the bottom and thermostatted. The diameter of the metal plunger is ~68 percent of the inside diameter of the glass tube. The weight of the plunger forces the liquid upward through the narrow, annular space between plunger and tube. The terminal or steady-state velocity of descent of the plunger is proportional to the viscosity of the liquid.

All of these instruments have guides to ensure that the probes descend along the vertical axis of the cylindrical containers.

**Rolling Ball Viscometers and Rheometers.** In rolling ball instruments, the ball rolls down the side of a tilted tube so that it follows the same path each time a measurement is made. In contrast to falling ball devices, the path is not always precisely the same. An additional advantage of rolling ball instruments is that the operator can adjust the angle at which the tube is tilted, thereby changing the effective shear stress and the time for the ball to pass between two marks. Furthermore, the use of balls of different composition, with different densities and/or different diameters (relative to the diameter of the tube), adds to the versatility and range of these instruments.

The apparent viscosity is given by Equation 50:

$$\eta = \frac{k(\rho_2 - \rho_1)}{v} \quad (50)$$

where  $k$  is an instrument constant,  $\rho_1$  and  $\rho_2$  are the densities of the ball and the fluid, respectively, and  $v$  is the velocity of the rolling sphere. The instrument constant  $k$  can be determined by calibration with known viscosity standards at a specific temperature, angle of inclination, ball and tube dimensions, and ball composition.

## TENSILE AND TORSION TESTERS; PENETROMETERS

In the case of semisolids or very viscous liquids, a cone or needle attached to a holding rod is released and plunges vertically

into the sample under the influence of its own or added weight. The depth of penetration within a given time interval, e.g., 10 s, is used to rate the consistency of the material. The results cannot be translated into absolute viscosity or yield values. A modern variation of this principle is illustrated by the "Texture Analyzer" ([www.texturetechnologies.com](http://www.texturetechnologies.com)), which can provide a wide range of static and dynamic measurements of penetration and stress.

## COMPARISON BETWEEN INSTRUMENTS

When a material is to be studied over a wide range of shear rates, more than one viscometer or rheometer may need to be used because each individual instrument may have too limited a range. It is advisable to use instruments in the range of overlapping shear rates to ensure that the corresponding flow curves do indeed coincide. When the flow curves are plotted as shear stress versus rate of shear, instruments of different dimensions, and even based on different principles, produce a single curve for a given material at a given temperature, *if the material is Newtonian*. Flow curves plotted in units other than shear stress and shear rate, such as torque units versus rpm, depend on the geometry of the viscometer and are *not* directly comparable.

In addition, the preceding discussion provides Newtonian parameters, even if the material being evaluated is non-Newtonian. In this case non-Newtonian corrections must be applied in order for flow curves from different viscometers to be comparable.

## NON-NEWTONIAN CORRECTIONS<sup>34-36</sup>

All of the preceding equations have been derived based on Newtonian behavior, which means that the shear rate is constant everywhere in the viscometer, e.g., in a cup-and-bob viscometer, at the bob surface and at the cup surface. This is not true for non-Newtonian fluids. Comparison of non-Newtonian fluids requires that viscosity data be corrected to a common reference point. The result is a correction to the shear rate term in reference to a fixed point in the viscometer, i.e., the bob surface in a cup-and-bob viscometer or the wall in a capillary viscometer. It depends on both the viscometer or rheometer and the fluid being tested. In general, the correction takes the form

$$\dot{\gamma}_{\text{corrected}} = \dot{\gamma} \cdot f(n) \quad (51)$$

where  $f(n)$  is the correction factor and  $n$  is the slope of a log-log plot shear stress as a function of shear rate. For many non-Newtonian fluids of pharmaceutical interest,  $n$  is a constant. If the log-log plot is not linear,  $n$  must be determined numerically at each data point. Flow curves plotted as shear stress as a function of corrected shear rates are then comparable between viscometers.

POWDERS AS A DOSAGE FORM 432

### INTRODUCTION

Powder applications are expanding in a variety of highly developed fields, such as foods, cosmetics, chemicals, and many other fundamental fields, particularly in pharmaceuticals. The majority of active pharmaceutical ingredients (APIs) are administered as solid dosage forms, prepared by processing and formation of powders. A powder is defined as a dry, solid substance, consisting of a large number of finely divided particles (varying 10nm-1000µm), and typically obtained by crushing, grinding, or comminuting.<sup>1</sup> Powders have a large specific surface area and surface free energy, therefore, exhibiting some physical and chemical properties. Some of the properties related to pharmaceuticals, such as particle size, shape, surface area, density, porosity, flowability, will influence the forming, packing, and processing of a variety of dosage forms, e.g. granules, tablets, capsules, suspensions, etc. Additionally, the solubility and bioavailability of a drug formulation can be affected by some basic characteristics of powders as well. Besides acting as pharmaceutical excipients, such as diluents, disintegrating agents, and lubricants, powders can also present as a pharmaceutical dosage form. In summary, powders are fundamental to pharmaceuticals, which have a significant impact on the development, manufacture, quality control, and packing of a variety of dosage forms, including tablets, capsules, granules, suspensions, microcapsules, microspheres, and dry powder inhalers (DPIs). This chapter is designed to provide a comprehensive understanding of powders, including fundamental properties of powders, primary methods of powder production, handling, and powders as a dosage form.

### PROPERTIES OF POWDERS

#### PARTICLE CHARACTERIZATION

##### Particle Size

Particle size is a basic property of a powder, which is essential to powder technology and dosage form design. Particles with different size and size distributions exhibit different behaviors. For instance, smaller particles have greater specific surface area and their bulk density, porosity, flowability, and solubility significantly differ from that of larger particles.

##### DEFINITION AND EXPRESSION OF PARTICLE SIZE

Particle size, typically expressed as particle diameter, is essential to characterizing powders. A powder is a plurality of solid particles; powders prepared using different methods, or by the same method, vary greatly in size and shape. The size of a single particle, having an ordinary spherical or cube shape, can be expressed by the diameter of a sphere or the length of a cube side. However, the majority of particles in a powder are non-spherical and irregular. As particle shape becomes more irregular, expressing the size of an individual particle is even more difficult. To fulfill the needs of production and research, scientists use a number of different expressions for particle size, based on size measurement.

The physical meaning of different particle size expressions is listed in Table 23-1.<sup>2,3</sup> Herein Feret's and Martin's diameter are intended to express the geometric size of powder particles. Feret's

diameter refers to a diameter measured between imaginary parallel lines tangential to a randomly oriented particle and perpendicular to the scale of measurement; Martin's diameter refers to a diameter measured from the length of the particle at the point that divides a particle into two equal projected areas.<sup>4</sup> These are statistical diameters that depend on both the orientation and measuring direction of particles. For irregularly shaped particles, a sphere with the same projected surface area or volume could represent as the equivalent sphere of the irregular particles, and the diameter of the irregular particles can be expressed by the diameter of the equivalent sphere, known as the surface area equivalent diameter, or volume equivalent diameter. When a particle is circumscribed by a circle, the diameter of the particle projection is called circumcircle equivalent diameter. There are other types of equivalent diameter, depending on the method used to measure the particle size, which is discussed in this chapter in detail.

##### MEAN DIAMETER AND PARTICLE SIZE DISTRIBUTION

Mean diameter represents the average size of a collection of particles; therefore, it is more practical and representative than a single particle diameter. Mean diameter can be expressed in different ways, for instance, the mean of a particle population, including arithmetic mean, geometric mean, weight mean, and volume mean, the median, and the mode (Fig. 23-1). Mean refers to the average of all the particles sizes; Median is the diameter for which 50% of the total are smaller and 50% are larger, the diameter corresponds to a cumulative fraction of 50%; and Mode represents the most frequent particle size. Different representations of mean diameter may have different numerical values, which must be specified correctly.

Arithmetic means are obtained by dividing the summarized parameters of all the particles in a powder by the total number of particles. These parameters include diameter, surface area, mass, and volume. In the following equations,  $D_d$ ,  $D_s$ ,  $D_m$ , and  $D_v$  refer to mean diameter based on diameter, surface area, mass, and volume, respectively.  $\sum dd$  is the sum of the diameter of all the particles, likewise for  $d_s$ ,  $d_m$ , and  $d_v$ , and  $\sum dn$  is the total particle number in the powder.

$$D_d = \frac{\sum dd}{\sum dn} \quad (1)$$

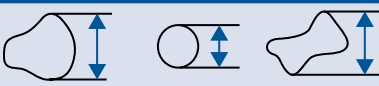

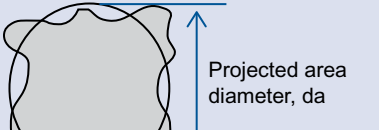

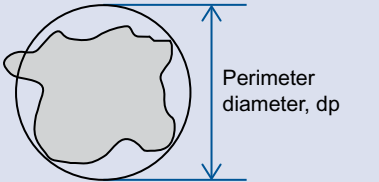

$$D_s = \sqrt{\frac{\sum ds}{\sum dn}} \quad (2)$$

$$D_m = \frac{\sum dm}{\sum dn} \quad (3)$$

$$D_v = \sqrt[3]{\frac{\sum dv}{\sum dn}} \quad (4)$$

The majority of powders consist of particles with a range of different diameters. Particle size distribution refers to the percentage of the particles within a certain size range. When referring to the properties of powders, particle size is not the only important parameter to be aware of; size distribution must also be considered as an essential factor. Particle size distribution is important for understanding powder uniformity, and it has a

**Table 23-1. Representation of Particle Size<sup>2,3</sup>**

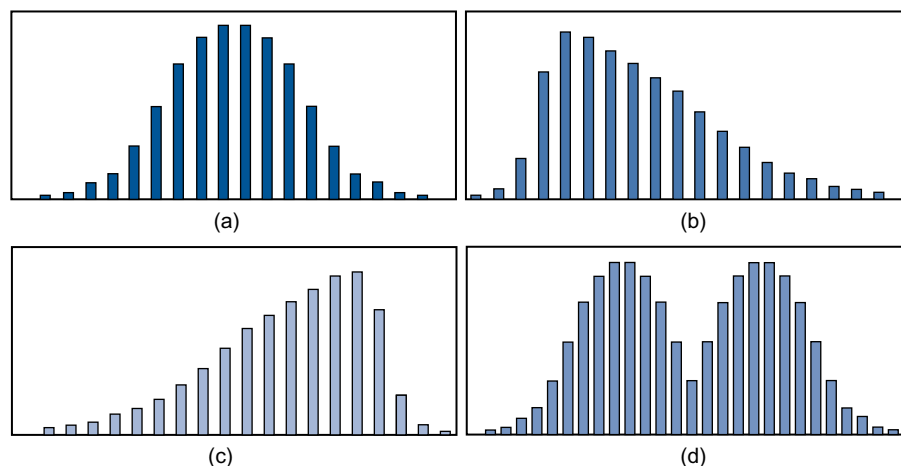

Expression of Diameter	Definition	Equation or Graphical Representation	Corresponding Determination Method
Feret's diameter, $d_F$	Distance between pairs of parallel tangents to the projected outline of the particle in some fixed direction		Microscopic method
Martin's diameter, $d_M$	Length of a chord equally dividing the projected outline of the particle in some fixed direction		Microscopic method
Projected area diameter, $d_a$	Diameter of a circle having the same area (A) as the projected area of the particle resting in a stable position		Light extinction method
Perimeter diameter, $d_p$	Diameter of a circle having the same perimeter as the projected outline of the particle		Light extinction method
Equivalent volume diameter, $d_v$	Diameter of a sphere having the same volume (V) as the particle	$V = \frac{\pi}{6} d_v^3$	Coulter counter method
Equivalent surface diameter, $d_s$	Diameter of a sphere having the same surface (S) area as the particle	$S = \pi d_s^2$	Surface method (Absorption, permeability)
Sieve diameter, $d_A$	Width of the minimum square aperture through which the particle can pass	$\frac{1}{2}(a_1 + a_2)$ or $\sqrt{a_1 a_2}$ $a_1, a_2$ : Openings of sieves	Sieving method
Stokes diameter, $d_{St}$	Diameter of a sphere having the same gravitational settling velocity as the particle	$d_{st}^2 = \frac{d_v^3}{d_d}$	Sedimentation method
Equivalent light-scattering diameter, $d_{ls}$	Diameter of a sphere giving the same intensity if the light scattering as the particle	None	Light scattering method
Aerodynamic diameter, $d_{Aero}$	Diameter of a sphere having the same terminal settling velocity in the gas as the particle	None	Impactor method (Anderson impactor, NGI)

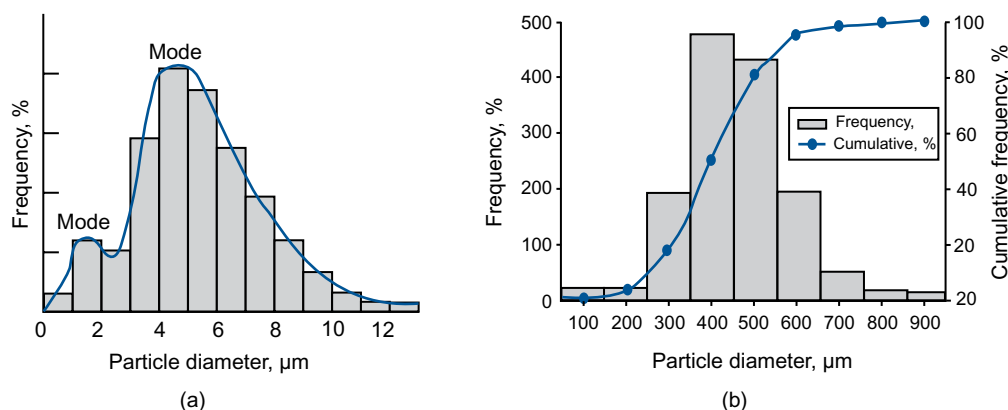

**Figure 23-1.** Mean, medium, and mode of a particle diameter. (From Silverman L, Billings CE, First MW. *Particle Size Analysis in Industrial Hygiene*. New York: Academic Press, 1971.)

great impact on the other properties of powders, including the drug dissolution profile. The cumulative percent represents the integral of the distribution function up to a certain value, or, in other words, the cumulative percent is the percentage of particles in the distribution that are less than that certain value.<sup>5</sup>

Particle size distribution can be expressed as the frequency distribution and the cumulative frequency distribution. To express size distribution in a more intuitive way, a histogram is often built based on frequency of particles within different size ranges. For frequency distribution, a histogram is constructed with the size, number, or weight percentage (i.e., frequency) of particles plotted on the y-axis and diameter range on the x-axis (Fig. 23-2). Such histograms represent the particle size distribution, and the percentage of particles having a given diameter can be determined from the histogram. For instance, the symmetrical distribution presented in Fig. 23-2a is a normally distributed histogram, where the particle size is distributed uniformly around a mean value. However, most powder particles will not exhibit a normal distribution. Their curves are usually skewed to one side of the histogram, depending on which size range occupies a larger portion of the powder solids, the smaller particles or the larger particles. The frequency distribution, shown in Fig. 23-2b, is referred to as positively skewed with a prolonged tail to the larger size particle range; the converse of this situation is referred to as being negatively skewed (Fig. 23-2c). Sometimes, a positively or a negatively skewed distribution can be transformed into a log normal distribution by replotting the x-axis with the logarithmic value of the diameter.

**Figure 23-2.** Histograms of particle size distribution, (a) a normal size distribution; (b) a positively skewed size distribution; (c) a negatively skewed size distribution; (d) a bimodal size distribution. (From Williams AC *et al* Research in primary dental care. *Br Dental J* 2004;197: 67-73).

**Figure 23-3.** Histograms of (a) a bimodal size distribution and (b) cumulative size distribution. (From Silverman L, Billings CE, First MW. *Particle Size Analysis in Industrial Hygiene*. New York: Academic Press, 1971.)

In some cases, more than one mode within a size distribution curve exists (Fig. 23-3a), for example, consisting of some unmilled coarser particles and some fractured fine particles. Herein, an alternative to the frequency distribution, the cumulative frequency distribution, is used to make comparisons between powders. For the cumulative frequency distribution, the histogram is constructed by plotting the percentage of particles that are smaller or larger than a specified particle size limit on the y-axis and the diameter of the particles on the x-axis (Fig. 23-3b). By using the cumulative frequency distribution, the geometric mean can be acquired from the plot.

Powders with the same mean particle size may vary greatly in size distribution. Generally, a narrow size distribution yields more uniform particles.

#### Determination of Particle Size

As discussed, it is difficult to measure the size of irregular particles accurately. To solve the problem, a factor (F) is introduced to adjust for the differences between the equivalent diameter (D) and the actual size (S), as shown by the following equation:

$$D = FS \quad (5)$$

F is a shape factor; when visual methods are used to determine the particle size, F can be a combination of both shape and extinction coefficient. However, in most cases, F is unknown, so different particle size analysis methods must be conducted to demonstrate the particle size of a powder.<sup>6</sup>

Commonly used methods for determination of particle size include microscopy, separation, sedimentation, electrical

stream sensing zone (Coulter counter), laser light scattering, and specific surface area (adsorption, permeability).

#### Microscopic Method

Microscopy is one of the most precise particle size determination methods, since individual particles are measured by direct viewing of the particles, instead of statistically averaging the diameter of a group of particles. Microscopy is often used to verify another particle sizing method, during development and validation of a particle sizing method. Microscopy measures the projection of the particles, rather than the particles themselves. For spherical particles, the particle size descriptor is the diameter; for irregularly shaped particles, the diameter of a sphere, which has the same projected area, is used to describe the size of the particles. Other parameters describing irregular particles, such as the perimeter diameter, Feret's diameter and Martin's diameter, can be used to describe the particle size of irregularly shaped particles. A sample size of at least 300–600 particles should be chosen, and, if the size difference between particle-to-particle is comparatively large, the sample size should be increased to get a more significant determination.

The fundamental principle of microscopy is based on the analysis of two-dimensional images of projected particles on a projection screen. The projected particles are compared with circles that are generated by the graticule of the microscope.<sup>2</sup> The diameter of the circle, which corresponds most similarly to the projected particle, is used to describe the size of the particle. The projection screen is divided into small sections to achieve simultaneous analysis of multiple particles. Light

**Figure 23-4.** TEM (A) and SEM (B) of silver nanotubes. (From Sun Y, Xia Y. Shape-controlled synthesis of gold and silver nanoparticles. *Science* 2002; 298: 2176–2179.)

microscopy can be used to characterize particle sizes between about 1 to 150 microns in diameter.

In addition, scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are used for particle size measurement as well. Both SEM and TEM can analyze particles having a much smaller size range than light microscopy, typically less than 1 micron in diameter (Fig. 23-4).<sup>7</sup> Additionally, SEM can acquire a three-dimensional image of particles, providing information about particle shape and thickness. When preparing powder samples for microscopic analysis, light microscopy requires a monodispersed layer on the slide to avoid agglomeration; for SEM, samples are placed on aluminum stubs and coated with a thin film of gold (i.e., nanometer thickness); and for TEM, samples are often embedded in resin, which is then cut by a microtome, set on a grid and coated with metal.<sup>3</sup>

Since hundreds of particles must be viewed in the microscopic method, it is very time-consuming. To overcome the difficulties brought about by manual analysis of particles, a variety of semiautomatic technologies have been incorporated into the microscopic methods to reduce the workload. One of the most popular techniques, the particle comparator, was introduced. Here, the instrument is designed to accept a photographic image of the particle projection, produced either by a light or an electron microscope. The photograph is projected onto a translucent screen, and the particles are compared with a superimposed spot of light projected from the other side. A computer, connected with the variable aperture iris, automatically ensures that the particle is counted and placed into the appropriate particle size category.<sup>8</sup> These semiautomatic technologies have many advantages, including easier and faster analysis, time savings, and no need for professional operators.

### Separation Methods

Separation methods rely on measuring the percentage by number or mass of the extracted size group corresponding to the feed concentration from the powder sample. Sieving (also referred to as screening) is one of the most conventional and simplest separation methods, having the advantage of low-cost and ease of operation. A predetermined weight of dry powder is passed through wire mesh screens, having openings of different sizes, and the weight of powder that is retained on each sieve is measured. The nest of sieves is arranged from coarser mesh opening to smaller mesh opening, top to bottom. As a result of a standardized period of agitation (i.e., by vibration, rotation/tapping, or ultrasound), particles pass through the nest of screens based on two-dimensional size in which the smallest lateral dimension of each particle determines its ability to pass through a given wire mesh opening of the sieve (Fig. 23-5). Vibration provides both horizontal motion (i.e., to loosen the packing of the powder) and vertical motion (i.e., to mix the particles). Vibration time is considered complete, when the weight contained on any of the sieves does not change by more than 5%.

**Figure 23-5.** Sieve shaker. (Courtesy of Fritsch Sieve Shaker Analysette 3 Spartan.)

US standard sieves are designed by a sieve mesh size, which corresponds to the pore size of the sieves in inches for larger sieve openings and by the number of pores per linear inch for sieves with small openings. Table 23-2 lists the particle size conversion for US standard sieves.

If the powders are suspended in a liquid suspension or the particles of the powder tend to agglomerate, dry sieving is not the best choice. In this case, a process called wet sieving can be used. Water or an organic solvent (i.e., alcohol or acetone) is chosen, depending on the wettability of the materials. The addition of water or organic solvent is designated to reduce surface tension, remove contamination, and dissolve unwanted binders, which can oppose the flow of the particles through the sieves. In the wet sieving process, a spray of the liquid is applied to both the sieving surface and the powder substance or the suspension of powder particles is poured directly onto the sieve. This wet sieving method is particularly designed for micron particles, usually 6–150  $\mu\text{m}$ .<sup>2</sup>

As shown in Table 23-1, the sieve diameter is defined as the width of the minimum square aperture through which particles can pass. Sources of error in the sieving method include the shape of the particles, weight of sample loaded onto the sieve, vibration intensity, and the phenomenon of static electricity caused by friction.

Impaction is another separation method commonly used to measure the aerodynamic diameter of aerosols. Aerosols are characterized by aerodynamic diameter, rather than geometric diameter. As shown in Table 23-1, aerodynamic diameter is an expression of a particle's aerodynamic behavior and diameter, as if it was a regularly shaped sphere with uniform density, which has the same terminal velocity. A cascade impactor is a typical type of impactor, based on the particle's inertial phenomenon for aerodynamic size distribution measurement of aerosols. Figure 23-6 shows the fundamental principle of the

cascade impactor. Briefly, for the cascade impactor, particles flowing in the air will pass through a series of successively smaller orifices consisting of rectangle slits or round holes and a collection plane surface close to the exit of the orifices, which is perpendicular to the direction of the flow. At each stage, the particles are supposed to make a right angle change of direction to follow the air stream. Larger particles, which are unable to make the right angle change in direction will impact on the collection surface; smaller particles will keep flowing in the air stream, until they interact with the correct surface. Usually, a filter is designated after the final stage to capture the smaller particles that successfully pass through the impactor. A suitable mathematical function is fitted with the amount of particles deposited on each collection surface and the cutoff size of

**Figure 23-6.** Schematic representation of the principle of cascade impactor. (From United States Pharmacopeial Convention. United States Pharmacopeia, 34th ed., and National Formulary, 29th ed. Baltimore, MD: United Book Press, 2001: p 319.)

each stage to describe the aerodynamic size distribution. A new cascade impactor, called the Next Generation Impactor (NGI), has been designed specifically for measuring the aerodynamic diameter of aerosols and is shown in Figure 23-7. The NGI has seven stages and a micro-orifice collector (MOC), which can capture the extremely small particles regularly collected on the filter of other impactors. The amount of particles deposited on the MOC can be analyzed in the same manner as other stages. The inlet flow rate of the NGI can be varied from 30 L/min up to 100 L/min. The orifice collection surfaces that are held in a tray can be readily removed from the NGI, so multiple trays are usually employed to facilitate fast sample turnaround times. Additionally, a maximum of approximately 40 mL of solvent can be added to the collection pans to accomplish appropriate drug recovery. All of the friendly features of the NGI provide a satisfactory impactor to the inhalation testing community.<sup>9,10</sup>

#### Sedimentation Method

Sedimentation refers to the settling of a single particle in a liquid medium under the influence of gravitational and centrifugal forces. Typically, the particle size distribution is determined by either placing a thin layer of powder on the surface of the liquid or the powder if homogeneously dispersed in the liquid. If the particles are spherical, the particle concentration is dilute, and their sedimentation is unaffected by interaction between particles, then particle settling in a liquid medium can be described by Stokes' law, when given the settling velocity of particles, the particle size can be calculated according to Stokes' equation as following:

**Figure 23-7.** Next Generation Impactor (NGI). (From Marple VA *et al* Next generation pharmaceutical impactor (a new impactor for pharmaceutical inhaler testing). Part I: Design. *J Aerosol Med* 2003; 16: 283–299.)

$$V = \frac{d^2(\rho_1 - \rho_2)g}{18\eta} \quad (6)$$

$$V = \frac{h}{t} \quad (7)$$

$$d = \sqrt{\frac{18\eta h}{(\rho_1 - \rho_2)gt}} \quad (8)$$

where  $V$  is the particle settling velocity (cm/s);  $r$  is particle radius (cm);  $\rho_1$  and  $\rho_2$  are the densities of the particles and dispersion medium, respectively;  $\eta$  is the viscosity of the dispersion medium ( $P$ : g/cm·s,  $1 P = 0.1 \text{ Pa}\cdot\text{s}$ );  $g$  is the gravity acceleration constant ( $\text{cm} / \text{s}^2$ );  $t$  is the sedimentation time (s); and  $h$  is the sedimentation height (cm).

One of the most commonly used instruments for the sedimentation method is Andreasen pipette (Fig. 23-8). The apparatus is composed of a 200 mm graduated cylinder with a pipette located in the center. First, samples are mixed with the liquid to form a suspension. Next, the suspension is placed into the Andreasen pipette, sedimentation medium is added, and the mixture is stirred by shaking the pipette. After that, the pipette is left undisturbed for a certain period of time. Then, 10 mL of the suspension is collected from a position of 200 mm below the surface of the suspension, and the weight of the solid obtained, after drying the sample, is measured to calculate the diameter according to the Stokes' equation.<sup>11</sup> One can also calculate a cumulative distribution from samples removed at appropriate time intervals.

Centrifugal sedimentation is used to measure the particle size between about 5–10  $\mu\text{m}$  in diameter. Upon centrifugation of a liquid medium containing the powder particles, the fraction of the total suspended powder that reaches the bottom of the centrifugation tube at different times is measured. The times are converted to their corresponding diameters, using equations based on the Stokes' equation, describing spherical particles moving through viscous media.

#### Electrical Sensing Zone Method (Coulter counter)

Figure 23-8 shows the fundamental principle of Coulter counter method. The testing tube is surrounded by a highly conducting electrolyte solution (i.e., about 0.1 M ionic strength), with particles dispersed in it. There is a small aperture on that tube, with two electrodes set at each side. Solution flow is initiated by the height difference between the liquid surfaces, which is caused by applying vacuum to the tube. When the particles pass

**Figure 23-8.** Schematic of Andreasen pipette. (From Kawachi S, Kasama S. Quantitative effect of micro-particles in iron ore on the optimum granulation moisture. *ISIJ International* 2009; 49: 637–644.)

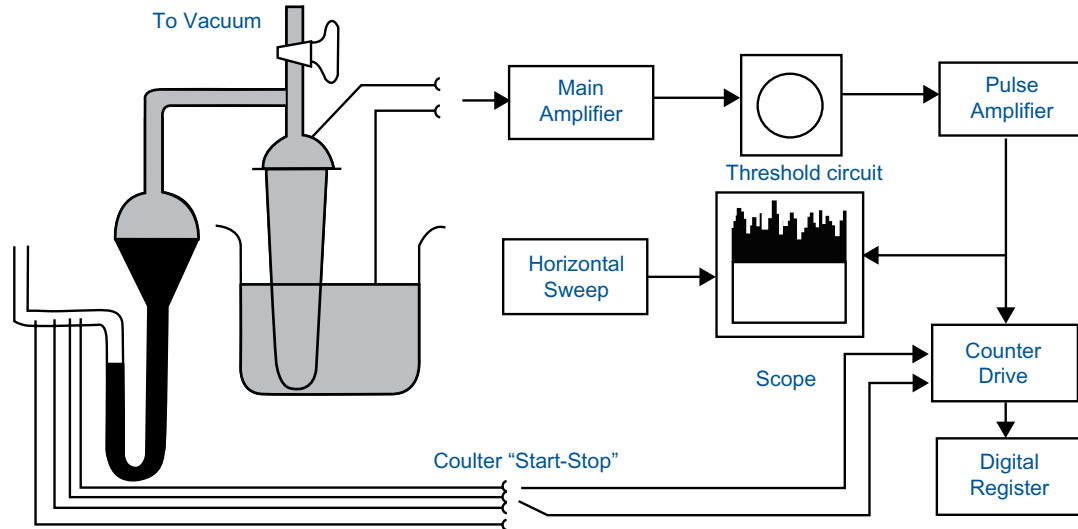

through the aperture, the instant change in resistance leads to voltage pulses, the extent of which is proportional to particle volume. These pulses are amplified and counted electronically, the number of the particles and the particle size distribution is displayed on the computer.<sup>12</sup> To obtain the size distribution over a large diameter range, making a change to the aperture size may be necessary.

A typical particle size range from about 0.6 to 120  $\mu\text{m}$  can be measured by the Coulter counter method, depending on how many apertures and tubes are used in the apparatus. There are some problems associated with this method. When multiple apertures and tubes are used, large particles may block the pathway or more than one particle may pass through the aperture at one time; particles smaller than the detection limit passing through the aperture may not be detected; and non-uniformity of the electrical field may lead to the abnormal voltage pulses.

#### Laser Light-Scattering Methods (Laser diffraction)

Laser light scattering methods are based on the fact that particles scatter light. The particle size of both large and small particles can be measured by this method.

Figure 23-10 shows low-angle laser light-scattering, also referred to as Fraunhofer diffraction. Light scattered by larger particles, those with a much larger size than the wavelength of light, has a forward direction and is slightly changing in angle. When the light emitted by a laser hits the samples, diffraction occurs and light-intensity is collected by a detector, after focusing of the scattered light by the lens. The light-intensity is

**Figure 23-9.** Diagram of Coulter counter apparatus. (From Masuda H. *Powder Technology Handbook*, 3rd ed. Boca Raton, FL: Taylor & Francis, 2006.)

**Figure 23-10.** Schematic of a low-angle laser light-scattering instrument. (From Masuda H. *Powder Technology Handbook*, 3rd ed. Boca Raton, FL: Taylor & Francis, 2006.)

proportional to the particle diameter. In some cases, a micro-processor is incorporated with the photo detector to analyze the particle size distribution data directly.<sup>13</sup>

Photo correlation spectroscopy (PCS) is used to measure small particles in liquid. Brownian motion is the fundamental theory of PCS. The collisions between small or large particles with relatively smaller molecules of the suspension medium (liquid or gas) lead to randomized movement of the particles. This phenomenon is known as Brownian motion and is independent of particle shape or the liquid medium. The following equation describes the calculation of the particle diameter using PCS:

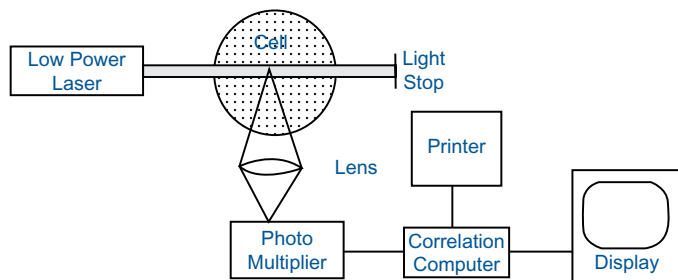

$$D = 1.38 \times 10^{-12} T 3 \pi d m 2 s^{-1}, \quad (9)$$

where  $T$  is the absolute temperature (Kelvin),  $\eta$  is the viscosity of the liquid, and  $d$  is the hydrodynamic diameter. Figure 23-11

shows a PCS instrument: a laser beam passes through the sample suspension cell, and the light scattered perpendicular to the beam is collected and auto-correlated by a computer. This generates an average particle size with a polydispersity factor, which refers to degree of variability around the average size value.<sup>14</sup>

#### Surface Area Methods

Specific surface area refers to the surface area of particles expressed per unit weight or volume. Surface area increases as the particle size decreases. Therefore, the particle size can be calculated from the specific surface area of a powder. Determination of the surface area is by gas adsorption (0.03–1  $\mu\text{m}$ ) and permeability (1–100  $\mu\text{m}$ ).

**Figure 23-11.** Schematic of a Photo correlation spectroscopy (PSC) apparatus. (From Masuda H. *Powder Technology Handbook*, 3rd ed. Boca Raton, FL: Taylor & Francis, 2006.)

When a solid is exposed to a gas, the gas molecules in contact with the surface may not be elastically bounced off, but, instead, may remain adsorbed onto the surface of the particle for a certain time at low temperature. This is called gas adsorption. When the powder sample is returned to room temperature, desorption of the gas molecules occurs. The sorption isotherms obtained in this process are demonstrated by the equation developed by Brunauer, Emmett, and Teller, typically referred as the BET method. Mostly nitrogen and krypton are the preferable gases used in BET. The gas to be adsorbed (adsorbate) is mixed with another inert, non-condensable, carrier gas, usually helium. A range of 5–30% adsorbate in carrier gas is often used. The surface area is calculated by the following equation:

$$\frac{P}{V(P_0 - P)} = \frac{1}{V_m C} + \frac{(C - 1)P}{V_m C P_0} \quad (10)$$

where  $V$  is volume of gas adsorbed at pressure  $P$ ;  $P$  is partial pressure of adsorbate;  $V_m$  is volume of gas adsorbed in monolayer;  $P_0$  is saturation pressure of adsorbate at experimental temperature; and  $C$  is a constant relating to the heats and condensation of the adsorbate.<sup>15</sup>

Permeability occurs when a gas or a liquid is passed through a powder bed. There are many factors that may affect the resistance of flow, including the surface area of the powder, the surface area of the bed, the pore size, and the viscosity of the fluid. The specific surface area can be calculated by the following equation:

$$\frac{\Delta p}{L} = \frac{150V_0\mu(1 - \varepsilon)^2}{\phi_s^2 D_p^2 \varepsilon^3} \quad (11)$$

where  $\Delta p$  is the pressure drop,  $L$  is the total height of the bed,  $V_0$  is the superficial or “empty-tower” velocity,  $\mu$  is the viscosity of the fluid,  $\varepsilon$  is the porosity of the bed,  $\phi_s$  is the sphericity of the particles in the packed bed, and  $D_p$  is the diameter of the related spherical particle.<sup>16</sup> Although this method does not provide size distribution data, it is very beneficial for rapidly estimating the mean particle size in some industrial applications.

### Particle Shape

Particle shape can be described as follows: in General Chapter <776> of the *US Pharmacopoeia* (31st Edition), the following particle shape descriptors are provided, including: a) Acicular, which means slender, needle-like particle of similar width and thickness; b) Columnar, which means long, thin particle with a width and thickness that are greater than those of the acicular particle; c) Flake, which means thin, flat particle of similar length and width; d) Plate, which means flat particles of similar length and width but with greater thickness than flakes; e) Lath, which means long, thin, and blade-like particles; and f) Equant,

which means particles of similar length, width and thickness, and include cubical and spherical particles.<sup>4</sup>

The shape of powder particles in pharmaceutical applications is very complex, due to the method of particle formation and the milling method used to reduce the size of the particles. Therefore, the particle shape is often irregular; the surface is very rough, making it difficult to use appropriate descriptor terms to describe the shape of these irregular powder particles. Also, particles in a sample may have aggregated or agglomerated into more complex structures, which must be accounted for.

The most commonly used method to characterize particle shape is the microscopic method, which has been described in detail in this chapter. Along with rapidly developing computer technologies, imaging technology has been well established over the past few decades. It is not difficult to obtain image information and geometric structure of powder particles. The significant challenge for scientists is how to transfer the image information into a more quantitative description of particle shape.

### Particle Density

**Definition** Density, another physical property of powders, is the ratio of mass to volume. To obtain the density of particles or powders, it is necessary to acquire the volume first. For non-porous solids, the estimation of the exact volume is straight forward. However, for powders with rough surfaces, cracks, and pores, the determination of volume is extremely complicated. According to different powder volume representations, the density for particles and powder can be classified as follows:

1. True density refers to the ratio of the mass of the particle to its actual volume, excluding pore volume and the volume of the gap between particles. A commonly used method for the determination of true density is helium pycnometry. Helium can readily penetrate into small pores; therefore, it is considered that the density measured by helium pycnometry approximates the true density. Conversely, liquids, such as water and alcohol, cannot penetrate small pores, so the density measured by these fluids is often slightly smaller than the true density. If a powder is compacted into tablets using high pressure, then the density of the tablet calculated from the weight and volume ratio (also referred as high pressure density), and the resultant density, is very close to the true density.
2. Particle density is defined as the ratio of particle mass to the particle volume, including the pores within the particle, but still excluding the gaps between particles. A commonly used method for determination of particle density is the mercury intrusion method. Since mercury has a high surface tension, it cannot pass through the small cracks or pores of the powder particles (<20  $\mu\text{m}$ ) under constant pressure, but can penetrate the gap between powder particles, so the volume measured by this method is sum of the volume of powder particles themselves and the volume of internal pores. Other than mercury, benzene, water, and carbon tetrachloride have been used to determine the particle density.
3. Bulk density is defined as the ratio of powder bed mass to volume of that powder bed, including both the pores and gap volume. Determination of powder bulk density is straight forward. The powder is filled into a cylinder, and, after vibration for a given time period and intensity, the volume of powder bed is measured directly from the cylinder. The bulk density is then calculated from the ratio of powder weight to volume.

A pycnometer is a typical apparatus for the liquid replacement method (Fig. 23-12). In this method, the particle density ( $\rho_p$ ) is calculated according to the following equation:

Figure 23-12. Pycnometer.

$$\rho_p = \frac{\rho_l (m_s - m_0)}{(m_1 - m_0) - (m_{s1} - m_s)} \quad (12)$$

where  $m_0$  is empty mass of the pycnometer;  $m_1$  is the pycnometer mass containing liquid;  $m_s$  is the pycnometer mass including sample particles;  $m_{s1}$  is the pycnometer mass, including both sample particles and liquid; and  $\rho_l$  is the density of liquid. A non-volatile liquid is necessary for this method, in which the particles are wettable and insoluble. Additionally, air bubbles must be removed by heating the liquid under reduced pressure, before the start of the measurement process.<sup>17</sup>

The constant gas volume method is a conventional gas replacement method. Figure 23-13 shows the fundamental mechanism of this method. When there are no particles in the cylinder, the piston is moving from A to B, causing the pressure to change from  $P_a$  to  $P_a + P_1$ ; by addition of particles to the cylinder, the procedure is repeated, and the pressure change is acquired from  $P_a$  to  $P_a + P_2$ , from which the particle volume is calculated as follows:

$$V_s = v_0 \left( \frac{P_a}{\Delta P_1} - \frac{P_a}{\Delta P_2} \right) \quad (13)$$

where  $v_0$  is the volume between position A and B, and  $V$  is the volume of the cylinder when piston is at position A.<sup>2</sup>

There are many other methods available for measurement of particle density, such as laser interferometer,<sup>18</sup> diffraction method,<sup>19</sup> differential mobility analyzer,<sup>20</sup> and sedimentation.<sup>21</sup>

### Particle Agglomeration and Aggregation

The terms “aggregation” and “agglomeration” are frequently used in powder science to describe assemblies of powder particles in the dry state or in liquid suspension. However, the confusion brought about by interchanging the use of the two terms requires that the terms be defined.

Particles form assemblages as a result of fusion, sintering, interparticle bonding, and growth (caking). They may combine during production (milling, crystallization), drying, or storage. The assemblages are often polycrystalline, with particles joined together in some random manner. Particles subjected to a milling process have very high surface energy, so small amounts of water may be adsorbed. The adsorbed water can induce partial

Figure 23-13. Constant gas volume method.

dissolution, leading to recrystallization at the surface, since it tends to lower its surface energy. Conversely, the glass transition temperature of amorphous solids can be reduced, due to the plasticizing effect of water, resulting in recrystallization.

According to the USP, an agglomerate is defined as fused or cemented particles, whereas an aggregate is defined as mass of adhered particles.<sup>4</sup> In a paper published by the Particle Characterization subgroup of the Pharmaceutical Analytical Sciences Group (PASG) operating in the United Kingdom (UK), agglomeration and aggregation are discussed and differentiated. The paper proposes to discontinue the use of “aggregate,” when that term refers to particle assemblages. The term “agglomerate” should be used exclusively to refer to particle assemblages. Before crystallization, the molecules of the particles may combine with each other, leading to a supramolecular state in which the term “aggregate” can be used to describe the process, including when the molecules combine into prenucleation structures, which have the potential to grow into crystals. The term “aggregate” should be restricted to describe this process; in addition, aggregates may turn into agglomerates at some later point.<sup>22</sup>

## BULK PROPERTIES OF POWDERS

### SPECIFIC SURFACE AREA

The specific surface area is an essential property for a powder, and it represents the void space on the surface of individual particles or agglomerates of particles. Moreover, the dissolution rate of a powder is partially impacted by its specific surface area. The most commonly used methods for determination of surface area for a powder are gas adsorption and permeability. There are a variety of other methods used for surface area determination. For instance, adsorption from solution, flow microcalorimeters, estimation of surface area from size distribution data, turbidity methods, and chemisorption have all been reported.

### POROSITY

As mentioned, pores of powder particles include the area of the pore interior and the gap between particles; hence, the porosity of powder particles refers to the ratio of the volume of the pore interior and the space between particles to the total volume of the powder, including the pore interior, the gaps between particles, and the inherent volume of particles. Powder porosity is affected by many factors, such as particle shape, size, and surface properties. When granules and tablets are made from fine powders, they tend to be porous, and the porosity of tablets has a great impact on the disintegration time. For tablets with higher porosity, water can penetrate the tablets, more readily resulting in a faster disintegration time. Another parameter to express the porosity is the pore size distribution. Many techniques have been developed to characterize the pore size distribution of a solid powder; the two most useful are gas adsorption and mercury porosimetry.<sup>23</sup>

As discussed above, gas adsorption is widely used for specific surface area determination. It is achieved by measuring the volume of gas adsorbed or desorbed at certain temperatures. Adsorption and desorption isotherms are generated by changing the pressure significantly in the range. BET surface area, along with pore size distribution information can be obtained with this method. However, pore size distributions measured by gas adsorption are limited by a narrower pore diameter range, as compared to mercury porosimetry. Therefore, mercury porosimetry is a preferred method for determination of pore size distribution of a porous solid powder.

Figure 23-14 shows a schematic of mercury porosimetry. The fundamental principle of this method is based on the capillary rise phenomenon, which means to push a non-wetting liquid (i.e., mercury) and cause it to enter into an extremely small volume (i.e., pores of powder particles), which requires extremely high pressure. First, the sample is weighed into the cell,

Figure 23-14. Diagram of a mercury porosimetry. (From Allen T. *Particle Size Measurement*, 5th ed. London: Chapman & Hall, 1997.)

degassed, and surrounded by mercury, and then the pressure is gradually increased. The volume of mercury forced into the sample at each pressure is measured. For a circularly shaped pore, the following equation demonstrates the relationship between pressure and pore size:

$$\Delta P = - \left( \frac{2\gamma}{r} \right) \cos \theta \quad (14)$$

where  $P$  is the pressure difference across the interface;  $\gamma$  is surface tension of the liquid;  $\theta$  is the contact angle of the liquid (about  $140^\circ$  for mercury); and  $r$  is the pore radius.  $\gamma$  and  $\theta$  are constant, so the equation can be simplified as follows: if  $P$  and  $r$  are expressed in psi and  $\mu\text{m}$ , respectively:

$$r = \frac{89.5}{P} \quad (15)$$

A curve is plotted of the pore radius versus pressure, according to this equation, and the pore size distribution can be obtained.<sup>16</sup>

## CRYSTALLIZATION AND AMORPHOUS STATES

### Definition and Characteristic

A powder is either in a crystalline or an amorphous state. As shown in Fig. 23-15a, crystalline means the molecules in the solid are arranged in a fixed order. Crystalline solids exhibit a melting point. The melting point is the temperature of a substance at which it changes state from solid to liquid. During the melting process, the molecules in the crystalline material obtain enough energy to break down the attractive forces that keep the molecules in the crystal structure.<sup>24</sup> The formation of crystals contributes greatly to powder production technology, which is discussed in detail in this chapter. The internal packing of molecules in a substance is important to its properties. Properties of the powder will change based on the internal packing of molecules, as well as the external shape of a crystal, which refers as the crystal habit. The crystal habit is defined as the outer appearance of a crystal. The terms used to describe the crystal habit include sphere, cube, and needle. Different crystal habits may have different surface properties, which leads to differences in powder properties, such as dissolution rate and powder flowability.<sup>25,26</sup>

The amorphous state of a material is defined as when the molecules in the substance are packed in a non-fixed, random order (Fig. 23-15b). The properties of an amorphous material differ greatly from a crystalline material. An amorphous solid does not have a melting point, as the crystalline form does.

Characteristic of an amorphous material is the glass transition temperature ( $T_g$ ), which refers to the temperature at which the state of the solid transforms between rubbery and glassy. When the temperature of the material is greater than the  $T_g$ , the substance exists in the rubbery state in which the mobility of molecules are great enough to lead to a rapid crystallization; when the temperature is lower than the  $T_g$ , the substance exists in the glassy state in which the mobility of molecules is low and the amorphous form can exist for a longer time, compared with the rubbery state. It is possible to lower the  $T_g$  of an amorphous solid by addition of a plasticizer. Water is an excellent plasticizer for most of the materials and will reduce the  $T_g$ . The water molecules can penetrate into the amorphous form of a material, due to the large void space left in the structure.<sup>27</sup> Hence, in most cases, amorphous solids tend to adsorb large amounts of water, thus, causing a stability challenge for pharmaceutical scientists. The amorphous state of a substance can be produced, when the solidification process is faster than the crystallization process, such as spray drying and ultra-rapid freezing, or by breaking the crystal form, such as by milling.<sup>28</sup> The state of a material, whether amorphous, crystalline, or both, has a great impact on the solubility or dissolution rate of a solid powder, which is discussed in the dissolution rate section.<sup>29,30</sup>

Polymorphism refers to crystals with different packing orders (Fig. 23-15c). Polymorphic forms are obtained by changing the crystallization conditions, for example, by changing to a different solvent or changing the stirring method. There are numerous examples of organic materials, including drugs and excipients that exhibit polymorphism.<sup>31-33</sup> They may exhibit many different polymorphic forms; however, only one form is most stable, and any other polymorphic forms will, eventually, convert to the more stable form. The most stable polymorphic form has the highest melting point and lowest dissolution rate. All of the other polymorphic forms are referred to as metastable, meaning they may exist for a certain period time, varying from seconds to months, based on the storage conditions. Since metastable polymorphic forms have a relatively high dissolution rate, they

Figure 23-15. Representation of (a) crystallization (b) polymorphism and (c) amorphous.

**Figure 23-16.** DSC pattern for celecoxib bulk powder (Form III) and polymorphic forms of celecoxib (Lot A and Lot B). (From Lu GW, *et al.* Characterization of a novel polymorphic form of celecoxib. *J Pharm Sci* 2006; 95: 305–317.)

might be a candidate for enhancing the bioavailability of poorly water soluble drugs. However, stabilization of the metastable form must be addressed to prevent it from converting to the stable polymorphic form. For instance, Lu *et al.*<sup>34</sup> prepared a polymorphic form of celecoxib in the presence of Polysorbate 80 and HPMC and characterized it with *in vitro* and *in vivo* studies. The DSC pattern, shown in Figure 23-16, indicates that the new polymorphic form has a melting onset at 145–148°C, which was approximately 12–15°C less than the melting point of bulk powder of celecoxib. Also, there was a faster dissolution rate (>2 times) of the polymorphic form observed, compared to the more stable form of celecoxib (Fig. 23-17). Correspondingly, the celecoxib suspension containing the polymorphic form had a significantly higher bioavailability (>4 times) than the marketed capsules and the suspension containing bulk powder of celecoxib (Fig. 23-18).

## MEASUREMENT

X-ray diffraction (XRD) has been widely used to determine the crystallinity of a solid powder. The basic principle of XRD is the measurement of identical intensity patterns, composed of peaks at different scattering angles, after diffraction of different powder samples. The XRD method is based on Bragg's law:

$$n\lambda = 2d\sin\theta \quad (16)$$

where  $n$  is the order of the diffraction pattern;  $\lambda$  is the wavelength of the incident beam; and  $d$  is the distance between the planes in the crystal and  $\theta$  is the angle of beam diffraction. As an example of the XRD pattern (Fig. 23-19), bulk itraconazole (ITZ) exhibits intense crystalline peaks at a variety of angles; conversely, the XRD patterns for wet-milled ITZ and URF-ITZ showed a reduced crystallinity.<sup>30</sup>

Thermal analysis methods are also widely used to evaluate the crystallinity of a solid powder. Differential scanning calorimetry (DSC) is frequently used. Sample and reference are maintained at the same temperature, and the heat flow required to maintain the sample and reference at the same temperature is measured. A DSC diffractogram is plotted by differentiating the rate of heating versus temperature. For instance, the crystal-

linity of bulk ITZ, wet-milled ITZ, and URF-ITZ were evaluated by DSC, as shown in Figure 23-20. For both wet-milled ITZ and bulk ITZ, there is one endothermic melting peak exhibited at about 163.4°C, indicating its crystallinity. The URF-ITZ powder exhibited a glass transition at approximately 50°C, one exothermic recrystallization peak, and a single endothermic melting peak at 165.7°C, confirmed its amorphous nature. These results agreed with the XRD results discussed previously.<sup>30</sup>

## Powder Flowability

### Definition and Significance

Flowability refers to the ease with which a powder will flow under a specified set of conditions. Flowability is a complex

**Figure 23-17.** Rotating disk dissolution for Form IV (polymorphic form) and Form III (bulk powders) of celecoxib. (From Lu GW, *et al.* Characterization of a novel polymorphic form of celecoxib. *J Pharm Sci* 2006; 95: 305–317.)

**Figure 23-18.** Pharmacokinetics of celecoxib capsules, control suspension and polymorphic form suspension in dogs ( $n = 6$ ). (From Lu GW, *et al.* Characterization of a novel polymorphic form of celecoxib. *J Pharm Sci* 2006; 95: 305–317.)

**Figure 23-19.** X-ray powder diffraction patterns (from the top to bottom): Wet-milled ITZ, URF-ITZ, and bulk ITZ. (From Yang W, *et al.* Comparison of bioavailability of amorphous versus crystalline itraconazole nanoparticles via pulmonary administration in rats. *Eur J Pharm Biopharm* 2010; 75: 33–41.)

phenomenon, referring to both physical properties affecting powder flow and the equipment required for handling, storage, and processing. Powder flowability is an essential property, which has a great impact on many pharmaceutical processes, such as blending, transfer, storage, compression, and handling, as well as the quality of pharmaceutical dosage forms. For example, when filling capsules with powders, powder flowability influences the accuracy of the amount filled into each capsule; when granules are compressed into tablets, the powder flowability and stratification can cause weight differences between tablets within the same batch; high speed tableting machines and direct compression methods require better powder flowability; reproducible sampling of powders and granulations is also associated with flow properties.<sup>35</sup>

In the case of pharmaceutical dry powder inhalers (DPIs), a size range of 1–5  $\mu\text{m}$  must be obtained for the APIs to reach the deep lung and compose an extremely cohesive powder. The adjustment and control of powder flowability is of key importance during formulation and process development of DPIs. For instance, one of the challenges is the mixing of such cohesive powders; also, the dry powder must be filled into the inhaler with high speed and precise control. In addition, the powder flowability may have a great impact on the perfor-

mance of DPIs. Emitting of the formulation from the inhaler and subsequent aerosolization of the powder into respirable particles upon inhalation is influenced by powder flowability. There are two ways to improve the flowability of DPIs: first is to form spherical API aggregates by adding micronized excipients; another more frequently used way is to mix the APIs with larger carrier particles, such as lactose, in which case the small APIs particles adhere to the surface of the carrier particles.

## DETERMINATION METHODS

There are numerous techniques that have been developed to characterize powder flowability. Only the most frequently reported are subsequently discussed.<sup>35</sup>

The angle of repose ( $\alpha$ ) has been widely used to describe powder flowability. For an accumulation of static powders, the angle between the free surface of the powder body and the horizontal plane is called the angle of repose. For instance, when adding additional powder to a powder mound, the angle between the side and the bottom surface reach a constant value, due to a balance between gravity and powder friction ( $\alpha = \tan^{-1}HR$ ). Figure 23-21 shows some methods. A smaller angle of repose indicates smaller frictional forces and greater flowability. For a free-flowing powder, the angle of repose is equal to or less than  $30^\circ$ ; powders with an angle of repose equal to or less than  $40^\circ$  have satisfactory flowability; and, when the angle of repose is greater than  $40^\circ$ , the powder does not flow freely. Different magnitudes for flowability data may be obtained, depending on which method is chosen. In addition, the reproducibility is typically poor for this method, so angle of repose is not always considered a perfect representation for powder flowability.<sup>36</sup>

Flowability can be estimated from the bulk density of the powder as well. Figure 23-22 is a typical tapped density measuring device. After the powder sample is tapped by the rotating cam, the bulk density of the powder increases from  $\rho_{\min}$  (poured bulk density) to  $\rho_{\max}$  (tapped bulk density). The percentage compressibility (Carr's Index) can be calculated by the following equation:

$$\% \text{ compressibility} = \frac{\text{Tapped density} - \text{Poured density}}{\text{Tapped density}} \times 100 \quad (17)$$

The relationship between powder flowability and compressibility is shown in Table 23-3.<sup>37</sup>

Hopper flow rate is a direct method to determine powder flowability, by measuring the rate of powder discharging from the hopper (Fig. 23-23). At the center of the hopper bottom, there is a small hole that can be covered by a shutter. By releasing and opening the shutter, the powder is discharged from the hopper. The flow rate is calculated by dividing the mass of the powder by the total time taken to remove all the powder in the container. Higher flow rate is a representation of better flowability.

## FACTORS AFFECTING POWDER FLOWABILITY

There are many factors that affect the flowability of powder solids, such as particle size, shape, porosity, density, and state of particles.<sup>38-40</sup>

**Table 23-3. Relationship Between Powder Flowability and Compressibility<sup>3</sup>**

Flowability	Extremely Poor	Very Poor	Poor	Fair	Good	Excellent
Compressibility (%)	>38	35-38	23-35	18-23	12-18	5-12

**Figure 23-20.** DSC profiles of bulk ITZ, wet-milled ITZ, and URF-ITZ. (From Yang W, *et al.* Comparison of bioavailability of amorphous versus crystalline itraconazole nanoparticles via pulmonary administration in rats. *Eur J Pharm Biopharm* 2010; 75: 33–41.)

**Figure 23-21.** Methods of measuring angle of repose, (a) fixed height cone method; (b) fixed base cone method; (c) tilting table method; (d) rotating cylinder method.

### Particle Size

As the particle size increases, the angle of repose decreases, so the powder has better flowability. Also, powders with particle sizes larger than 200  $\mu\text{m}$  have smaller angles of repose and good flowability; for particles sized between 100 and 200  $\mu\text{m}$ , cohesion and friction forces increase, and the angle of repose increases as well, leading to the reduction of flowability; for particles less than 200  $\mu\text{m}$ , agglomeration occurs, and particles exhibit tackiness or stickiness.

### Particle Shape and Surface Roughness

When the particle shape becomes more irregular, the surface is rougher, hence, more work must be done to overcome the frictional forces, and the powder has poor flowability.

**Figure 23-22.** Tap density tester.

### Water Content

Cohesive forces are related to the amount of water contained in the powder. Within a certain range, the angle of repose increases with increasing moisture content, due to increasing cohesive forces, and flowability decreases. However, when the water content reaches a critical peak value, the angle of repose starts to

Figure 23-23. Hopper flow rate measuring device.

decrease, because a lubrication effect occurs when the gaps between particles are filled with water, and flowability increases.

### Addition of Lubricants or Glidants

Lubricants and glidants are powders consisting of very fine particles. When adding lubricants and glidants to a powder with rough surfaces, the fine particles of lubricants and glidants can fill the hollow parts on the powder surfaces. The surface properties are improved, and particles are separated from each other, leading to a reduction of frictional forces between particles and, thus, enhancing powder flowability. If too much lubricants and glidants are added to the powder, there are too many fine particles in the powder, and the powder flowability decreases instead.

## SOLUBILITY AND DISSOLUTION RATE

### Definitions and Significances

For a solid powder, solubility and dissolution rate are extremely important properties, which have great influence on many pharmaceutical applications. But most essential, the bioavailability of solid dosage forms is influenced by solubility and dissolution. When molecules or ions are transferred from a solid into solution, this phenomenon is called dissolution. The extent of dissolved substance is known as the solubility of the solute in the solvent. The solubility of a substance is defined as the amount of substance in the solution when equilibrium is achieved between the dissolved and non-dissolved substance. When the concentration of solution is higher than the equilibrium concentration, a supersaturated concentration exists. All of the solubility and dissolution rates mentioned in this chapter are specified for solids in liquids.

### Mechanism of Dissolution

The dissolution process consists of three steps. First, the molecules of solid are removed from the surface and replaced by liquid molecules. There is a phase transfer involved in this stage, the attraction forces between solid and liquid molecules must endure the cohesive forces between solid molecules; second, molecules of the solid enter into the pores (free spaces) between liquid molecules, after leaving the solid surface; and finally, diffusion occurs, which means the molecules of the solid pass through the boundary layers and into the bulk solution. According to this process, Fick's first law describes the dissolution rate of the solid powder:

$$\frac{dC}{dt} = k \frac{S}{h} (C_s - C) \quad (18)$$

where constant  $k$  is the diffusion coefficient;  $S$  is the surface area of the solid;  $h$  is the thickness of the diffusion layer; and

$C_s$  and  $C$  are drug concentration at the solid surface (saturated) and in the bulk solution, respectively. Intrinsic dissolution rate (IDR) is the dissolution rate, which is independent of agitation speed, surface area, diffusion layer thickness, and the volume of solvent.<sup>3</sup> Thus,

$$IDR = kC_s \quad (19)$$

### Measurement

There are many reported methods that have been developed to measure the dissolution rate of solids in liquids. The most commonly used are based on the flask-stirrer method, rotating basket method, paddle method, and rotating and static disc method.<sup>41</sup> These methods only differ in respect to the sample holder or agitation method. For all the methods, solute concentrations at different time points are measured and plotted as a function of time; the curve obtained is often referred to as the dissolution profile. The dissolution rate of different formulations can be compared from the curves visually, or quantitative parameters related to dissolution rate can be obtained by computer modeling.

### Improvement of Solubility and Dissolution Rate of Powder Solids in Pharmaceutical Applications

A variety of methods have been employed to improve the dissolution rate of solid powder in pharmaceutical science, which are listed subsequently:

#### PARTICLE SIZE REDUCTION

According to the previous equation, the dissolution rate is proportional to the surface area of the solid, and the surface area of the particles is inversely proportional to particle size. Hence, by particle size reduction techniques (i.e., milling), the dissolution rate of the solid can be enhanced. For example, when the surface area of griseofulvin was increased from 0.3 to 2.4 m/g,<sup>2</sup> the relative absorption of griseofulvin at the same dose increased 1.5 times; for chloramphenicol powder with a particles size of 50  $\mu\text{m}$ , the peak plasma concentration was reached at 1 hour, whereas, for 800  $\mu\text{m}$  powder particles of chloramphenicol, the peak plasma concentration was reached at 3 hours.

#### INCREASING THE POROSITY OF POWDER

The dissolution medium may be able to penetrate the pores in the powder to yield an increase in the dissolution rate.

#### ADDITION OF WETTING AGENT

Powder particles may agglomerate in the dissolution medium. By adding wetting agents, the dispersibility of the solid is improved; agglomeration of particles can be prevented.

#### COSOLVENTS

In most cases, drug is more soluble in a mixture of solvents (i.e., water with water-miscible organic solvent) than in a single solvent (i.e., water).

#### SURFACTANTS

Surfactants can reduce the surface tension between solid particles and the air/liquid interface to improve the dissolution rate.

#### POLYMORPHISM AND AMORPHOUS

As previously discussed, polymorphism is a metastable form that can achieve supersaturated dissolution profiles. The supersaturated concentration can be formulated to last longer to improve the bioavailability of a poorly water-soluble drug. Similarly, for an amorphous form of the drug (see Fig. 23-24), improvement in the dissolution of two different morphologies (one is crystalline, the other is amorphous) at supersaturated conditions is shown. Clearly, the amorphous URF-ITZ displayed a much higher dissolution rate than the crystalline wet-milled ITZ.<sup>29,30</sup>

**Figure 23-24.** Dissolution profiles of crystalline wet-milled ITZ and amorphous URF-ITZ at supersaturation conditions. (From Yang W, *et al.* Comparison of bioavailability of amorphous versus crystalline itraconazole nanoparticles via pulmonary administration in rats. *Eur J Pharm Biopharm* 2010; 75: 33–41.)

## PRODUCTION METHODS

### MOLECULAR AGGREGATION

#### Precipitation and Crystallization

Pharmaceutical powders can be produced by precipitation and crystallization. They are relatively similar processes, by making a solid solute precipitate out of solution. To achieve this, first, a supersaturated solution of the solute is a necessary condition, which means the concentration of the solute in the solution is higher than the equilibrium solubility of the solute. Supersaturation does not yield a thermodynamically stable system; the exceeded solute tends to precipitate out. Second, after it reaches supersaturated concentration in the solution, the crystal or amorphous form starts to experience nucleation and growth. Nucleation is known as the process whereby solute molecules are gathered into a small mass on which the crystals or amorphous form can continue growing; growth means there are more solute molecules coming onto this small mass.

Many approaches have been developed to accomplish precipitation or crystallization:

- Raising the concentration of solute in the solvent to a higher level, by removing a certain amount of solvent, such as by solvent evaporation.
- In most cases, the solubility of solid powder decreases, when the temperature of the solution is lowered, so, by cooling the

solution, precipitation or crystallization can be achieved.

- Mixing the solution with another antisolvent in which the solid powder is insoluble or has very low solubility. For instance, for a poorly water-soluble drug, precipitation or crystallization can be obtained by adding water to the drug organic solution. In fact, there is a relatively new technology, called supercritical fluid method (SCF), based on this mechanism. Briefly speaking, a supercritical fluid is a substance maintained at a certain temperature and pressure above its critical point, which has both the properties of liquid and gas phases. It can penetrate like a gas and dissolve solids like a liquid. Supercritical fluid is a substitute for organic solvents to dissolve poorly water soluble drugs for powder generation, because the solubility of that powder in SCF can be easily altered by changing the temperature and pressure.<sup>42</sup>

### Spray Drying

Spray drying is a technique to generate powders by transforming the feed from a liquid state into a dry form, by spraying the feed into a hot drying medium (Fig. 23-25). The feed can be a solution, suspension, dispersion, or emulsion. The spray drying process mainly consists of five steps:<sup>43</sup>

1. **Concentration**—Before introduced to the spray dryer, feedstock is usually concentrated.
2. **Atomization**—Favors evaporation to a dry powder, by having optimum properties.
3. **Droplet-Air Contact**—In the chamber, atomized liquid contacts with hot gas, leading to evaporation of a majority of the water or solvent contained in the droplets within a few seconds.
4. **Droplet Drying**—Water or solvent evaporation takes places.
5. **Separation**—Cyclones, bag filters, and electrostatic precipitators may be used for the final separation stage.

Spray drying technology has many applications in the pharmaceutical industry, especially for powder technology.<sup>44</sup> Spherical or non-spherical particles, hollow or solid particles, the size of the particles (frequently ranging 10–600  $\mu\text{m}$ ), and the uniformity of a powder can be altered by changing the parameters of the spray drier. By spray drying a poorly water-soluble drug, a coprecipitate with a polymer in a stable amorphous solid dispersion can be made. Therefore, the dissolution rate and bioavailability of many drugs can be greatly improved, such as tolbutamide, indomethacin, and ibuprofen.<sup>45</sup> In addition, particles produced by spray drying can be controlled to have very a good aerodynamic performance, making them suitable for inhalation.<sup>42</sup>

**Figure 23-25.** Schematic of spray drying. (From Patel RP, *et al.* *Indian J Sci Technol* 2009; 2: 44–47.)

## Spray Freeze Drying (SFD)

Spray freeze drying (SFD) is a technique based on the principle that the rapid solidification process induced by freezing prevents the molecules from packing in a certain order (refers to crystallization). SFD combined with freeze-drying, consists of the following steps (Fig. 23-26 shows a typical SFD apparatus):

1. Atomization of feed using ultrasound, droplets are generated by one or two fluid nozzles or vibrating orifice (feed can be solution, suspension, or emulsion).
2. Freezing of the droplets in a cryogenic liquid or cryogenic vapor, usually liquid nitrogen.
3. Sublimation of solvent at low temperature and pressure by lyophilization or atmospheric freeze-drying using a cold desiccant gas stream.
4. SFD has similar pharmaceutical applications as spray drying<sup>46</sup>.

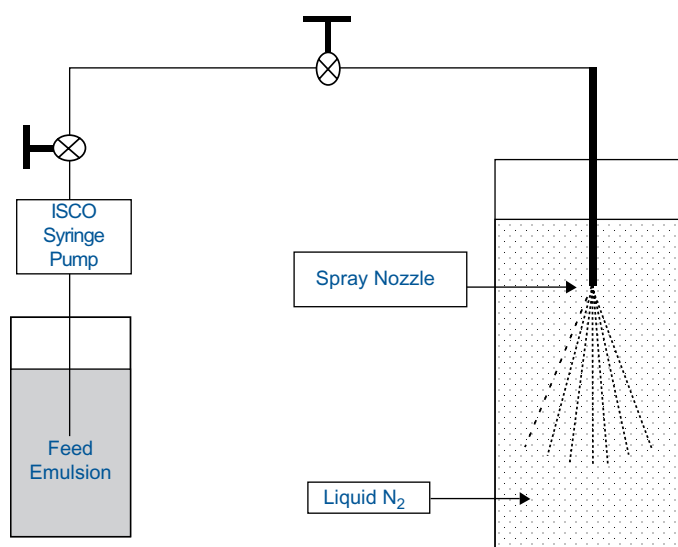

## PARTICLE SIZE REDUCTION

### DEFINITION AND MECHANISM

Comminution is defined as a process that breaks larger particles of solid into smaller particles of appropriate size, by application of mechanical forces.<sup>47</sup> The purpose of comminution includes:

1. Reduction of drug particle size, increasing surface area, improve bioavailability.
2. Alteration of powder flow, improve mixing efficiency of different drugs and reduce powder irritation propensity.
3. Acceleration of dissolution rate of powder.
4. Further facilitate formulation of powder into various dosage forms, such as suspensions, tablets, and capsules.

In general, the fundamental mechanism of powder comminution is by employment of external mechanical forces to decrease the cohesion forces between the powder particles, which lead to a size reduction and surface area enhancement. Therefore, comminution is a process that transfers mechanical energy into surface energy. Comminution consists of a variety of operations, such as cutting, chopping, crushing, grinding, and milling, and is dependent on the type of equipment

**Figure 23-26.** Diagram of spray-freezing into liquid. (From Rogers TL, et al. Micronized powders of a poorly water soluble drug produced by a spray-freezing into liquid-emulsion process. *Eur J Pharm Biopharm* 2003; 55: 161–172.)

selected. The choice of equipment is determined by the properties of the solid powder, such as the initial particle size and the desired size reached after size reduction. In most cases, solid powders have a relatively large particle size initially, resulting in a need for crushing or cutting operations required prior to grinding.

It has been proposed that less than 2% of the total mechanical energy is effective on the size reduction process. All of the remaining energy is lost in different ways, including elastic or plastic deformation of particles, deformation of cracks and metal equipment parts, interparticle friction, particle-equipment wall friction, heat, sound, and vibration. Three fundamental theories have advanced to describe the relationship between energy input and size reduction performance:

$$\text{Rittinger's theory: } E = k_R (S_n - S_i) \quad (20)$$

$$\text{Kick's theory: } E = \frac{K_K \log d_i}{d_n} \quad (21)$$

$$\text{Bond's theory: } E = 2K_B \left( \frac{1}{d_n} - \frac{1}{d_i} \right) \quad (22)$$

where  $K_R$ ,  $K_K$  and  $K_B$  are Rittinger's constant of energy per unit area, Kick's constant of energy per unit mass, and Bond's work index, respectively;  $S_i$  is the initial surface area and  $S_n$  is the new surface area; and  $d_i$  is the initial particle diameter and  $d_n$  is the new particle diameter.<sup>36,48</sup>

## METHODS CLASSIFICATION

### Mixing and Single Comminution

Drugs are generally processed by a single comminution, especially for drugs prone to oxidation and reduction reactions, which may cause an explosion. For expensive drugs, to reduce losses and ease of operation, single comminution should be used.

### Dry and Wet Comminution

Drugs are usually processed by dry comminution. In the dry comminution process, the moisture content in the solid powder is lowered to a certain limit (<5%), prior to comminution. Conversely, wet comminution is when the comminuting process includes an amount of liquid (water or ethanol) incorporated into the dry powder to make the comminution process easy to operate. Wet comminution can avoid dust generation. Some poorly water soluble chemical agents, such as cinnabar, calamine, and talc, require smaller particle sizes and are often processed by wet comminution methods.

### Comminution at Low Temperature

Some materials are difficult to comminute at room temperature, such as resins, gums, and dry extract. They can be comminuted at low temperatures, at which they have increased brittleness.

### Rapid Expansion of Supercritical Solution (RESS)

RESS is a novel technology in which fine powder is produced by rapid expansion of supercritical solution. RESS is a combination of liquid-liquid extraction, based on material differences in solubility, and evaporation, based on material differences in volatility, and was developed from supercritical fluid extraction (SFE). Generally, a solution is formed when the solids are dissolved in a supercritical fluid, and then the solution is sprayed from a nozzle in an extremely short time ( $10^{-8}$ – $10^{-5}$  s), rapidly expanding to atmospheric pressure. Due to the decreased pressure, the solubility of solid in the supercritical fluid is reduced significantly. The concentration of solution reaches a supersaturated level and precipitation occurs. The advantage of RESS is the achievement of both narrow size distribution and finely divided particles (nanometer level). The most commonly used supercritical fluid is  $\text{CO}_2$ , due to its non-toxic,

non-corrosive, non-flammable, readily available, inexpensive, inert to most substances, and low critical parameter.<sup>49</sup>

## COMMINUTION EQUIPMENT

There are numerous types of large-scale comminution equipment available in pharmaceutical industry, which can be classified into three categories based on feed and size:<sup>2,50</sup>

- Coarse crushers (e.g., jaw, gyratory, roll, and impact crushers), with feed materials ranging from 1.5 to 60 inches.
- Intermediate grinders (e.g., rotary cutters, disk, hammer, roller, and chaser mills), with produce provided between 20 and 200 mesh.
- Fine grinding mills (e.g., ball, rod, hammer, colloid, and fluid-energy mills; high-speed mechanical screen and centrifugal classifier), in which particles can pass through 200 mesh.

Only the most frequently used are subsequently discussed. For comminution equipment, three fundamental actions are involved in the comminution process:<sup>3</sup>

1. Attrition—breaking down of the material by a rubbing action of two surfaces;
2. Rolling—uses heavy rolling to crush and pulverize the material; and
3. Impact—the operation of hammers at high-speed impacts the lumps of material and breaks large particles to smaller ones, until the desired size is achieved.

Frequently, a combination of these three actions might occur, rather than only one action.

## Crushers

### JAW CRUSHER

A diagram is shown in Fig. 23-27a. It has two crushing surfaces; one is fixed, the second reciprocates by changing the pressure applied to it. Products need to be small enough to pass through the small hole at the bottom of the machine.

### GYRATORY CRUSHER

Similar to the Jaw crusher, but having two moving surfaces, which approach each other and crush the powder (Fig. 23-27b).

### CRUSHING ROLL

A typical crushing roll, shown in Fig. 23-27c, is composed of two rotating cylinders on horizontal shafts, driving in opposite directions. The distance between the cylinders can be adjusted to achieve the desired particle size.

## Intermediate Grinding Mills

### ROLLER MILLS

Fig. 23-27d shows a typical roller mill in which the feed is placed in the central rotating table, and material is ground on the concave table and by many rollers.

### HAMMER MILLS

As shown in Fig. 23-27e, hammer mills consist of many hammers placed on the rotating shafts. When the feed enters the machine, the rapid moving hammers impact the solid material and break it down to relatively small particles.

### CUTTER MILLS

In a cutter mill (Fig. 23-27f), many knives are attached to the rotating shafts, and, when the feed contacts with the knives, they cut the solid material into small fragments based on fracture of particles.

**Figure 23-27.** (a) Jaw crusher, (b) Gyratory crusher, (c) Crushing roll, (d) roller mill, (e) hammer mill and (f) cutter mill. (From Masuda H. *Powder Technology Handbook*, 3rd ed. Boca Raton, FL: Taylor & Francis, 2006.)

## Fine Grinding Mills

### BALL MILLS:

A horizontal rotating cylinder contains balls that occupy about 30-50% of the total volume of the cylinder. The balls have different sizes, so the void gaps between the balls are reduced. Large balls can break down the solid into pieces, and the small balls can break the solid into fine particles with the desired size. Both impaction and attrition are involved in this process (Fig. 23-28).

Figure 23-28. Ball mill.

### VIBRATION MILLS

Vibration mills contain steel balls that occupy about 80% of its volume. When milling starts, the whole chamber of the vibration mill is vibrated, and the particle size of the solid is reduced by impaction.

### FLUID ENERGY MILL

Also refer as jet mill (Fig. 23-29), the fluid energy mill contains a hollow housing having a diameter of approximately 20–200 cm. A fluid (usually air) is injected into the loop at very high pressure, which forms the turbulence zone. When the feed passes through the turbulence zone, impaction of particle to particle is achieved, due to the high energy of air. Size reduction occurs, based on impaction and attrition.

### STIRRED MILL

Recently, to fulfill the demand for ultrafine particles (submicron), some grinding equipment that can produce particles less than 1  $\mu\text{m}$  has been developed in the pharmaceutical industry, this includes the stirred mill. It has an agitating tank, and the balls and pebbles in the tank can facilitate agitation in the vertical direction.

To select the appropriate crushing and grinding equipment, many factors should be considered, including the starting particle size of the solid powder, the desired particle size for final product, and particle toughness and hardness. In some cases,

Figure 23-29. Fluid energy mill (jet mill). (From Parrott EL. Milling of pharmaceutical solids. *J Pharm Sci* 1974; 63: 813–829.)

even the cost of the size reduction method is considered, when accurate particle sizing is not required.<sup>47</sup>

## POWDER HANDLING

### POWDER MIXING

#### Definition and Significance

Powder mixing is an operation that serves to make two or more components uniformly distributed in the powder bed. In most cases, solid dosage forms do not only contain one component. Several ingredients are combined together to contribute to either the manufacturing process or to the bioavailability. For instance, a tablet formulation often consists of the active ingredient (API) and many other excipients, such as diluents, binders, disintegrants, and lubricants. As a result, the mixing process is necessary to ensure that the API and other components are homogeneously distributed throughout the tablet. Powder mixing processes are involved in nearly every preparation process of pharmaceutical products, such as tablets, capsules, granules, pellets, bulk powders, and dry powder inhalers.<sup>51</sup>

#### Mechanisms

There are three main mechanisms involved in the mixing process, related to the different kinds of particle motion.

- **Convection:** The large group of particles are moving together in the mixer, driven by the rotational force provided by a mixer vessel, paddle, blade, ribbon, or gas flow. The rotating flow leads to convective motion of particles and mainly contributes to the macroscopic mixing, rather than microscopic mixing. The mixing rate of this process is relatively high, however, to achieve a more uniform mixing, prolonged times are required, because particles within the moving group are not able to mix well.
- **Shear:** Shear refers to the action that one layer of powder particles moves relative to another layer of particles. Shear mixing can be caused by particles from a different powder layer, having different velocities developed in a rotary vessel or due to the compression force and extension of a layer of particles. Hence, shear mixing is the movement of a layer of particles, rather than the movement of individual particles. The rate of shear mixing is intermediate and mainly causes semimicroscopic mixing.
- **Diffusion:** Diffusion is known as the motion of individual particles, due to random motion of powder particles. When the powder bed is placed in a mixer, the volume of that powder bed increases, due to convection and shear forces, which drive the powder flowing around the mixer. Therefore, the voids between particles increase, leading to great potential for individual particles to mix with each other. The rate of diffusive mixing is relatively low, compared with convection and shear mixing; however, it contributes to the microscopic mixing.

For most of the mixing operations, all of these mechanisms are involved, rather than only one or two of them.<sup>52</sup>

In a mixing process, the degree of mixedness is often defined as the uniformity of the powder components throughout the entire powder mixture, which is frequently calculated based on some statistic and expressed by variance of the composition from the mean value of the powder mixture. Imaging samples are randomly taken from the powder mixture,  $x_i$  is the composition of sample number  $i$ , the variance of samples can be calculated as follows:

$$\sigma = \sqrt{\frac{\sum_{i=1}^n [(x_i) - \bar{x}]^2}{(n-1)}} \quad (23)$$

where  $\bar{x}$  is the mean value of the composition.<sup>2,3</sup>

Powder segregation (demixing) is the opposite process of mixing, which means the separation of the drug from the powder components. Under some circumstances, the mixing process provides the necessary situations for powder to segregate, because, during the mixing process, particles are moving relatively close to each other, and their movement may differ due to their different properties, such as size, shape, or density. Conversely, particles having similar properties tend to move together, causing that region of the powder bed to have a higher composition concentration. Some other handling processes may also cause powder segregation, such as transportation, packing, feeding, and storage. The smallest region that can measure the homogenous state in a powder mixture is called the scale of scrutiny and can be a length, area, or volume. The scale of scrutiny is a scale of the finished product. For instance, for a 100mg tablet, the scale of scrutiny is 100 mg. When the scale of scrutiny is large or the particle size is small, which indicates a large number of particles are present in the sample, the powder mixture are relatively uniform. Segregation can never be completely avoided, so powder sampling is preferred for the final product.<sup>52,53</sup>

## Mixing Equipment

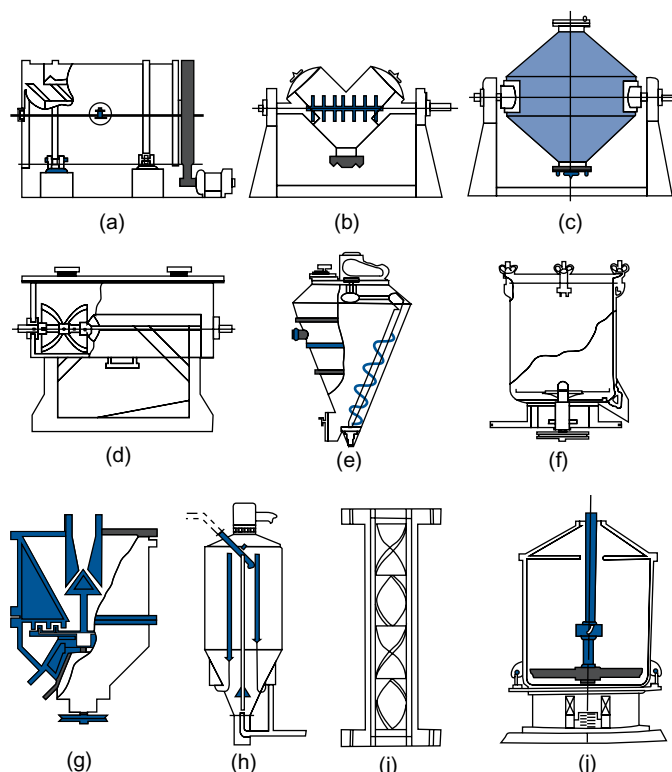

- The mortar and pestle represent one of the most commonly used small scale mixing equipment. The mortar and pestle method combines comminution and mixing in a single operation. Hence, it is very useful when some degree of particle size reduction, as well as mixing, is required. Mortars can be made of different materials and shapes, and pestles are made of the same materials as the mortars. Conventional mortars include glass mortars, Wedgwood mortars, and porcelain mortars, and there is an increasing use of a newly developed mortar, called the electronic mortar and pestle (EMP), among pharmacists. Different types of mortars have specific utility in compounding different materials. For example, glass mortars are suitable for preparing solutions, suspensions, and ointments; Wedgwood mortars are designed primarily for size reduction for most of the materials in modern pharmacy practice; porcelain mortars are similar to Wedgwood mortars, but they are more preferable for comminution of soft aggregates, crystals, and mixing of powders with uniform particle size; EMP is specifically designed for blending of creams, ointments, and oral liquids. The EMP uses a spinning blade and a moving arm to mix products. The largest benefit of EMP is that the materials can be weighed, mixed, and dispensed all in the same container.
- Tumbling mixers/blenders are most commonly used for powders with similar densities. There are different types of tumbling mixers, including V-shaped, rotating cube, cylindrical, double-cone, oblique, and Y-cone mixers (Fig. 23-30a, b, c). Tumbling mixers are likely to mix powders with good flowability and granules, rather than cohesive or powders with poor flowability, because shear force provided by these mixers is not enough to separate the individual particles from agglomerates. The regular loading ability of tumbling mixers ranges from approximately 50 g to 100 kg. For this equipment, segregation tends to occur, if particle size differs significantly.
- In the ribbon mixer, spiral ribbons, paddles, or blades are mounted on a shaft, which is located in the center of the mixing equipment (Fig. 23-30d). Rotating of the shaft leads to the circular movement of the blades and subsequent mixing of the powder. The ribbon mixer can mix powders with poor flowability and avoid segregation as compared to tumbling mixers.
- A diagram of an industrial planetary mixer is shown in Fig. 23-30g. There is a mixing bowl located at the bottom of the equipment, which can move up and down. The

bowl is used for feeding and discharging of the product. The bowl can be raised to the position of the mixing blades for the actual mixing process. The mixing blades or paddles are located off the center of the mixer. They rotate around their center and simultaneously rotate around the center of the mixer. This double rotating process can cause a more complete mixing of the entire equipment, so “dead spots” are avoided. Planetary mixers can break agglomerates easily.

- The Nautamixer (Fig. 23-30e) is composed of a bottom discharger with a rotating screw fastened to the upper end of the rotating arm. The screw conveys the product to the top, where it can flow back to the powder feed. Hence, for this equipment, the vertical impeller and horizontal rotating arm are combined together to induce a combination of convection, shear, and diffusive mixing.
- The fluid-bed mixer is usually used for powder mixing, prior to granulation in the same bowl. Therefore, the fluid-bed mixer is part of a fluid-bed granulator system (Fig. 23-30f). Fluidization of the powder particles can be achieved by blowing heated and filtered air into the equipment. Efficient mixing is achieved by circulation of the fluidized powder. After mixing, granulation liquid is pumped from the liquid receiver/holder through a spray nozzle and on to the fluidized powder bed to facilitate granulation. When sufficient liquid has been sprayed to achieve appropriate granule size, the nozzle is turned off and the wet granules are dried by the fluidizing heated air.

## POWDER SAMPLING

When powders are poured into a pile, segregation occurs. Particles with small size (fine particles) will stay in the center of the pile, and coarser particles tend to concentrate at the periphery. Size segregation is unavoidable, during powder transportation, storage, or packing. Therefore, powder sampling is important for the quality control of the final product. Certain

**Figure 23-30.** Typical powder mixers. (From Masuda H. *Powder Technology Handbook*, 3rd ed. Boca Raton, FL: Taylor & Francis, 2006.)

**Table 23-4. Summary of Sampling Methods<sup>53</sup>**

Apparatus	Type of sampler	Method of sampling	Scale	Advantages	Disadvantages
Sample thief	Manual	Tubular steel retains a core sample when inserted into powder	Large and small	Good for free-flowing powders	Additional weight at bottom of bag may vary sample size; Can be hard to push into powder; Fines may lodge between tubes; Particles can fracture; Fines compact, impeding flow; Segregation may occur as fines percolate into sample more easily than coarse particles; A plug of powder can be pushed ahead of thief and surface material contaminates sample; Personal preference introduces bias for the area sample
Hand scoop	Manual	Cross-sectional sample from moving stream, bags, or barrels	Large	Simple and cheap	Thin layer may remain on belt, leading to bias; Overfilling can lead to an excess of fines.
Shovel	Manual	Pits are dug in the powder bed and a shovelful taken from bottoms and sides	Large, up to several tons	Simple and cheap	Cannot be used with particles of more than 5 cm diameter
Cross-cut sampling	Manual/semiautomatic/automatic	Material is shovelled from the conveyor belt	Large	Simple	Can leave a layer on the belt and result in bias
Pneumatic lance	Semiautomatic	Air flow used on entry and exit of lance from powder bed	Large	Disturbance of powder minimized over sample thief; Porous plate prevents too many fines due to strong air current	Personal preference may bias sample.
Vacuum probe sampler	Semiautomatic	Powder extracted by vacuum	Large	Simple	Difficult to sample below surface without contamination; Personal preference leads to bias; Fines more easily extracted than coarse particles.
Gravity-flow auger sampler	Semiautomatic	Slotted tube in flowing powder rotates and worm screw carries out material	Large and small	Easy to use	Bias is still a problem here; Difficult to sample all of powder stream, therefore bias.
Sampling from a moving stream	Manual/automatic	Powder is sampled as it falls off the conveyor	Large	If carried out properly can be very good sampling technique; easily designed into a new plant.	If overfilled, a greater number of fines than coarse particles are collected; Difficult and expensive to fit into an existing plant; Obtaining a fixed sample is difficult; Difficult to prevent dust escaping.
Full-stream trough sampler	Automatic	Powder is sampled as it falls off the conveyor	Large	Can be used to sample dusty material	Must not overflow; Difficult and expensive to install into existing plant.
Arc path cutter	Automatic	Chute moves through powder stream, and collects sample	Large	No operator bias	Difficult to take more than one sample size; Must cover the whole of the stream to avoid bias.
Straight path cutter	Automatic	Rectangular chute moves through powder stream	Large	Different sample sizes can be taken easily	Must cover the whole of the stream to avoid bias

Moving-flap sample divider	Automatic	A flap in the stream samples powder or allows it to be stored depending on its position	Large	Efficient as covers the whole of the stream when sampling	Resultant sample is large and subsampling needed. Bias may be introduced here; Bias is present due to one side being sampled more than the other.
Integrated automatic sampling plant	Automatic	Primary sample is selected and repeatedly screened, resulting in the final sample	Large	Quick	Variations in materials can cause problems
Chute splitter	Sub-sampler	A series of chutes split sample repeatedly	Large	Can be repeated until desired sample size is achieved	If segregation occurs the result can be misleading; Prone to operator bias.
Cone and quartering	Sub-sampler	Powder poured through cone and divided into four equal parts. This is repeated until the desired sample size is reached	Small	Simple	Prone to operator bias as fine particles remain in the center of the cone; Symmetry is difficult to achieve but essential for accuracy.
Spinning riffler	Sub-sampler	A steady stream of powder flows into a rotating basket of containers	Large/ small	Good for sub-sampling large samples; Good for powders with good flow properties; Minimal bias; More efficient than other samplers tested.	Air currents may displace fines but can be avoided with a slower rotation speed; Expensive; Time-consuming; Segregation may be a problem.
Free-fall tumbler mixer	Sub-sampler	A ladle in the lid of the mixer collects a good representative sample	Large/ small	Can be used with fines present; Representative sample produced in a short time period.	
Hopper sample divider	Sub-sampler	Hoppers oscillate and powder falls into two containers. Only one of the contents is kept.	Small	Sample size can be controlled by monitoring time over each container	Large number of increments needed for accuracy
Table sampler	Sub-sampler	Powder flows down inclined plane and prisms and holes split the powder	Small	Simple	Very low accuracy; After each separation should be a complete mix to avoid errors.

rules of sampling are typically applied: sample from a moving stream of powder; and sample the whole of the stream for many equal periods of time. This makes sure all parts of the powder have equal chances to be sampled, leading to a maximized accuracy and minimized error. However, sampling errors can be caused by the non-uniform distribution of the particles or the inherent differences in physicochemical properties of particles. Table 23-4 summarized a complete listing of sampling methods.<sup>53</sup>

## STORAGE

In most cases, powders are stored in bins (silos). Silos are classified by their height: shallow bins ( $h \leq 1.5d$  or  $1.5a$ ) and deep bins ( $h < 1.5d$  or  $1.5a$ ), where  $h$  is the height of the silo,  $d$  is the inside diameter of a circular silo, and  $a$  is the short side length of a rectangular silo. Silos can also be classified by bin numbers, such as single bins and group bins. Most of the silos are closed, such as vacuum silos; some are open, like ore silos. There are advantages to storing powders in the silos, such as large storage capacity, reduced cost of transportation or feeding, automatic loading, unloading and volume control, no damage or changing to the stored powders, and relative ease of incorporation to a manufacturing system.

## POWDERS AS A DOSAGE FORM

When the term “powder” is referred to as a dosage form, it represents a formulation that is a mixture of powdered drug and excipients. Powders are one of the most conventional dosage forms. Nowadays, with the rapid development of formulations containing high potent compounds, the use of powders as a dosage form has declined. Most of the powders are replaced by tablets and capsules. However, under certain circumstances, powders still have some advantages over solid dosage forms on the market. Advantages of powders include: chemically stable; relatively convenient, when able to provide a large dose of drugs, rather than capsules or tablets; and the dissolution rate of oral powders containing water soluble drugs is generally faster than tablets or capsules, in which disintegration of the tablet or the capsule shell is required prior to dissolution. Disadvantages of powders as a dosage form include: they are not convenient for patients to carry, compared to capsules or tablets; masking unpleasant tastes is difficult; potent drugs requiring low doses may not be appropriate; and irritating drugs, which can cause damage to the stomach, are not suitable. There are a variety of powdered dosage forms commercially available, such as bulk powders, divided powders, dusting powders, insufflations, and dry powder inhalers.

## BULK POWDERS

Bulk powders refer to a mixture of all the materials, packed into a properly designed bulk container, such as a glass or plastic bottle. The major problem of bulk powders is the inaccuracy of dose. The dose of bulk powders can be affected by many factors, including the measuring device (spoon), storage humidity, degree of settling, and patient factors. For example, the dose of bulk powder may vary for patients using differently sized spoons, or even those using the same spoon according to their technique. In addition, drugs present in the bulk powders are better suited, if they have a wider therapeutic window, a large dose, and pleasant taste. Effervescent powders are a special type of bulk powder. In addition to drugs and other excipients, effervescent powders contain an effervescent couple (i.e., sodium bicarbonate and citric acid), which react and effervesce when in contact with water. The effervescent dosage form is helpful to cover the unpleasant taste of salty or bitter drugs. In this chapter, bulk powders are described for internal use, including oral powders, as well as powders for injection. For drugs that are not stable when dissolved in an aqueous pharmaceutically acceptable diluent, such as water, sterile liquid can be added to sterile powders contained in ampoules to form the solution just prior to use.

## DIVIDED POWDERS

Divided powders are bulk powders in which the individual dose has been packed separately. The traditional packing of divided powders is in wrapped paper. However, many problems are involved in this, when the materials are volatile, hygroscopic, or deliquescent. Therefore modern packing methods are developed to replace the use of paper wrapping, such as foil and plastic laminates. Effervescent powders can be packed into individual doses, because the plastic laminates can protect powders from moisture adsorption. The powdered product should always be protected from exposure to moisture.

## DUSTING POWDERS

Dusting powders are designed for external use, acting as a therapeutic, lubricant, or protective. Dusting powders act locally and are intended to have no systemic absorption. Dusting powders are usually dispensed in a relatively fine state (micronized) to increase efficacy and decrease irritation. Dusting powders can be packed in glass or metal containers with a perforated lid to allow the powders to be dusted to the effective area. Excellent flowability is necessary for this dosage form. Pressure aerosols are another delivery form that can generate dusting powders. They are more expensive than the sifter-container, but several advantages are realized, such as convenient operation, and protection from moisture, air, and contamination.

## INSUFFLATIONS AND DRY POWDER INHALERS (DPI)

Insufflations are fine powders of drugs, which are dosed into the nose, ear, or throat by the use of an insufflator. The use of conventional insufflators has declined, due to poor patient compliance and dose non-uniformity. Some newly developed devices have been introduced to replace the traditional insufflators. In these devices, drugs are usually dispensed with a carrier excipient, such as lactose, and placed into a hard gelatin capsule. When the device is operated, the capsule is broken and the fine powder is inhaled into the patient's body.<sup>42</sup>

Pulmonary delivery of dry powder formulations is a popular approach to deliver the drug to the lung locally, for the treatment of such diseases as asthma and chronic obstructive pulmonary disease (COPD). Dry powder inhalers are similar to the new insufflators previously discussed above.<sup>54</sup>

**NONAQUEOUS SOLUTIONS** 446

**EMULSIONS** 448

**SUSPENSIONS** 458

**EXTRACTS** 465

The dosage forms described in this chapter are prepared by employing pharmaceutically and therapeutically acceptable vehicles. The active ingredient(s) may be dissolved in aqueous media, an organic solvent, or a combination of the two, by suspending the drug (if it is insoluble) in an appropriate medium or by incorporating the active pharmaceutical ingredient into one of the phases of an oil and water emulsion. Such solutions, suspensions, and emulsions are further defined in subsequent paragraphs, but some, with similar properties and applications, are considered in greater detail elsewhere in Remington.

These dosage forms are useful for a number of reasons. They can be formulated for different routes of administration: orally, introduction into body cavities, or external application. The dose can easily be adjusted by dilution, making the oral liquid form ready to be administered to children or people unable to swallow tablets or capsules. Extracts eliminate the need to isolate the drug in pure form, allow several ingredients to be administered from a single source (e.g., pancreatic extract), and permit the preliminary study of drugs from natural sources. Occasionally, solutions of drugs, such as potassium chloride, are used to minimize adverse effects in the gastrointestinal tract.

The preparation of these dosage forms involves several considerations on the part of the pharmacist, namely; the purpose of the drug, internal or external use, solubility and concentration of the drug, selection of the liquid vehicle(s), physical and chemical stability of the drug and any excipients, preservation of the preparation, and use of appropriate excipients, such as buffers, solubility enhancers, suspending agents, emulsifying agents, viscosity controlling agents, colors, and flavors. Oral preparations require consideration be given to improving patient compliance by making an acceptable product; consequently, color, odor, and taste must be considered. The viscosity of a product must also be considered, so it has the proper palatability for an oral preparation and has the appropriate suspending properties, if it is an emulsion or suspension. The theory of solutions, which involves solubility, ionization, pH control through the use of buffers, and solubilization, is discussed in Chapters 13 (Solutions and Phase Equilibria) and 15 (Ionic Solutions and Electrolyte Equilibria). Due to the complexity of some manufactured products, compounding may be carried out with the aid of linear programming models to obtain the optimal product. Chapters 26 through 28 should be consulted for information on the preparation and characteristics of those liquid preparations that are intended for parenteral and ophthalmic use.

Much has been written about the biopharmaceutical properties of solid dosage forms. Many researchers begin their absorption studies of drugs administered in solution to assess the

bioavailability relative to tablets and capsules. Absorption occurs when drugs are in a dissolved state, thus, it is frequently observed that the bioavailability of oral dosage forms decreases in the following order: aqueous solution > aqueous suspension > tablet or capsule. Formulation may influence the bioavailability and pharmacokinetics of drugs in solution, including drug concentration, volume of liquid administered, pH, ionic strength, buffer capacity, surface tension, specific gravity, viscosity, and excipients. Emulsions and suspensions are more complex systems; consequently, the bioavailability and pharmacokinetics of these systems may be affected by additional formulation factors, such as surfactants, type of viscosity agent, particle size and particle-size distribution, polymorphism, and solubility of drug in the oil phase.

Liquid preparations may be dispensed in one of three ways: 1) in its original container, 2) repackaging a bulk product at the time a prescription is presented by the patient, or 3) compounding the solution, suspension, or emulsion in the dispensary. Compounding may involve nothing more than mixing marketed products in the manner indicated on the prescription or, in specific instances, may require the incorporation of active ingredients and excipients in a logical and pharmaceutically acceptable manner into aqueous or organic solvents that will form the bulk of the product.

The pharmacist, in the first instance, depends on the pharmaceutical manufacturer to produce a product that is safe, efficacious, elegant, and stable until its expiration date, when stored at conditions described on its label. Manufacturers guarantee efficacy of their products, but, in some instances, consumer preference is variable. For example, cough syrups marketed by two different manufacturers may contain the same active ingredient(s), and the relative merits of the two products may appear interchangeable. In such instances, the commercial advantage may be based on factors, such as flavor, color, aroma, mouth feel, and packaging.

### SOLVENTS FOR LIQUID PHARMACEUTICAL PREPARATIONS

The pharmacist's knowledge of the physical and chemical characteristics of a given drug dictates the selection of the appropriate solvent for a particular formulation. In addition to solubility, solvent selection is also based on clarity, toxicity, viscosity, compatibility with excipients, chemical inertness, palatability, odor, color, and economy. In most cases, especially solutions for oral, ophthalmic, or parenteral administration, water is the preferred solvent, because it meets the majority of the above criteria better than other available solvents. Often, an auxiliary solvent is also employed to augment the solvent action of water

or to contribute to a product's chemical or physical stability. Alcohol, glycerin, and propylene glycol have been frequently used for these purposes.

Solvents, such as acetone and isopropyl alcohol, are too toxic for use in oral pharmaceutical preparations, but they are useful as solvents in organic chemistry and in the preparatory stages of drug development. For purposes such as this, certain solvents are officially recognized in the compendia. A number of fixed oils, such as corn oil, cottonseed oil, peanut oil, and sesame oil, serve useful solvent functions, particularly in the preparation of oleaginous injections, and are recognized in the compendia for this purpose.

## WATER

The major ingredient in most of the dosage forms described herein is water. It is used both as a vehicle and as a solvent for the desired flavoring or medicinal ingredients. Its tastelessness, freedom from irritating qualities, and lack of pharmacological activity make it ideal for such purposes. There is, however, a tendency to assume its purity is constant and it can be stored, handled, and used with a minimum of care. Although true that municipal supplies must comply with Environmental Protection Agency (EPA) regulations (or comparable regulations in other countries), drinking water must be purified before it can be used in pharmaceuticals. Water quality can have a significant impact on the stability of pharmaceutical dosage forms.<sup>1</sup> In manufacturing environments, the design of purified water systems must meet standards outlined in the United States Pharmacopeia (USP) and be validated.<sup>2-5</sup>

Five of the eight solvent waters described in the USP are used in the preparation of parenterals, irrigations, or inhalations. Purified Water must be used for all other pharmaceutical operations, dosage forms, and, as needed, in all USP tests and assays. It must meet rigid specifications for chemical purity. Purified Water is obtained by deionization, distillation, ion-exchange, reverse osmosis, filtration, or other suitable procedures. For parenteral administration, Water for Injection, Bacteriostatic Water for Injection, or Sterile Water for Injection must be used. Sterile Water may be sterile at the time of production but may lose this characteristic, if stored improperly.

The major impurities in water are calcium, iron, magnesium, manganese, silica, and sodium. These cations are combined with the bicarbonate, sulfate, or chloride anions. Hard waters are those that contain calcium and magnesium cations. Bicarbonates are the major impurity in alkaline waters. Deionization processes do not necessarily produce Purified Water that will comply with EPA requirements for drinking water. Resin columns retain phosphates and organic debris. Either alone or in combination, these substances can act as growth media for micro-organisms. Observations have shown that deionized water containing 90 organisms/mL contained 106 organisms/mL after 24-hour storage. Ultraviolet radiant energy (240–280 nm), heat, or filtration can be used to limit the growth of, kill, or remove micro-organisms in water. The latter method employs membrane filters and can be used to remove bacteria from heat-labile materials.

The phenomenon of osmosis involves the passage of water from a dilute solution across a semi-permeable membrane to a more concentrated solution. Flow of water can be stopped by applying pressure to the concentrated solution equal to the osmotic pressure. The flow of water can be reversed by applying a pressure greater than the osmotic pressure. The process of reverse osmosis uses the latter principle; by applying pressure greater than the osmotic pressure to the concentrated solution (e.g., tap water), pure water may be obtained. Organic molecules are rejected on the basis of a sieve mechanism related to their size and shape. Small organic molecules, with a molecular weight smaller than approximately 200, will pass through the membrane material. Because there are few organic molecules with a molecular weight of less than 200 in the municipal water

supply, reverse osmosis is sufficient for the removal of organic material. The pore sizes of the selectively permeable reverse-osmosis membranes are between 0.5 and 10 nm. Viruses and bacteria larger than 10 nm are rejected, if no imperfections exist in the membrane. The membranes may and do develop openings that permit the passage of micro-organisms. Due to the semi-static conditions, bacteria can grow both upstream and downstream of the membrane.

## ALCOHOLS

Next to water, alcohol is the most commonly used solvent in pharmacy for many organic compounds. When mixed with water, a hydroalcoholic mixture is formed capable of dissolving both alcohol-soluble and water-soluble substances, a feature especially useful for extraction and purification of active constituents from crude drugs and synthetic procedures. Alcohol, USP, is 94.9–96.0% by volume, at 15.56°C of C<sub>2</sub>H<sub>5</sub>OH, and Dehydrated Alcohol, USP, contains not less than 99.5% C<sub>2</sub>H<sub>5</sub>OH by volume. Dehydrated alcohol is utilized when an essentially water-free alcohol is necessary. Alcohol is widely used for its miscibility with water and its ability to dissolve many water-insoluble ingredients, including drug substances, flavors, and antimicrobial preservatives. Alcohol is used in liquid products as an antimicrobial preservative or in conjunction with parabens, benzoates, sorbates, and other agents. Diluted Alcohol, NF, is prepared by mixing equal volumes of Alcohol, USP, and Purified Water, USP. Due to contraction upon mixing, the final volume of such mixtures is not the sum of the individual volumes of the two components, but is about 3% less.

The United States Food and Drug Administration (FDA) has expressed concern regarding undesired pharmacologic and potential toxic effects of alcohol when ingested by children. For this reason, manufacturers of over-the-counter (OTC) oral drug products have been asked to restrict, if possible, the use of alcohol and include appropriate warnings in the labeling. For OTC oral products intended for children under 6 years of age, the recommended alcohol content limit is 0.5%; for products intended for children 6–12 years of age, the recommended limit is 5%; and for products recommended for children older than 12 years of age and for adults, the recommended limit is 10%.

Rubbing Alcohol, USP, must be manufactured in accordance with the requirements of the US Treasury Department, Bureau of Alcohol, Tobacco, and Firearms, Formula 23-H (8 parts by volume of acetone, 1.5 parts by volume of methyl isobutyl ketone, and 100 parts by volume of ethyl alcohol). It contains not less than 68.5% and not more than 71.5% by volume of dehydrated alcohol, the remainder consisting of water and the denaturants with or without color additives and perfume oils. Rubbing Alcohol contains in each 100 mL not less than 355 mg of sucrose octaacetate or not less than 1.40 mg of denatonium benzoate. The preparation may be colored with one or more color additives listed by the FDA for use in drugs, and a suitable stabilizer may be added. The use of this denaturant mixture makes the separation of ethyl alcohol from the denaturants a virtually impossible task with ordinary distillation apparatus. This discourages the illegal removal and use of the alcoholic content of rubbing alcohol as a beverage. The product is volatile and extremely flammable and should be stored in tight containers remote from ignition sources. It is used externally as a soothing rub for bedridden patients, a germicide for instruments, and a skin cleanser prior to injection.

Isopropyl Rubbing Alcohol is about 70% by volume isopropyl alcohol, the remainder consisting of water with or without color additives, stabilizers, and perfume oils. It is used exclusively as a vehicle in topical products and applications. This preparation and a commercially available 91% isopropyl alcohol solution are commonly employed to disinfect needles and syringes for hypodermic injections of insulin and for disinfecting the skin.

Glycerin is a clear, syrupy liquid with a sweet taste and is miscible with water and alcohol. Glycerin is used in a wide variety of pharmaceutical formulations, including oral, otic, ophthalmic, topical, and parenteral preparations. In topical pharmaceutical formulations and cosmetics, glycerin is used primarily for its humectant and emollient properties. In parenteral formulations, glycerin is used mainly as a solvent. In oral solutions, glycerin is used as a solvent, sweetening agent, antimicrobial preservative, and viscosity-increasing agent.

Propylene glycol has become widely used as a solvent, extractant, and preservative in a variety of liquid pharmaceutical formulations, including parenterals. Propylene glycol is a viscous liquid and is miscible with water and alcohol. It is a useful solvent with a wide range of applications and is often used in place of glycerin. As an antiseptic, it is similar to ethanol, and against molds it is similar to glycerin and only slightly less effective than ethanol. Propylene glycol is also used as a carrier for emulsifiers and as a vehicle for flavors, as opposed to ethanol, due to its lack of volatility.

## STABILITY CONSIDERATIONS

The stability of the active ingredient in the final product is a primary concern to the formulator, the pharmacist, and the patient. In general, drug substances are less stable in aqueous media than solid dosage forms, and it is important to properly stabilize and preserve solutions, suspensions, and emulsions that contain water. Acid-base reactions, acid or base catalysis, oxidation, and reduction can occur in these products. Reactions and interactions (adsorption) can arise from ingredient-ingredient interactions or container-product interactions. For pH sensitive compounds, any of these interactions may alter the pH and cause precipitation.

Vitamins, essential oils, and almost all fats and oils can be oxidized. Formulators use the word “auto-oxidation,” when the ingredient(s) reacts with oxygen but without drastic external interference. Such reactions can be initiated by heat, light, including ultraviolet radiant energy, peroxides, or other labile compounds or heavy metals, such as copper or iron. This initiation step results in the formation of a free radical that then reacts with oxygen. The free radical is regenerated and reacts with more oxygen (propagation). The reactions are terminated, when the free radicals react with one another.

The effect of trace metals can be minimized, using chelating agents, such as citric acid or EDTA. Antioxidants may retard or delay oxidation by rapidly reacting with free radicals as they are formed (quenching). Common antioxidants include propyl, octyl, and dodecyl esters of gallic acid, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and the tocopherols or vitamin E. Connors and coworkers provide a detailed approach for the prevention of oxidative degradation of pharmaceuticals.<sup>6</sup> Table 24-1 lists common antioxidants and chelating agents used in pharmaceutical preparations.

The USP states that, if a product must be repackaged, the container specified by the compendium must be used. For example, a suitable opaque plastic container should be used, if a light-resistant container is specified. If a product is diluted, or where two products are mixed, the pharmacist should use his or her knowledge to guard against incompatibility and instability. Oral antibiotic preparations constituted into liquid form should never be mixed with other products. If the chemical stability of extemporaneously prepared liquid preparations is unknown, their use should be minimized and every care taken to ensure product characteristics will not change while used by the patient.

Due to the number of excipients and additives in these preparations, it is recommended that all the ingredients be listed on the container to reduce the risks that confront hypersensitive patients when these products are administered. Finally, the pharmacist should inform the patient regarding the appropriate use of the product, the proper storage conditions, and the time after which it should be discarded.

**Table 24-1. Common Antioxidants and Chelating Agents Used in Liquid Pharmaceutical Dosage Forms**

Antioxidants	Alpha tocopherol Ascorbic acid Acorbyl palmitate Butylated hydroxyanisole Butylated hydroxytoluene Monothioglycerol Potassium metabisulfite Propionic acid Propyl gallate Sodium ascorbate Sodium bisulfite Sodium metabisulfite Sodium sulfite
Chelating Agents	Citric acid monohydrate Disodium edetate Dipotassium edetate Edetic acid Fumaric acid Malic acid Phosphoric acid Sodium edetate Tartaric acid Trisodium edetate

## PRESERVATIVES

In addition to stabilization of pharmaceutical preparations against chemical and physical degradation, liquid and semisolid preparations must be protected against microbial contamination. Nearly all products described in this chapter contain water and, thus, with certain exceptions, such as aqueous acids, will support microbial growth. Aqueous solutions, syrups, emulsions, and suspensions often provide excellent growth media for micro-organisms, such as molds, yeast, and bacteria (typically *pseudomonas*, *E.coli*, *salmonella* and *staphylococcus*).

Kurup and Wan describe many preparations that are not preserved adequately and are not able to resist microbial contamination.<sup>7</sup> Products, such as ophthalmic and injectable preparations, are sterilized by autoclaving (20 minutes at 15 pounds of pressure at 120°C, followed by dry heat at 180°C for 1 hour) or filtration. However, many require the presence of an antimicrobial preservative to maintain aseptic conditions throughout their stated shelf life.<sup>8</sup> Certain hydroalcoholic and alcoholic preparations do not require addition of a chemical preservative, if the alcohol content is sufficient to prevent microbial growth. An alcohol content of 15% by weight in acid solutions and 18% by weight in alkaline solutions is sufficient to prevent microbial growth. Most alcohol containing preparations, such as elixirs, spirits, and tinctures, are self-preserving and do not require preservation. Indeed, the formulator should challenge any new preparation by procedures described in the General Tests and Assays, parts <51> and <61> of the USP, and other methods reported in the literature.<sup>9-12</sup>

When a preservative is required, its selection is based on several considerations, in particular, the site of use, whether internal, external, or ophthalmic.<sup>13</sup> Several researchers have described various interactions that must be considered when preservatives are selected.<sup>14-15</sup> The major criteria that should be considered in selecting a preservative are as follows: its physicochemical properties, such as solubility and dissociation constant, and it should be effective against a wide spectrum of micro-organisms, stable for its shelf life, nontoxic, nonsensitizing, compatible with the ingredients in the dosage form, inexpensive, and relatively free of taste and odor.

The chosen preservative should be sufficiently stable and soluble to achieve adequate concentration to provide protection. This choice is more critical in two and three phase emulsion

systems in which the preservative may be more soluble in the oil phase than in the aqueous phase.<sup>12,16</sup> The pH of the preparation must be considered to ensure the preservative does not dissociate, rendering it ineffective or degrade by acid or base catalyzed hydrolysis. The undissociated moiety or molecular form of a preservative possesses preservative capacity, because the ionized form is unable to penetrate micro-organisms. The preservative must be compatible with the formulation ingredients and the product container and closure. Finally, the preservative must not impact the safety or comfort of the patient when administered. For instance, preservatives used in ophthalmic preparations must be non-irritating. Chlorobutanol, benzalkonium chloride, and phenylmercuric nitrate are commonly used in these applications.

Although few micro-organisms are viable below a pH of 3 or above a pH of 9, most aqueous pharmaceutical preparations are manufactured within the favorable pH range. Acidic preservatives, such as benzoic acid, boric acid, and sorbic acid, are less dissociated and more effective in acidic formulations. Similarly, alkaline preservatives are less effective in acidic or neutral conditions and more effective in alkaline formulations. The scientific literature is rife with examples of incompatibilities between preservatives and other pharmaceutical adjuncts.<sup>17–19</sup> Commonly used macromolecules, including cellulose derivatives, polyethylene glycol, and tragacanth gum, have been reported to cause preservative failure, due to binding and adsorption.<sup>20,21</sup>

The mode of action by which preservatives interfere with microbial growth, multiplication, and metabolism occurs through one of several mechanisms. Preservatives often alter cell membrane permeability, causing leakage of cell constituents (partial lysis), complete lysis and cytoplasmic leakage, and/or coagulation of cytoplasmic constituents (protein precipitation). Other preservatives inhibit cellular metabolism by interference with enzyme systems or cell wall synthesis, oxidation of cellular constituents, or hydrolysis.

Table 24-2 lists preservatives commonly used in pharmaceutical products with typical concentration levels. Preservatives may be grouped into a number of classes, depending upon

their molecular structure. These basic groups are subsequently discussed.

### Alcohols

Ethanol is useful as a preservative, when it is used as a solvent; however, it does need a relatively high concentration, somewhat greater than 15%, to be effective. Too high a concentration may result in incompatibilities in suspension and emulsion systems. Propylene glycol also is used as a solvent in oral solutions and topical preparations, and it can function as a preservative in the range of 15–30%. It is not volatile like ethanol and is used frequently not only in solutions, but also in suspensions and emulsions. Chlorobutanol and phenylethyl alcohol are other alcohols used in lower concentrations (approximately 1%) as preservatives.

### Acids

Benzoic acid has a low solubility in water, about 0.34% at 25°C, but the apparent aqueous solubility of benzoic acid may be enhanced by the addition of citric acid or sodium acetate to the solution. The concentration range used for inhibitory action varies from 0.1 to 0.5%. Activity depends on the pH of the medium, because only the undissociated acid has antimicrobial properties. Optimum activity occurs at pH values below 4.5; at values above pH 5, benzoic acid is almost inactive.<sup>22</sup> It has been reported that antimicrobial activity of benzoic acid is enhanced by the addition of the basic protein protamine.<sup>23</sup> Sorbic acid also has a low solubility in water, 0.3% at 30°C. Suitable concentrations for preservative action are in the range of 0.05–2%. Its preservative action is due to the nonionized form; consequently, it is only effective in acid media. The optimum antibacterial activity is obtained at pH 4.5, and practically no activity is observed above pH 6. Sorbic acid is subject to oxidation, particularly in the presence of light and in aqueous solutions. Activity against bacteria can be variable, due to its limited stability. Thus, sorbic acid is frequently used in combination with other antimicrobial preservatives or glycols in which synergistic effects occur.

**Table 24-2. Common Preservatives Used in Liquid Pharmaceutical Dosage Forms and Their Typical Concentration Levels**

Antimicrobial Preservatives	Typical Usage Level (% w/w)	Antifungal Preservatives	Typical Usage Level (% w/w)
Benzalkonium Chloride	0.002–0.02%	Butyl Paraben	0.1–0.4%
Benzethonium Chloride	0.01–0.02%	Methyl Paraben	0.1–0.25%
Benzyl Alcohol	3.0%	Ethyl Paraben	0.1–0.25%
Bronopol	0.01–0.1%	Propyl Paraben	0.1–0.25%
Cetrimide	0.005%	Benzoic Acid	0.1–0.5%
Cetylpyridinium chloride	0.0005–0.0007%	Potassium sorbate	0.1–0.2%
Chlorhexidine	0.002–0.5%	Sodium Benzoate	0.1–0.2%
Chlorobutanol	0.5%	Sodium Propionate	5–10%
Chlorocresol	0.2%	Sorbic Acid	0.05–0.2%
Chloroxylenol	0.1–0.8%		
Cresol	0.15–0.3%		
Ethyl Alcohol	15–20%		
Glycerin	20–30%		
Hexetidine	0.1%		
Imidurea	0.03–0.5%		
Phenol	0.1–0.5%		
Phenoxyethanol	0.5–1.0%		
Phenylethyl Alcohol	0.25–0.5%		
Phenylmercuric Nitrate	0.002–0.01%		
Propylene Glycol	15–30%		
Thimerosal	0.1%		

## Esters

Parabens are esters of *p*-hydroxybenzoic acid and include the methyl, ethyl, propyl, and butyl derivatives. The water solubility of the parabens decreases as the molecular weight increases from 0.25% for the methyl ester to 0.02% for the butyl ester. These compounds are used widely in pharmaceutical products, stable over a pH range of 4–8, and have a broad spectrum of antimicrobial activity, although they are most effective against yeasts and molds. Antimicrobial activity increases as the chain length of the alkyl moiety is increased, but aqueous solubility decreases; therefore, a mixture of parabens is frequently used to provide effective preservation. Preservative efficacy is also improved by the addition of propylene glycol (2–5%) or by using parabens in combination with other antimicrobial agents, such as imidurea. Activity is reduced in the presence of nonionic surface active agents, due to binding. In alkaline solutions, ionization takes place, and this reduces their activity; in addition, hydrolytic decomposition of the ester group occurs with a loss of activity.

## Quaternary Ammonium Compounds

Benzalkonium chloride is a mixture consisting principally of the homologs  $C_{12}H_{25}$  and  $C_{14}H_{29}$ . This preservative is used at a relatively low concentration, 0.002–0.02%, depending on the nature of the pharmaceutical product. This class of compounds has an optimal activity over the pH range of 4–10 and is quite stable at room temperature. Due to the cationic nature of this type of preservative, it is incompatible with many anionic compounds and can bind to nonionic surfactants. It is used in preparations for external use or those solutions that come in contact with mucous membranes. In ophthalmic preparations, benzalkonium chloride is widely used at a concentration of 0.01–0.02% w/w. Often, it is used in combination with other preservatives or excipients, particularly 0.1% w/v disodium edetate, to enhance its antimicrobial activity against strains of *Pseudomonas*. A concentration of 0.002–0.02% is used in nasal and otic formulations, sometimes in combination with 0.002–0.005% thimerosal. Benzalkonium chloride 0.01% w/v is also employed as a preservative in small-volume parenteral products.

Clearly, when the pharmacist dispenses or compounds liquid preparations, responsibility is assumed, along with the manufacturer, for the maintenance of product stability. General chapter <1191> of the USP describes stability considerations for dispensing, which should be studied in detail.<sup>9</sup> Stock should be rotated and replaced, if expiration dates on the label so indicate. Products should be stored in the manner indicated on the manufacturer's label or in the compendium. Further, products should be checked for evidence of instability. With respect to solutions, elixirs, and syrups, major signs of instability are color change, precipitation, and evidence of microbial or chemical gas formation. Emulsions may cream, but, if they break (i.e., there is a separation of an oil phase), the product is considered unstable. Sedimentation and caking are primary indications of instability in suspensions. The presence of large particles may mean excessive crystal growth has occurred (Ostwald Ripening). Additional details on these topics are provided in the pertinent sections of this chapter.

## SOLUTIONS

A solution is a homogeneous mixture that is prepared by dissolving a solid, liquid, or gas in another liquid and represents a group of preparations in which the molecules of the solute or dissolved substance are dispersed among those of the solvent. Most solutions are unsaturated with the solute; in other words, the concentration of the solute in the solution is below its solubility limit. The strengths of pharmaceutical solutions are expressed in terms of percentage strength, although for very dilute preparations expressions of ratio strength are sometimes used. The term percentage when used without qualification

(as with w/v, v/v, or w/w) means percentage weight-in-volume for solutions or suspensions of solids in liquids; percentage weight-in-volume for solutions of gases in liquids; percentage volume-in-volume for solutions of liquids in liquids; and weight-in-weight for mixtures of solids and semisolids.

Solutions may also be classified on the basis of physical or chemical properties, method of preparation, use, physical state, number of ingredients, and particle size. For the pharmacist and pharmaceutical scientist, solutions are more defined by site of administration and composition than by physicochemical definitions. For instance, pharmaceutical solutions may be classified as an oral solution, otic solution, ophthalmic solution, or topical solution. These solutions may also be classified based upon their composition. Syrups are aqueous solutions containing a sugar; elixirs are sweetened hydroalcoholic (combinations of water and ethanol) solutions; spirits are solutions of aromatic materials, if the solvent is alcoholic, or aromatic waters, if the solvent is aqueous. Depending on their method of preparation and concentration, tinctures or fluid extracts are solutions prepared by extracting active constituents from crude drugs.

Many pharmaceutical chemicals are only slowly soluble in a given solvent and require an extended time for complete dissolution. To increase the dissolution rate, a pharmacist and pharmaceutical scientist may employ one or several techniques, such as applying heat, reducing the particle size of the solute, utilizing of a solubilizing agent, or subjecting the ingredients to rigorous agitation. In most cases, solutes are more soluble in solvents at elevated temperatures than at room temperature or below, due to the endothermic nature of the dissolution process. The pharmacist should ensure that the materials are heat stable and non-volatile, when using heat to facilitate the dissolution rate.

## AQUEOUS SOLUTIONS

The narrower definition in this subsection limits the solvent to water and excludes those preparations that are sweet and/or viscid in character and nonaqueous solutions. This section includes those pharmaceutical forms that are designated as Aromatic Waters, Aqueous Acids, Solutions, Douches, Enemas, Gargles, Mouthwashes, Juices, Nasal Solutions, Otic Solutions, and Irrigation Solutions.

### Aromatic Waters

The USP defines Aromatic Waters as clear, saturated aqueous solutions (unless otherwise specified) of volatile oils or other aromatic or volatile substances.<sup>9</sup> Their odors and tastes are similar, respectively, to those of the drugs or volatile substances from which they are prepared, and they are free from empyreumatic and other foreign odors. Aromatic waters may be prepared by distillation or solution of the aromatic substance, with or without the use of a dispersing agent. They are used, principally, as flavored or perfumed vehicles.

Peppermint Water USP and Stronger Rose Water USP are examples of aromatic waters. Concentrated waters, such as peppermint, dill, cinnamon, and caraway, may be prepared as follows:

Dissolve 20 mL of the volatile oil in 600 mL of 90% ethanol. Add sufficient purified water in successive small portions to produce 1000 mL. Shake vigorously after each addition. Add 50 g of sterilized purified talc. Shake occasionally for several hours, and filter.

The aromatic water is prepared by diluting the concentrate with 39 times its volume of water.

The chemical composition of many of the volatile oils is known, and suitable synthetic substances may be used in preparing pharmaceuticals and cosmetics. Similarly, many synthetic aromatic substances have a characteristic odor; for example, geranyl phenyl acetate has a honey odor. Such substances, either alone or in combination, can be used in nonofficial preparations.

The principal difficulty experienced in compounding prescriptions containing aromatic waters is "salting out" certain

ingredients, such as very soluble salts. A replacement of part of the aromatic water with purified water is permissible, when no other function is being served than that of a vehicle. Aromatic waters will deteriorate with time and should, therefore, be made in small quantities, protected from intense light and excessive heat, and stored in airtight, light-resistant containers.

### Aqueous Acids

Inorganic acids and certain organic acids, although of minor significance as therapeutic agents, are of great importance in pharmaceutical manufacturing and analysis. This is especially true of acetic, hydrochloric, and nitric acids. Many of the more important inorganic acids are available commercially in the form of concentrated aqueous solutions. The percentage strength varies from one acid to another and depends on the solubility and stability of the solute in water and on the manufacturing process. Thus, Hydrochloric Acid contains from 36.5 to 38.0% by weight of HCl, whereas Nitric Acid contains from 69 to 71% by weight of HNO<sub>3</sub>.

Because the strengths of these concentrated acids are stated in terms of percent by weight, it is essential that specific gravities also be provided, if one is to calculate conveniently the amount of absolute acid contained in a unit volume of the solution as purchased. The mathematical relationship involved is given by the equation:

$$M = V \times S \times F,$$

where  $M$  is the mass in g of absolute acid contained in  $V$  mL of solution, having a specific gravity  $S$  and a fractional percentage strength  $F$ .

As an example, Hydrochloric Acid containing 36.93% by weight of HCl has a specific gravity of 1.1875. Therefore, the amount of pure HCl supplied by 100 mL of this solution is given by:

$$M = 100 \times 1.1875 \times 0.3693 = 43.85 \text{ g HCL.}$$

Although many of the reactions characteristic of acids offer opportunities for incompatibilities, only a few are of sufficient importance to require more than casual mention. Acids and acid salts decompose carbonates with liberation of carbon dioxide; in a closed container, sufficient pressure may be developed to produce an explosion. Inorganic acids react with salts of organic acids to produce the free organic acid and a salt of the inorganic acid. If insoluble, the organic acid will be precipitated. Thus, salicylic acid and benzoic acid are precipitated from solutions of salicylates and benzoates. Boric acid, likewise, is precipitated from concentrated solutions of borates. By a similar reaction, certain soluble organic compounds are converted into an insoluble form. Phenobarbital sodium, for example, is converted into phenobarbital that will precipitate in aqueous solution.

The ability of acids to combine with alkaloids and other organic compounds containing a basic nitrogen atom is used in preparing soluble salts of these substances. Certain solutions, syrups, elixirs, and other pharmaceutical preparations may contain free acid, which causes these preparations to exhibit the incompatibilities characteristic of the acid. Acids also possess the incompatibilities of the anions they contain, and, in the case of organic acids, these are frequently of prime importance. These are discussed under the specific anions.

### Diluted Acids

The diluted acids in the USP are aqueous solutions of acids of a suitable strength (usually 10% w/v, but Diluted Acetic Acid is 6% w/v) for internal administration or for the manufacture of other preparations.

The strengths of the official undiluted acids are expressed as percentages in weight (w/w), whereas the strengths of the official diluted acids are expressed as percentages in volume (w/v). It, therefore, becomes necessary to consider the specific

gravities of the concentrated acids, when calculating the volume required to make a given quantity of diluted acid. The following equation will give the number of milliliters required to make 1000 mL of diluted acid:

$$\frac{\text{Strength of diluted acid} \times 1,000}{\text{Strength of undiluted acid} \times \text{Specific gravity of undiluted acid}}$$

Thus, if one wishes to make 1000 mL of Diluted Hydrochloric Acid USP (10% w/v) using Hydrochloric Acid that assays 37.5% HCl (sp gr 1.18), the amount required is

$$\frac{10 \times 1,000}{37.5 \times 1.18} = 226 \text{ mL}$$

Diluted Hydrochloric Acid, USP has been used in the treatment of achlorhydria. However, it may irritate the mucous membrane of the mouth and attack the enamel of the teeth. The usual dose is 2–4 mL, well-diluted with water. In the treatment of achlorhydria, no attempt is made to administer more than a relief-producing dose.

### Douches

A douche is an aqueous solution directed against a part or into a cavity of the body. It functions as a cleansing or antiseptic agent. An eye douche, used to remove foreign particles and discharges from the eyes, is directed gently at an oblique angle and allowed to run from the inner to the outer corner of the eye. Pharyngeal douches are used to prepare the interior of the throat for an operation and cleanse it in suppurative conditions. Similarly, there are nasal douches and vaginal douches. Douches are directed to the appropriate body part by using bulb syringes.

Douches are often dispensed in the form of a powder with directions for dissolving in a specified quantity of water (usually warm). However, tablets for preparing solutions are available (e.g., Dobell's Solution Tablets), or the solution may be prepared by the pharmacist. If powders or tablets are supplied, they must be free from insoluble material to produce a clear solution. Tablets are produced by the usual processes, but any lubricants or diluents used must be readily soluble in water. Boric acid may be used as a lubricant, and sodium chloride is normally used as a diluent. Many tablets deteriorate on exposure to moist air and should be stored in airtight containers.

Douches are not official as a class of preparations, but several substances in the compendia are frequently employed as such in weak solutions. Vaginal douches are the most common type of douche and are used for cleansing the vagina and hygienic purposes. Liquid concentrates or powders, which may be prepared in bulk or as single-use packages, should be diluted or dissolved in the appropriate amount of warm water prior to use. The ingredients used in vaginal douches include antimicrobial agents, such as benzalkonium chloride, the parabens or chlorothymol, and anesthetics or antipruritics, such as phenol or menthol. Astringents, such as zinc sulfate or potassium alum, surface-active agents, such as sodium lauryl sulfate, and chemicals to alter the pH, such as sodium bicarbonate or citric acid, are also used.

### Enemas

A number of solutions are administered rectally for the local effects of the medication (e.g., hydrocortisone) or for systemic absorption (e.g., aminophylline). In the case of aminophylline, the rectal route of administration minimizes the undesirable gastrointestinal reactions associated with oral therapy.<sup>24</sup> Clinically effective blood levels of the agents are obtained within 30 minutes following rectal instillation. Corticosteroids are administered as retention enemas or continuous drip as adjunctive treatment of some patients with ulcerative colitis.

Enema preparations are rectal injections employed to evacuate the bowel (evacuation enemas), influence the general

system by absorption, or to affect a local disease. The latter two are called retention enemas. They may possess anthelmintic, nutritive, sedative, or stimulating properties, or they may contain radiopaque substances for roentgenographic examination of the lower bowel.

Sodium chloride, sodium bicarbonate, sodium monohydrogen phosphate, sodium dihydrogen phosphate, glycerin, docosate potassium, and light mineral oil are used in enemas to evacuate the bowel. These substances may be used alone, in combination with each other, or in combination with irritants, such as soap. Evacuation enemas are given at body temperature in quantities of 1 to 2 pt injected slowly with a syringe.

An official retention enema used for systemic purposes is aminophylline. Retention enemas are to be retained in the intestine and should not be used in quantities larger than 150 mL for an adult. Usually, the volume is considerably smaller, such as a few milliliters. "Microenema" is a term used to describe these small-volume preparations. Vehicles for retention microenemas have been formulated with small quantities of ethanol and propylene glycol, and no significant difference in irritation, as compared with water, was found. A number of other drugs, such as valproic acid, indomethacin, and metronidazole, have been formulated as microenemas for the purpose of absorption.

### Gargles

Gargles are aqueous solutions frequently containing antiseptics, antibiotics, and/or anesthetics used for treating the pharynx and nasopharynx by forcing air from the lungs through the gargle held in the throat; subsequently, the gargle is expectorated. Many gargles must be diluted with water prior to use. Although mouthwashes are considered as a separate class of pharmaceuticals, many are used as gargles either as is or diluted with water.

A gargle/mouthwash containing the antibiotic tyrothricin has been shown to provide higher levels of gramicidin, a component of tyrothricin, in saliva when used as a gargle, rather than a mouthwash<sup>25</sup>. Higher saliva levels of gramicidin were obtained, when a lozenge formulation was employed. Rapid relief of pharyngeal and oral pain was obtained, when Cepacaine solution, which contains a topical anesthetic, was used as a gargle.<sup>26</sup>

Nystatin is administered in both powder and liquid form to treat oral fungal infections.<sup>27</sup> The medication is taken by placing one-half of the dose in each side of the mouth, swishing it around as long as possible, gargling, and swallowing. Hydrogen peroxide is a source of nascent oxygen and a weak topical antibacterial agent. Hydrogen peroxide topical solution has been used as a mouthwash or gargle in the treatment of pharyngitis or Vincent's stomatitis.<sup>28-29</sup> Hydrogen peroxide has also been applied in root canals of teeth or other dental pulp cavities. Although used topically as a 1.5-3% solution for cleansing wounds, hydrogen peroxide is diluted with an equal volume of water for use as a mouthwash or gargle.

### Mouthwashes

Mouthwashes are aqueous solutions, often in concentrated form, containing one or more active ingredients and excipients. They are used by swishing the liquid in the oral cavity. Mouthwashes can be used for two purposes: therapeutic and cosmetic. Therapeutic rinses or washes can be formulated to reduce plaque, gingivitis, dental caries, and stomatitis. Cosmetic mouthwashes may be formulated to reduce bad breath through the use of antimicrobial and/or flavoring agents.

Recent information indicates that mouthwashes are being used as a dosage form for a number of specific problems in the oral cavity; for example, mouthwashes containing a combination of antihistamines, hydrocortisone, nystatin, and tetracycline have been prepared from commercially available suspensions, powders, syrups, or solutions for the treatment of stomatitis, a painful side effect of cancer chemotherapy. Other drugs include allopurinol, also used for the treatment of stomatitis,<sup>30</sup> pilocarpine for xerostoma (dry mouth),<sup>31</sup> amphotericin

B for oral candidiasis,<sup>32</sup> and chlorhexidine gluconate for plaque control.<sup>33</sup> Mouthwashes may be used for diagnostic purposes. For example, oral cancer and lesions are detected using toluidine blue mouth rinse.<sup>34</sup>

Commercial products (e.g., Cepacol, Listerine, Micrin, or Scope) vary widely in composition. Tricca has described the excipients found in Mouthwashes as alcohols, surfactants, flavors, and coloring agents.<sup>35</sup> Alcohol is often present in the range of 10-20%. It enhances the flavor, provides sharpness to the taste, aids in masking the unpleasant taste of active ingredients, functions as a solubilizing agent for some flavoring agents, and may function as a preservative. Humectants, such as glycerin and sorbitol, may form 5-20% of the mouthwash. These agents increase the viscosity of the preparation and provide a certain body or mouth feel to the product. They enhance the sweetness of the product and, along with the ethanol, improve the preservative qualities of the product.

Surfactants of the nonionic class, such as polyoxyethylene/polyoxypropylene block copolymers or polyoxyethylene derivatives of sorbitol fatty acid esters, may be used. The concentration range is 0.1-0.5%. An anionic surfactant used occasionally is sodium lauryl sulfate. Surfactants are used, because they aid in the solubilization of flavors and in the removal of debris by providing foaming action. Cationic surfactants, such as cetylpyridinium chloride, are used for their antimicrobial properties, but these tend to impart a bitter taste.

Flavors are used in conjunction with alcohol and humectants to overcome disagreeable tastes; at the same time, flavors must be safe to use. The principle flavoring agents are peppermint, spearmint, cinnamon, wintergreen oils, menthol, or methyl salicylate. Other flavoring agents may be used singly or in combination. Finally, coloring agents are also used in these products.

### Juices

A juice is prepared from fresh ripe fruit, is aqueous in character, and is used in making syrups employed as vehicles. The freshly expressed juice is preserved with benzoic acid and allowed to stand at room temperature for several days, until the naturally present pectins are destroyed by enzymatic action, as indicated by the filtered juice yielding a clear solution with alcohol. Pectins, if allowed to remain, would cause precipitation in the final syrup.

Cherry Juice and Tomato Juice are described in the USP. Artificial flavors now have replaced many of the natural fruit juices. Although they lack the flavor of the natural juice, they are more stable and easier to incorporate into the final pharmaceutical form. Commercial juices, such as orange, apple, grape, and mixed vegetables, have been used recently to prepare extemporaneous preparations of cholestyramine<sup>36</sup> and nizatidine.<sup>37</sup> Information on cranberry juice indicates it may be effective in controlling some urinary tract infections and urolithiasis.<sup>38</sup>

### Nasal Solutions

Nasal solutions are aqueous solutions designed to be administered to the nasal passages in drops or sprays. Other nasal preparations may be in the form of emulsions or suspensions. The adult nasal cavity has about a 20 mL capacity with a large surface area (about 180 cm<sup>2</sup>) for drug absorption afforded by the microvilli present along the pseudo-stratified columnar epithelial cells of the nasal mucosa.<sup>39</sup> The nasal tissue is highly vascularized, making it an attractive site for rapid and efficient systemic absorption. Another advantage of nasal delivery is it avoids first-pass metabolism by the liver. For some peptides and small molecular compounds, intranasal bioavailability has been comparable to that of injections. However, bioavailability decreases as the molecular weight of a compound increases, and, for proteins composed of more than 27 amino acids, bioavailability is quite low.<sup>40</sup> Various pharmaceutical techniques and functional excipients, such as surfactants, have been shown capable of enhancing the nasal absorption of large molecules.<sup>41-42</sup>

Many drugs are administered for their local sympathomimetic effects to reduce nasal congestion, such as Ephedrine Sulfate Nasal Solution, USP, or Naphazoline Hydrochloride Nasal Solution, USP. A few other preparations, Lypressin Nasal Solution, USP, and Oxytocin Nasal Solution, USP, are administered in spray form for their systemic effect for the treatment of diabetes insipidus and milk letdown prior to breast feeding, respectively. Table 24-3 lists examples of commercial products for nasal use.

Nasal solutions are formulated to be similar to nasal secretions with regard to tonicity, pH, and viscosity, so normal ciliary action is maintained. Thus, aqueous nasal solutions are isotonic and slightly buffered to maintain a pH of 5.5–6.5. In addition, antimicrobial preservatives, similar to those used in ophthalmic preparations, and appropriate drug stabilizers, if required, are included in the formulation.

Current studies indicate that nasal sprays are deposited mainly in the atrium and cleared slowly into the pharynx with the patient in an upright position. Drops spread more extensively than the spray, and three drops cover most of the walls of the nasal cavity with the patient in a supine position and head tilted back and turned left and right.<sup>43,44</sup> It is suggested that drop delivery, with appropriate movement by the patient, leads to extensive coverage of the walls of the nasal cavity.

Most nasal solutions are packaged in dropper or spray bottles, containing 15–30 mL of medication. The pharmaceutical scientist should ensure the product is stable in the containers, and the pharmacist should keep the packages tightly closed during

periods of nonuse. The patient should be advised that, should the solution become discolored or contain precipitated matter, it must be discarded.

### Otic Solutions

These solutions are occasionally referred to as ear or aural preparations. Other otic preparations include suspensions and ointments for topical application in the ear. Ear preparations are placed in the ear canal by drops or in small amounts for the removal of excessive cerumen (ear wax) or for the treatment of ear infections, inflammation, or pain.

The main classes of drugs used for topical administration to the ear include analgesics, such as benzocaine; antibiotics, such as neomycin; and anti-inflammatory agents, such as cortisone (Table 24-4). The USP preparations include Antipyrine and Benzocaine Otic Solution. The Neomycin and Polymyxin B Sulfates and Hydrocortisone Otic Solutions may contain appropriate buffers, solvents, and dispersants in an aqueous solution. The main solvents used in these preparations include glycerin or water. The viscous glycerin vehicle permits the drug to remain in the ear for a long time. Anhydrous glycerin, being hygroscopic, tends to remove moisture from surrounding tissues, thus, reducing swelling. Viscous liquids like glycerin or propylene glycol are used either alone or in combination with a surfactant to aid in the removal of cerumen (ear wax). To provide sufficient time for aqueous preparations to act, it is necessary for patients to remain on their side for a few minutes, so the

**Table 24-3. Examples of Commercial Nasal Preparations**

Product Name	Manufacturer	Active Ingredient	Indication
Atrovent Nasal Spray	Boehringer Ingelheim	Ipratropium bromide 0.06%	Seasonal or Allergic Rhinitis
Beconase AQ Nasal Spray	GlaxoSmithKline	Beclomethasone dipropionate, monohydrate 42 mcg	Seasonal or Allergic Rhinitis
Miacalcin	Novartis	Calcitonin-salmon, 2200 I.U. per mL	Postmenopausal osteoporosis
Nasal crom Nasal Spray	Pharmacia	Cromolyn sodium 5.2 mg	Seasonal or Allergic Rhinitis
Nasarel Nasal Spray	IVAX	Flunisolide	Seasonal or perennial rhinitis
Nicotrol Nasal Spray	Pfizer	Nicotine 0.5 mg	Smoking Cessation
Neo-Synephrine	Bayer	Oxymetazoline hydrochloride 0.05%	Decongestion
Rhinocort Aqua Nasal Spray	Astra-Zeneca	Budesonide 32mcg	Seasonal or Allergic Rhinitis
Stadol Nasal Spray	Bristol-Myers Squibb	Butorphanol tartrate, 1 mg	Pain Relief, Migraines
Stimate Nasal Spray	Aventis	Desmopressin Acetate 1.5 mg/mL	Hemophilia A or von Willebrand disease
Synarel Nasal Solution	Searle	Nafarelin acetate 2 mg/mL	Endometriosis
Tyzine	Bradley Pharmaceuticals	Tetrahydrozoline hydrochloride	Decongestion

**Table 24-4. Examples of Commercial Otic Preparations**

Product Name	Manufacturer	Active Ingredient	Indication
Americaine-Otic	Celltech	Benzocaine	Local Anesthetics
Cerumenex Ear Drops	Purdue	Triethanolamine polypeptide oleate-condensate	Removal of earwax
Chloromycetin Otic	Pfizer	Chloramphenicol	Antiinfective
Cipro HC Otic	Alcon	Ciprofloxacin hydrochloride and hydrocortisone	Acute otitis externa
Cortisporin	GlaxoSmithKline	Neomycin and Polymyxin B Sulfates and Hydrocortisone	Antibacterial and anti-inflammatory
Debrox® Drops	GlaxoSmithKline	Carbamide peroxide	Removal of earwax
Floxin Otic	Daiichi	Ofloxacin	Antiinfective
Tympagesic	Savage	Antipyrine, Benzocaine, and Phenylephrine Hydrochloride	Topical anesthetic

drops do not run out of the ear. Otic preparations are dispensed in a container that permits the administration of drops.

### Irrigation Solutions

Irrigation solutions are sterile, non-pyrogenic solutions used to wash or bathe surgical incisions, wounds, or body tissues. Because they come in contact with exposed tissue, they must meet stringent USP requirements for sterility, total solids, and bacterial endotoxins. These products may be prepared by dissolving the active ingredient in Water for Injection. They are packaged in single-dose containers, preferably Type I or Type II glass, or suitable plastic containers, and then sterilized. A number of irrigations are described in the USP, including Acetic Acid Irrigation for bladder irrigation, Dimethyl Sulfoxide Irrigation for relief of internal cystitis, Glycine Irrigation for transurethral prostatic resection, Ringer's Irrigation for general irrigation, Neomycin and Polymyxin B Sulfates Solution for Irrigation for infection, and Sodium Chloride Irrigation for washing wounds.

Extemporaneous formulations frequently are prepared using an isotonic solution of sodium chloride as the solvent. For example, cefazolin or gentamicin in 0.9% sodium chloride is used as anti-infective irrigations,<sup>45</sup> and 5-fluorouracil in 0.9% sodium chloride is employed for bladder irrigation.<sup>46</sup> Alum, either potassium or ammonium, in either sterile water or 0.9% sodium chloride for irrigation, has been used for bladder hemorrhage. Amphotericin in sterile water has been used for the treatment of localized infections on the dermis, the bladder, and the urinary tract.<sup>47</sup> All the extemporaneous preparations should meet the general requirements noted for USP irrigations.

### PREPARATION OF SOLUTIONS

The method of preparation for many solutions is given in the compendia. These procedures fall into three main categories: simple solutions, solution by chemical reaction, and solution by extraction.

Simple Solutions are prepared by dissolving the solute in most of the solvent, mixing until dissolved, then adding sufficient solvent to bring the solution up to the proper volume. The solvent may contain other ingredients that stabilize or solubilize the active ingredient. Calcium Hydroxide Topical Solution USP (Lime Water), Sodium Phosphate Oral Solution USP, and Strong Iodine Solution USP are examples.

Calcium Hydroxide Topical Solution USP contains, in each 100 mL, not less than 140 mg of Ca(OH)<sub>2</sub>. The solution is prepared by agitating vigorously 3 g of calcium hydroxide with 1000 mL of cool, purified water. Excess calcium hydroxide is allowed to settle out, and the clear, supernatant liquid dispensed. An increase in solvent temperature implies an increase in solute solubility. This rule does not apply, however, to the solubility of calcium hydroxide in water, which decreases with increasing temperature. The official solution is prepared at 25°C.

Solutions containing hydroxides react with the carbon dioxide in the atmosphere.

Calcium Hydroxide Topical Solution, therefore, should be preserved in well-filled, tight containers, at a temperature not exceeding 25°C.

Strong Iodine Solution USP contains, in each 100 mL, 4.5–5.5 g of iodine and 9.5–10.5 g of potassium iodide. It is prepared by dissolving 50 g of iodine in 100 mL of purified water containing 100 g of potassium iodide. Sufficient purified water is then added to make 1000 mL of solution. One gram of iodine dissolves in 2950 mL of water. However, solutions of iodides dissolve large quantities of iodine. Strong Iodine Solution is, therefore, a solution of polyiodides in excess iodide.

Doubly charged anions may be found also.

Strong Iodine Solution is used in the treatment of iodide deficiency disorders, such as endemic goiter.

Several antibiotics (e.g., cloxacillin sodium, nafcillin sodium, and vancomycin), because they are relatively unstable in aqueous solution, are prepared by manufacturers as dry powders or granules in combination with suitable buffers, colors, diluents, dispersants, flavors, and/or preservatives. These preparations, Cloxacillin Sodium for Oral Solution, Nafcillin for Oral Solution, and Vancomycin Hydrochloride for Oral Solution, meet the requirements of the USP. Immediately prior to dispensing to the patient, the pharmacist adds the appropriate amount of water. The products are stable for up to 14 days when refrigerated.<sup>48</sup> This period provides sufficient time for the patient to complete the administration of all the medication.

Solutions by chemical reaction are prepared by reacting two or more solutes with each other in a suitable solvent. An example is Aluminum Subacetate Topical Solution USP. Aluminum sulfate (145 g) is dissolved in 600 mL of cold water. The solution is filtered, and precipitated calcium carbonate (70 g) is added, in several portions, with constant stirring. Acetic acid (160 mL) is added slowly, and the mixture is set aside for 24 hours. The product is filtered, and the magma on the Buchner filter is washed with cold water, until the total filtrate measures 1,000 mL.

The solution contains pentaquohydroxo- and tetraquodihydroxoaluminum(III) acetates and sulfates dissolved in an aqueous medium saturated with calcium sulfate. The solution contains a small amount of acetic acid. It may be stabilized by the addition of not more than 0.9% boric acid. The reactions involved in the preparation of the solution are subsequently given. The hexaquo aluminum cations are first converted to the nonirritating [Al(H<sub>2</sub>O)<sub>5</sub>(OH)]<sup>2+</sup> and [Al(H<sub>2</sub>O)<sub>4</sub>(OH)<sub>2</sub>]<sup>+</sup> cations.

As the concentration of the hexaquo cations decreases, secondary reactions involving carbonate and bicarbonate occur.

The pH of the solution now favors the precipitation of dissolved calcium ions as the insoluble sulfate. Acetic acid is now added. The bicarbonate formed in the final stages of the procedure is removed as carbon dioxide.

Aluminum Subacetate Topical Solution is used in the preparation of Aluminum Acetate Topical Solution USP (Burow's Solution). The latter solution contains 15 mL of glacial acetic acid, 545 mL of Aluminum Subacetate Topical Solution, and sufficient water to make 1000 mL. It is defined as a solution of aluminum acetate in approximately 5%, by weight, of acetic acid in water. It may be stabilized by the addition of not more than 0.6% boric acid.

Often, drugs or pharmaceutical necessities of vegetable or animal origin are extracted with water or with water containing other substances. Preparations of this type may be classified as solutions but, more often, are classified as extracts and are described at the end of this chapter.

### SWEET AND OTHER VISCID AQUEOUS SOLUTIONS

Solutions that are sweet or viscid include syrups, honeys, mucilages, and jellies. All of these are viscous liquids or semisolids. The basic sweet or viscid substances giving body to these preparations are sugars, polyols, and/or polysaccharides.

#### Syrups

Syrups are concentrated, viscous, aqueous solutions of sugar or a sugar substitute with or without flavors and medical

**Table 24-5. Examples of Commercial Medicated Syrups**

Product Name	Manufacturer	Active Ingredient & Dose	Indication
Chlor-Trimeton	Schering-Plough	2 mg chlorpheniramine maleate / 5 mL	Allergic rhinitis
Children's Benadryl	Pfizer	12.5 mg diphenhydramine HCl / 5 mL	Allergic rhinitis
Demerol Syrup	Sanofi	50 mg meperidine HCl / 5 mL	Narcotic analgesic
Ditropan Syrup	Ortho-McNeil	5 mg Oxybutynin chloride / 5 mL	Overactive bladder
Dramamine	Pfizer	12.5 mg dimenhydrinate / 5 mL	Antiemetic
Phenergan Syrup	Wyeth-Ayerst	25 mg promethazine HCl / 5 mL	Antiemetic
Symmetrel Syrup	Endo	50 mg amantadine HCl / 5 mL	Antiviral

substances. When Purified Water alone is used in making the solution of sucrose, the preparation is known as “syrup,” or “simple syrup,” if the sucrose concentration is 85%. Syrups are also used to apply sugar coatings to tablets, particularly those with disagreeable aromas or acrid taste. In addition to sucrose, certain other polyols, such as glycerin or sorbitol, may be added to retard crystallization of sucrose or to increase the solubility of added ingredients. Alcohol often is included as a preservative and also as a solvent for flavors; further resistance to microbial attack can be enhanced by incorporating antimicrobial agents. When the aqueous preparation contains some added medicinal substance, the syrup is called a medicated syrup. Flavored syrups are not medicated, but rather contain various aromatic or pleasantly flavored substances and are intended to be used as a vehicle or flavor for prescriptions, such as Acacia, Cherry, Cocoa, Orange, and Raspberry USP.

Flavored syrups offer unusual opportunities as vehicles in extemporaneous compounding and are accepted readily by both children and adults. Because they contain no, or very little, alcohol, they are vehicles of choice for many of the drugs prescribed by pediatricians. Their lack of alcohol makes them superior solvents for water soluble substances. However, sucrose based medicines continuously administered to children apparently cause an increase in dental caries and gingivitis; consequently, alternate formulations of the drug either unsweetened or sweetened with non-cariogenic substances should be considered. A knowledge of the sugar content of liquid medicines is useful for patients who are on a restricted calorie intake; a list has been prepared by Greenwood.<sup>49</sup>

As noted, sucrose based syrups may be substituted in whole or in part by other agents in the preparation of medicated syrups. A solution of sorbitol, or a mixture of polyols, such as sorbitol and glycerin, is commonly used. Sorbitol Solution, USP, which contains 64% by weight of the polyhydric alcohol sorbitol, is often used in sugar free and children's preparations. However, reports of adverse reactions to sorbitol are largely due to its action as an osmotic laxative when ingested orally.<sup>50</sup> Ingestion of large quantities of sorbitol (>20 g/day in adults) should, therefore, be avoided.

Syrups possess remarkable taste masking properties for bitter or saline drugs. Syrups flavored with Glycyrrhizin, a triterpene glycoside extracted from licorice root, has been recommended for disguising the salty taste of bromides, iodides, and chlorides.<sup>51</sup> This has been attributed to its colloidal character and its double sweetness—the immediate sweetness of the sugar and the lingering sweetness of the glycyrrhizin. This syrup is also of value in masking bitterness in preparations containing the B complex vitamins. Acacia Syrup USP is of particular value, as a vehicle for masking the disagreeable taste of many medications, due to its colloidal character. Raspberry Syrup, USP, is one of the most efficient flavoring agents and is especially useful in masking the taste of bitter drugs. Many factors, however, enter into the choice of a suitable flavoring agent. Literature reports are often contradictory, and there appears to be no substitute for the taste panel, when developing new formulations.<sup>52</sup>

It is important that the concentration of sucrose approach, but not quite reach, the saturation point. In dilute solutions,

sucrose provides an excellent nutrient for molds, yeasts, and other micro-organisms. In concentrations of 65% by weight or more, the solution will retard the growth of such micro-organisms. However, a saturated solution may lead to crystallization of a part of the sucrose under conditions of changing temperature. Several commercial medicated syrups are available for a variety of indications (Table 24-5).

### Preparation of Syrups

Syrups are prepared using one of four techniques: solution with heat, solution by agitation, addition of sucrose to a liquid medication or flavored liquid, and percolation. The method of choice depends on the physical and chemical characteristics of the substances entering into the preparation. In many cases, syrups may be successfully prepared by more than one method, and the selection may simply be a matter of preference on the part of the pharmacist. Many of the compendial syrups do not have a designated method for preparation, because most are commercially available and are not prepared extemporaneously by the pharmacist.

**Solution with Heat**—This method is a suitable preparation method, if the constituents are not volatile or degraded by heat, and when it is desirable to make the syrup rapidly. Purified water is heated to 80–85°C, and then removed from its heat source. Sucrose is added with vigorous agitation. Then, other required heat-stable components are added to the hot syrup, the mixture is allowed to cool, and its volume is adjusted to the proper level by the addition of purified water. In instances in which heat labile agents or volatile substances, such as flavors and alcohol, are added, they are incorporated into the syrup after cooling to room temperature.

When heat is used in the preparation of syrups, there is almost certain to be an inversion of a slight portion of the sucrose. Sucrose, a disaccharide, may be hydrolyzed into monosaccharides, dextrose (glucose), and fructose (levulose). This hydrolytic reaction is referred to as “inversion,” and the combination of the two monosaccharide products is “invert sugar.” Sucrose solutions are dextrorotary, but, as hydrolysis proceeds, the optical rotation decreases and becomes negative when the reaction is complete. The rate of inversion is increased greatly by the presence of acids; the hydrogen ion acts as a catalyst in this hydrolytic reaction. Invert sugar is more readily fermentable than sucrose and tends to be darker in color. Nevertheless, its two reducing sugars are of value in retarding the oxidation of other substances.

The fructose formed during inversion is sweeter than sucrose, thus, the resulting syrup is sweeter than the original syrup. The relative sweetness of fructose, sucrose, and dextrose is in the ratio of 173:100:74. Thus, invert sugar is  $1/100 (173 + 74)1/2 = 1.23$  times as sweet as sucrose. Fructose is responsible for the darkening of syrup, as it is amber in color. If the syrup is significantly overheated, sucrose caramelizes and becomes darker. Excessive heating of syrups is undesirable, because inversion occurs with an increased tendency to ferment. Syrups cannot be sterilized in an autoclave without some caramelization.

**Agitation without Heat**—This method is used in cases in which heat would cause degradation or volatilize formulation constituents. On a small scale, sucrose and other formulation

ingredients may be dissolved in purified water by placing the ingredients in a vessel of greater capacity than the volume of syrup to be prepared, allowing intense agitation without spillage. This process is more time consuming than Solution with Heat, but the product has greater stability. Large glass lined and stainless steel tanks equipped with mechanical mixers are employed in the large scale preparation of syrups.

Often, simple syrup or some other non-medicated syrup, rather than sucrose, is employed as the sweetening agent and vehicle. When solid agents are added to a syrup, it is best to dissolve them in a minimal amount of purified water and then incorporate the resulting solution into the syrup. When solid substances are added directly to syrups, they dissolve slowly, because the viscous nature of the syrup does not permit the solid substance to distribute readily.

This method and that previously described are used for the preparation of a wide variety of preparations that are described popularly as syrups. Most cough syrups, for example, contain sucrose and one or more active ingredients. Many other active ingredients (e.g., ephedrine sulfate, dicyclomine hydrochloride, chloral hydrate, or chlorpromazine hydrochloride) are marketed as syrups. Like cough syrups, these preparations are flavored, colored, and recommended in those instances in which the patient cannot swallow the solid dosage form.

**Addition of Sucrose to a Liquid Medication or Flavored Liquid**—This method is often used with fluidextracts or tinctures. Syrups made in this way develop precipitates, because alcohol is often an ingredient of the liquids used, and the resinous and oily substances solubilized by the alcohol precipitate when water is added. A modification of this process entails mixing the fluidextract or tincture with the water, allowing the mixture to stand to permit the separation of insoluble constituents, filtering and then dissolving the sucrose in the filtrate. It is obvious that this procedure is not permissible when the precipitated ingredients are the valuable medicinal agents.

**Percolation**—In the percolation method, either purified water or the source of the medicinal component is passed slowly through a bed of crystalline sucrose, thus, dissolving it and forming a syrup. This latter method really involves two separate procedures: first, the preparation of the extractive of the drug, and then the preparation of the syrup. To be successful in using this process, technique is critical: 1) the percolator used should be cylindrical or semi-cylindrical and cone-shaped as it nears the lower orifice; and 2) a coarse granular sugar must be used, otherwise it will coalesce into a compact mass, which the liquid cannot permeate. The percolation method is applied on a commercial scale for the making of compendial syrups, as well as those for confectionary use.

Ipecac syrup is prepared by percolation by adding glycerin and syrup to an extractive of powdered ipecac obtained by percolation. The drug ipecac consists of the dried rhizome and roots of *Cephaelis ipecacuanha* and contains the medicinally active alkaloids: emetine, cephaeline, and psychotrine. These alkaloids are extracted from the powdered ipecac by percolation with a hydroalcoholic solvent. The syrup is categorized as an emetic with a usual dose of 15 mL. This amount of syrup is commonly used in the management of poisoning in children, when the evacuation of stomach contents is desirable. About 80% of children given this dose will vomit within 30 minutes. Bulimics have used ipecac to bring on attacks of vomiting in an attempt to lose more weight.<sup>53</sup> Pharmacists must be aware of this abuse and warn these individuals, because one of the active ingredients is emetine. With chronic abuse of the syrup, emetine builds up toxic levels within body tissues and, in 3–4 months, can do irreversible damage to heart muscles, resulting in symptoms mimicking a heart attack.

Syrups should be made in quantities that can be consumed within a few months, except in those cases where special facilities can be employed for their preservation; a low temperature is the best method. Concentration without super-saturation is also a condition favorable to preservation. The USP states that syrups

may contain preservatives. Glycerin, methylparaben, benzoic acid, and sodium benzoate may be used to prevent bacterial and mold growth. Combinations of alkyl esters of *p*-hydroxybenzoic acid are effective inhibitors of yeasts that have been implicated in the contamination of commercial syrups. Syrups should be preserved in well-dried bottles, preferably those that have been sterilized. These bottles should not hold more than is likely to be required during 4–6 weeks and should be filled completely, carefully closed, and stored in a cool, dark place.

Some examples of syrup formulations are noted:

#### Ferrous Sulfate Syrup

FERROUS SULFATE	40.0 G
CITRIC ACID	2.1 G
PEPPERMINT SPIRIT	2 ML
SUCROSE	825 G
PURIFIED WATER TO MAKE	1000.0 ML

Dissolve the Ferrous Sulfate, the Citric Acid, the Peppermint Spirit, and 200 g of the Sucrose in 450 mL of Purified Water, and filter the solution until clear. Dissolve the remainder of the Sucrose in the clear filtrate, and add Purified Water to make 1000 mL. Mix, and filter, if necessary, through a pledget of cotton.

#### Amantadine Hydrochloride Syrup

AMANTADINE HYDROCHLORIDE	10.0 G
CITRIC ACID	2.1 G
ARTIFICIAL RASPBERRY FLAVOR	2 ML
METHYL PARABEN	2 G
PROPYL PARABEN	0.5 G
SORBITOL SOLUTION TO MAKE	1000 ML

Dissolve the amantadine hydrochloride, the Citric Acid, flavor and preservatives in the sorbitol solution.

Syrups are useful for preparing liquid oral dosage forms from not only the pure drug, as described, but also injections, capsules, or tablets, if the pure drug is not readily available. If the drug and all the excipients in the preparation, such as injectables or capsules, are water soluble, a solution should result, if a syrup is prepared. Conversely, if the preparation used contains water-insoluble ingredients, as is the case with tablets and some capsules, a suspension will be formed. Several of these preparations have been described in the literature, in regard to their formulation, stability, and bioavailability. Some drugs that have been prepared from either the pure drug or an injectable form include midazolam, atropine, aminocaproic acid, terbutaline, procainamide, chloroquine, propranolol, and citrated caffeine.<sup>54,55</sup> If the appropriate salt of the drug is used, a solution will result.

When tablets are introduced to a syrup formulation, a suspension is often formed, because there are water insoluble ingredients used in tablet preparations. Examples of medicated syrups prepared from tablets are clonidine hydrochloride, cefuroxime axetil, famotidine, terbutaline sulfate, spironolactone, ranitidine, and rifampin.<sup>56,57</sup> The resulting suspensions should have a uniform distribution of particles, so a consistent dose is obtained. If the materials are not distributed uniformly, more appropriate suspending formulations should be considered. If pharmaceutical preparations contain a liquid insoluble in water, such as valproic acid or simethicone, to be incorporated into syrups, an emulsion will form, and it will be difficult to prepare a uniform product.

#### Honeys

Honeys are thick liquid preparations somewhat allied to the syrups, differing in that honey, instead of syrup, is used as a base. They are unimportant as a class of preparations today,

but, at one time, before sugar was available and honey was the most common sweetening agent, they were used widely. Honey and sugar pastes are used to a small extent and have been discussed in the pharmaceutical literature for topical application for the treatment of certain types of ulcers and abscesses.<sup>58</sup>

### Mucilages

Mucilages are thick, viscid, adhesive liquids, produced by dispersing gum in water or by extracting the mucilaginous principles from vegetable substances with water. The mucilages are prone to decomposition, showing appreciable decrease in viscosity on storage; they should never be made in quantities larger than can be used immediately, unless a preservative is added. Mucilages are used primarily to aid in suspending insoluble substances in liquids; their colloidal character and viscosity help prevent immediate sedimentation. Examples include sulfur in lotions, resin in mixtures, and oils in emulsions. Both tragacanth and acacia are either partially or completely insoluble in alcohol. Tragacanth is precipitated from solution by alcohol, but acacia, conversely, is soluble in diluted alcoholic solutions. A 60% solution of acacia may be prepared with 20% alcohol, and a 4% solution of acacia may be prepared even with 50% alcohol.

Recent research on mucilages includes the preparation of mucilage from plantain and the identification of its sugars, the preparation and suspending properties of cocoa gum, the preparation of glycerin ointments using flaxseed mucilage, and the consideration of various gums and mucilages obtained from several Indian plants for pharmaceutical purposes.

Several synthetic mucilage-like substances, such as polyvinyl alcohol, methylcellulose, carboxymethylcellulose, and related substances, are used at the appropriate concentration as mucilage substitutes and emulsifying and suspending agents. Methylcellulose is used widely as a bulk laxative, because it absorbs water and swells to a hydrogel in the intestine, in much the same manner as psyllium or karaya gum. Methylcellulose Oral Solution, USP, is a flavored solution of the agent. It may be prepared by slowly adding the methylcellulose to about one-third the amount of boiling water, with stirring, until it is thoroughly wetted. Cold water should then be added, and the wetted material allowed to dissolve while stirring. The viscosity of the solution will depend upon the concentration and the specifications of the methylcellulose. The synthetic gums are non-glycogenetic and may be used in the preparation of diabetic syrups. Sodium carboxymethyl cellulose of a medium grade in water (0.25 – 1%) is suitable for preparing a suspending vehicle. Several formulas for such syrups, based on sodium carboxymethylcellulose, have been proposed.

Uniformly smooth mucilages are sometimes difficult to prepare, due to the uneven wetting of the gums. It is best to use fine gum particles and disperse them with agitation in a small quantity of 95% alcohol or in cold water (except for methylcellulose). The appropriate amount of water can then be added with constant stirring. A review of the chemistry and properties of acacia and other gums has been prepared.<sup>59</sup>

### Jellies

Jellies are a class of gels in which the structural coherent matrix contains a high portion of liquid, usually water. They are similar to mucilages, in that they may be prepared from similar gums, but they differ from the latter in having a jelly-like consistency. A whole gum of the best quality, rather than a powdered gum, is desirable to obtain a clear preparation of uniform consistency. Although the specific thickening agent in the USP jellies is not indicated, reference is usually made in the monograph to a water-soluble, sterile, viscous base. These preparations may also be formulated with water from acacia, chondrus, gelatin, carboxymethylcellulose, hydroxyethylcellulose, and similar substances.

Jellies are used as lubricants for surgical gloves, catheters, and rectal thermometers. Lidocaine Hydrochloride Jelly, USP,

is used as a topical anesthetic. Therapeutic vaginal jellies are available, and certain jelly-like preparations are used for contraceptive purposes, which often contain surface-active agents to enhance the spermicidal properties of the jelly. Aromatics, such as methyl salicylate and eucalyptol, are often added to give the preparation a desirable odor.

Jellies are prone to microbial contamination and, therefore, contain preservatives; for example, methyl *p*-hydroxybenzoate is used as a preservative in a base for medicated jellies. One base contains sodium alginate, glycerin, calcium gluconate, and water. The calcium ions cause a cross-linking with sodium alginate to form a gel of firmer consistency.

## NONAQUEOUS SOLUTIONS

It is difficult to fairly evaluate the importance of nonaqueous solvents in pharmaceutical processes. That they are important in the manufacture of pharmaceuticals is an understatement. However, pharmaceutical preparations and, in particular, those intended for internal use rarely contain more than minor quantities of the organic solvents common to the manufacturing or analytical operation. Commercial products intended for internal use may contain solvents, such as ethanol, glycerin, propylene glycol, certain oils, and liquid paraffin. Preparations intended for external use may contain other solvents in addition to those mentioned, namely isopropyl alcohol, polyethylene glycols, various ethers, and certain esters.

Although the lines between aqueous and nonaqueous preparations tend to blur in those cases in which the solvent is water soluble, it is possible to categorize a number of products as nonaqueous. This section is, therefore, devoted to groups of nonaqueous solutions: thealecoholic or hydroalcoholic solutions (e.g., elixirs and spirits), ethereal solutions (e.g., collodions), glycerin solutions (e.g., glycerins), oleaginous solutions (e.g., liniments, oleovitamins, and toothache drops), inhalations, and inhalants.

Although this list is limited, a wide variety of solvents are used in various pharmaceutical preparations. Solvents, such as glycerol formal, dimethylacetamide, and glycerol dimethylacetal, have been suggested for some products produced by the industry. However, the toxicity of many of these solvents is not well established, and, for this reason, careful clinical studies should be carried out on the formulated product, before it is released to the marketplace. It is essential that the toxicity of solvents be tested appropriately and approved to avoid problems; for example, lives were lost in 1937, when diethylene glycol was used in an elixir of sulfanilamide. The result of this tragedy was the 1938 Federal Food, Drug, and Cosmetic Act, which required that products be tested for both safety and effectiveness.

### COLLODIONS

Collodions are liquid preparations containing pyroxylin, a partially nitrated cellulose, in a mixture of ethyl ether and ethanol. They are applied to the skin by means of a soft brush or other suitable applicator and, when the ether and ethanol have evaporated, leave a film of pyroxylin on the surface. Salicylic Acid Collodion, USP, contains 10% w/v of salicylic acid in Flexible Collodion, USP, and is used as a keratolytic agent in the treatment of corns and warts. Collodion, USP, and Flexible Collodion, USP, are water-repellent protectives for minor cuts, scratches, and chigger bites. Collodion is made flexible by the addition of castor oil and camphor. Collodion has been used to reduce or eliminate the side effects of fluorouracil treatment of solar keratoses.<sup>60</sup> Vehicles other than Flexible Collodion, such as a polyacrylic base, have been used to incorporate salicylic acid for the treatment of warts with less irritation.

### ELIXIRS

Elixirs are clear, pleasantly flavored, sweetened hydroalcoholic liquids intended for oral use. The main ingredients in elixirs are ethanol and water but glycerin, sorbitol, propylene glycol, flavoring agents, preservatives, and syrups are often used in the

preparation of the final product. The solvents are often used to increase the solubility of the drug substance in the dosage form. Elixirs are more fluid than syrups, due to the use of less viscous ingredients, such as alcohol, and the minimal use of viscosity-improving agents, such as sucrose. They are used as flavors and vehicles, such as Aromatic Elixir, USP, for drug substances; when such substances are incorporated into the specified solvents, they are classified as medicated elixirs, such as Dexamethasone Elixir, USP, and Phenobarbital Elixir, USP.

The distinction between some of the medicated syrups and elixirs is not always clear. For example, Ephedrine Sulfate Syrup, USP, contains between 20 and 40 mL of alcohol in 1000 mL of product. Definitions are sometimes inconsistent and, in some instances, not too important with respect to the naming of the articles of commerce. To be designated an elixir, however, the solution must contain alcohol. The alcoholic content will vary greatly, from elixirs containing only a small quantity to those that contain a considerable portion as a necessary aid to solubility. For example, Aromatic Elixir, USP, contains 21–23% alcohol; Compound Benzaldehyde Elixir, USP, conversely, contains 3–5%.

Elixirs may also contain glycerin and syrup. These may be added to increase the solubility of the medicinal agent, for sweetening purposes, or to decrease the pharmacological effects of the alcohol. Some elixirs contain propylene glycol. Claims have been made for this solvent as a satisfactory substitute for both glycerin and alcohol.

Although alcohol is an excellent solvent for some drugs, it does accentuate the saline taste of bromides and similar salts. It is often desirable, therefore, to substitute some other solvent that is more effective in masking such tastes for part of the alcohol in the formula. If taste is a consideration, the formulator is more prone to use a syrup, rather than a hydroalcoholic vehicle.

Because only relatively small quantities of ingredients have to be dissolved, elixirs are more readily prepared and manufactured than syrups, which frequently contain considerable amounts of sugar. An elixir may contain both water and alcohol soluble ingredients. If such is the case, the following procedure is indicated:

Dissolve the water soluble ingredients in part of the water. Add and solubilize the sucrose in the aqueous solution. Prepare an alcoholic solution containing the other ingredients. Add the aqueous phase to the alcoholic solution, filter, and make to volume with water.

Sucrose increases viscosity and decreases the solubilizing properties of water and must be added after the primary solution has been effected. A high alcoholic content is maintained during preparation, by adding the aqueous phase to the alcoholic solution. Elixirs should always be brilliantly clear. They may be strained or filtered and, if necessary, subjected to the clarifying action of purified talc or siliceous earth.

Elixirs, and many other liquid preparations intended for internal use, such as the diabetic syrups thickened with sodium carboxymethylcellulose or similar substances, contain saccharin, aspartame, acesulfame potassium, and other sweeteners. Cyclamates and saccharin have been banned in some countries as ingredients in manufactured products. Much research has been done to find a safe synthetic substitute for sucrose.

Research concerning the preparation of a dry elixir has been conducted by Kim and coworkers.<sup>61</sup> Dry Elixirs containing a non-steroidal anti-inflammatory drug and ethanol were encapsulated in a dextrin. The dissolution rate constant of the drug from the microcapsules increased considerably, compared to the drug alone, possibly due to the cosolvent ethanol. It is suggested that this type of dosage form may be useful to improve the solubility, dissolution rate, and bioavailability of the drug.

Because elixirs contain alcohol, incompatibilities of this solvent are an important consideration during formulation. Alcohol precipitates tragacanth, acacia, and agar from aqueous solutions. Similarly, it will precipitate many inorganic salts from similar solutions. The implication is that such substances should be absent from the aqueous phase or present in such concentrations that there is no danger of precipitation on standing.

If an aqueous solution is added to an elixir, a partial precipitation of alcohol soluble ingredients may occur. This is due to the reduced alcoholic content of the final preparation. However, the alcoholic content of the mixture is not sufficiently decreased to cause separation. As vehicles for tinctures and fluidextracts, the elixirs cause a separation of extractive matter from these products, due to a reduction of the alcoholic content. Many of the incompatibilities between elixirs, and the substances combined with them, are due to the chemical characteristics of the elixir per se, or of the ingredients in the final preparation. Thus, certain elixirs are acid in reaction, whereas others may be alkaline and will, therefore, behave accordingly.

Some example formulations of medicated elixirs are as follows:

Phenobarbital Elixir	
PHENOBARBITAL	4.00 G
PROPYLENE GLYCOL	50 ML
ALCOHOL	200 ML
SORBITOL SOLUTION	600 ML
SACCHARIN SODIUM	5.0 G
FLAVOR	Q.S.
PURIFIED WATER, TO MAKE	1000 ML

Theophylline Elixir	
THEOPHYLLINE	5.3 G
CITRIC ACID	10.0 G
SYRUP	132.0 ML
GLYCERIN	50.0 ML
SORBITOL SOLUTION	324.0 ML
ALCOHOL	200.00 ML
FLAVOR	Q.S.
PURIFIED WATER, TO MAKE	1000.0 ML

## GLYCERINS

Glycerins or glycerites are solutions or mixtures of medicinal substances in not less than 50% by weight of glycerin. Most of the glycerins are extremely viscous, and some are of a jelly-like consistency. Few of them are used extensively. Glycerin is a valuable pharmaceutical solvent forming permanent and concentrated solutions not otherwise obtainable. Glycerin is used as the sole solvent for the preparation of Antipyrine and Benzocaine Otic Solution, USP. Glycerins are hygroscopic and should be stored in tightly closed containers.

## INHALATIONS AND INHALANTS

Inhalation preparations are so used or designed that the drug is carried into the respiratory tree of the patient. The vapor or mist reaches the affected area and gives prompt relief from the symptoms of bronchial and nasal congestion. The USP defines Inhalations in the following way:

Inhalations are drugs or solutions or suspensions of one or more drug substances administered to the nasal or oral respiratory route for local or systemic effect. Solutions of drug substances in sterile water for inhalation or in sodium chloride inhalation solution may be nebulized by the use of inert gases. Nebulizers are suitable for the administration of inhalation solutions only if they give droplets sufficiently fine and uniform in size so that the mist reaches the bronchioles. Nebulized solutions may be breathed directly from the nebulizer, or the nebulizer may be attached to a plastic face mask, tent or intermittent positive pressure breathing (IPPB) machine.

Another group of products, also known as metered-dose inhalers (MDIs) are propellant-driven drug suspensions or solutions

in liquefied gas propellant (chlorofluorocarbons and hydrofluoroalkanes) with or without a cosolvent and are intended for delivering metered doses of the drug to the respiratory tract. An MDI contains multiple doses, often exceeding several hundred. The most common single dose volumes delivered are from 25 to 100  $\mu\text{L}$  (also expressed as mg) per actuation. Examples of MDIs containing drug solutions are Epinephrine Inhalation Aerosol, USP, and Isoproterenol Hydrochloride and Phenylephrine Bitartrate Inhalation Aerosol, respectively. Both the solubility and stability of the drug in the propellant mixture must be investigated during formulation development. Ethanol is commonly used as a cosolvent for hydrofluoroalkane propellants, and was reported to significantly increase the solubility of steroids.<sup>62</sup>

As stated in the USP, particle size is of major importance in the administration of this type of preparation. The various mechanical devices used in conjunction with inhalations are described in Chapter 33 (Aerosols). It has been reported that the optimum particle size for penetration into the pulmonary cavity is of the order of 0.5–7.0  $\mu\text{m}$ .<sup>63</sup> Fine mists are produced by pressurized aerosols and, hence, possess basic advantages over the older nebulizers; in addition, metered aerosols deliver more uniform doses. A number of inhalations are described in the USP.

The USP defines “inhalants” as follows:

A special class of inhalations termed “inhalants” consists of drugs or combinations of drugs that, by virtue of their high vapor pressure, can be carried by an air current into the nasal passage where they exert their effect. The container from which the inhalant is administered is known as an inhaler.

Amyl nitrate, USP, and Propylhexedrine Inhalant, USP, are two examples. Amyl nitrite is a clear, yellowish, volatile liquid that acts as a vasodilator when inhaled. The drug is prepared in sealed glass vials covered with a protective gauze cloth. Upon use, the glass vial is broken in the fingertips, and the cloth soaks up the liquid, which is then inhaled. The vials contain 0.3 mL of the drug substance. The effects of the drug are rapid and are used in the treatment of anginal pain.

Propylhexedrine is the active ingredient in the widely used Benzedrex and Dristan Inhalers. Propylhexedrine is a liquid, vasoconstrictor agent that volatilizes slowly at room temperature. This quality enables it to be effectively used as an inhalant. The official inhalant consists of cylindrical rolls of suitable fibrous material impregnated with propylhexedrine, aromatized to mask its amine like odor, and contained in a suitable inhaler. The vapor of the drug is inhaled into the nostrils when needed to relieve nasal congestion due to colds and hay fever. It may also be employed to relieve ear block and the pressure pain in air travelers. Each plastic tube of the commercial product contains 250 mg of propylhexedrine with aromatics. The containers should be tightly closed after each opening to prevent loss of the drug vapors.

## LINIMENTS

Liniments are alcoholic or oil based solutions or emulsions containing therapeutic agents intended for external application. These preparations may be liquids or semisolids that are rubbed onto the affected area; due to this, they were once called “embrocations.”

Liniments are applied with friction and rubbing of the skin, the oil or soap base providing for ease of application and massage. Alcoholic liniments are used for their rubefacient, counterirritant, mildly astringent, and penetrating effects. Such liniments penetrate the skin more readily than do those with an oil base. Oily liniments, therefore, are milder in their action but are more useful when massage is required. Depending on their ingredients, such liniments may function solely as protective coatings. Liniments should not be applied to skin that is bruised or broken.

Other liniments contain antipruritics, astringents, emollients, or analgesics and are classified on the basis of their active ingredient. Dermatologists prescribe products of this type, but only

those containing the rubefacients are advertised extensively and used by consumers for treating minor muscular aches and pains. It is essential that these applications be marked clearly “For External Use Only.” Liniments containing a capsaicin are being investigated for treatment of pruritus.<sup>64</sup>

## OLEOVITAMINS

Oleovitamins are fish liver oils diluted with edible vegetable oil or solutions of the indicated vitamins or vitamin concentrates (usually vitamin A and D) in fish-liver oil. The definition is broad enough to include a wide variety of marketed products.

In Oleovitamin A and D, USP, vitamin D may be present as ergocalciferol or cholecalciferol obtained by the activation of ergosterol or 7-dehydrocholesterol, or may be obtained from natural sources. Synthetic vitamin A, or a concentrate, may be used to prepare oleovitamin A. The starting material for the concentrate is fish-liver oil, the active ingredient being isolated by molecular distillation or by a saponification and extraction procedure. These vitamins are unstable in the presence of rancid oils; therefore, these preparations should be stored in small, tight containers, preferably under vacuum or under an atmosphere of an inert gas, protected from light and air.

## SPIRITS

Spirits, sometimes known as essences, are alcoholic or hydroalcoholic solutions of volatile substances. Like the aromatic waters, the active ingredient in the spirit may be a solid, liquid, or gas. The genealogical tree for this class of preparations begins with a distinguished pair of products, Brandy (*Spiritus Vini Vitis*) and Whisky (*Spiritus Frumenti*), and ends with a wide variety of products that comply with the definition given. Physicians have debated the therapeutic value of the former products and these are no longer compendial.

The alcohol concentration of spirits is rather high, over 60%. Due to the greater solubility of aromatic or volatile substances in alcohol than in water, spirits can contain a greater concentration of these materials than the corresponding aromatic waters. When mixed with water or with an aqueous preparation, the volatile substances present in spirits separate from solution and form a milky preparation. Salts may be precipitated from their aqueous solutions by the addition of spirits, due to their lesser solubility in alcoholic liquids. Some spirits show incompatibilities characteristic of the ingredients they contain. For example, Aromatic Ammonia Spirit cannot be mixed with aqueous preparations containing alkaloids (e.g., codeine phosphate). An acid–base reaction (ammonia-phosphate) occurs, and, if the alcohol content of the final mixture is too low, codeine will precipitate. Spirits should be stored in tight, light-resistant containers in a cool place. This tends to prevent evaporation and volatilization of either the alcohol or the active principle and to limit oxidative changes.

Spirits may be used pharmaceutically as flavoring agents and medicinally for the therapeutic value of the aromatic solute. As flavoring agents, they are used to impart the flavor of their solute to other pharmaceutical preparations. For medicinal purposes, spirits may be taken orally, applied externally, or used by inhalation, depending upon the particular preparation. When taken orally, they are mixed with a portion of water to reduce the pungency of the spirit. Depending on the materials utilized, spirits may be prepared by simple solution, solution by maceration, or distillation. The spirits still listed in the USP/NF are aromatic ammonia spirit, camphor spirit, compound orange spirit, and peppermint spirit.

## EMULSIONS

An emulsion is a two-phase system prepared by combining two immiscible liquids, in which small globules of one liquid are dispersed uniformly throughout the other liquid. The liquid dispersed into small droplets is called the dispersed, internal, or discontinuous phase. The other liquid is the dispersion

medium, external phase, or continuous phase. Where oil is the dispersed phase and an aqueous solution is the continuous phase, the system is designated as an oil-in-water (O/W) emulsion. Conversely, where water or an aqueous solution is the dispersed phase and oil or oleaginous material is the continuous phase, the system is designated as a water-in-oil (W/O) emulsion. Emulsions may be employed orally, topically, or parenterally, depending on the formulation ingredients and the intended application. Many pharmaceutical emulsions may not be classified as such, because they are described by another pharmaceutical category more appropriately. For instance, certain lotions, liniments, creams, ointments, and commercial vitamin drops may be emulsions but may be preferentially referred to in these terms.

Emulsions possess a number of important advantages over other liquid forms:

- Poorly water soluble drugs may be easily incorporated with improved dissolution rates and bioavailability.
- The unpleasant taste or odor of oils can be masked partially or wholly, by emulsification.
- The absorption rate and permeation of medicaments can be controlled.
- Absorption may be enhanced by the diminished size of the internal phase.
- Formulation and technology for organ targeted delivery is available.
- Various particle sizes of the internal phase can be achieved by preparation technique, from micro emulsions (micron sized particles) to nanoparticles.
- Water is an inexpensive diluent and a good solvent for the many drugs and flavors that are incorporated into an emulsion.

It is possible to prepare emulsions that are basically nonaqueous. For example, investigations of the emulsifying effects of anionic and cationic surfactants on the nonaqueous immiscible system, glycerin and olive oil, have shown that certain amines and three cationic agents produced stable emulsions. Although the USP definition is broad enough to encompass nonaqueous systems, emphasis is placed on those emulsions that contain water, as they are the most common in the pharmaceutical sciences.

When it is necessary to administer oils by the oral route, patient acceptance is enhanced when the oil is prepared in emulsion form. Thus, mineral oil (a laxative), valproic acid (an anticonvulsant), oil-soluble vitamins, vegetable oils, and preparations for enteral feeding are formulated frequently in an O/W emulsion form to enhance their palatability.

The bioavailability of oils for absorption may be enhanced when the oil is in the form of small droplets. Furthermore, the absorption of some drugs, such as griseofulvin, may be enhanced when they are prepared in the form of an O/W emulsion.<sup>65</sup> Emulsion formulations of drugs, such as erythromycin and physostigmine salicylate, have been considered to improve their stability.<sup>66,67</sup> Finally, the greatest use of emulsions is for topical preparations. Both O/W and W/O emulsions are used widely, depending on the effect desired. Emulsion bases of the W/O type tend to be more occlusive and emollient than O/W emulsion bases, which tend to be removed more easily by water. The effects of viscosity, surface tension, solubility, particle size, complexation, and excipients on the bioavailability of emulsions have been reported.<sup>68</sup>

Although this section on emulsions focuses primarily on those for oral use and, to a lesser degree, those for topical application, it should be noted that there are a number of emulsions used parenterally described in specialized books listed in the Bibliography at the end of this chapter. For example, emulsions of the O/W type are used for intravenous feeding of lipid nutrients. These are used to provide a source of calories and essential fatty acids. These emulsions must meet exacting standards in regard

to particle size, safety, and stability. Examples of commercial products include Diprivan Injectable Emulsion (AstraZeneca), EMLA Cream (AstraZeneca), Renova 0.02% Cream (OrthoNeutrogena), Bactroban Cream (GlaxoSmithKline), Cordran Lotion (Watson), Differin Cream (Galderma), and Renova 0.05% Cream (OrthoNeutrogena). Other specialized uses of emulsions include radiopaque emulsions used as diagnostic agents for X-ray examination.

## THEORIES OF EMULSIFICATION

Several theories have been proposed to explain how emulsifying agents act in producing the multi-phase dispersion and in maintaining the stability of the resulting emulsion. Some of these theories apply to specific types of emulsifying agents and to certain conditions, such as pH of the system and the physicochemical nature and proportions of the internal and external phases. The most prevalent theories are the surface-tension theory, the oriented-wedge theory, and the interfacial film theory.

Liquids assume a shape to minimize their surface area, which is spherical for a small drop. In a spherical drop of liquid, there are attractive forces between the molecules of the liquid, resisting distortion into a less spherical form. If two or more drops of the same liquid come into contact with one another, it is more thermodynamically favorable for them to coalesce, making a larger drop with a decreased surface area, compared to the total surface area of the individual drops. The tendency of liquids to minimize their surface area can be measured quantitatively, and, when the liquid is surrounded by air, the measurement is called the surface tension.

When a liquid is in contact with another liquid in which it is insoluble and immiscible, the force causing each liquid to resist breaking into smaller particles is called interfacial tension. Surface active agents, or surfactants, are substances that reduce the resistance of a droplet to form smaller droplets. Surfactants are also called emulsifiers and wetting agents. According to the surface tension theory of emulsification, the use of surfactants results in a reduction in the interfacial tension of the two immiscible liquids, reducing the repellent force between the liquids and diminishing each liquid's attraction for its own molecules. Thus, surfactants enable large globules to break into smaller globules, and prevent small globules from coalescing into larger globules.

The oriented wedge theory proposes that the surfactant forms monomolecular layers around the droplets of the internal phase of the emulsion. The theory is based on the assumption that emulsifying agents orient themselves about and within a liquid relative to their solubility in that particular liquid. In a system containing two immiscible liquids, the emulsifying agent is preferentially soluble in one of the two liquids and becomes more embedded with that phase relative to the other. Many surfactants have a hydrophilic or water loving portion and a hydrophobic or water hating portion (but usually lipophilic or oil-loving), and the molecules position or orient themselves into each phase. Depending on the shape and size of the molecules, their solubility characteristics, and, thus, their orientation, the wedge shape theory proposes that emulsifiers surround either oil globules or water globules.

An emulsifying agent, having a greater hydrophilic character than hydrophobic character, will promote oil in water emulsions. Conversely, water in oil emulsions result with the use of an emulsifier that is more hydrophobic than hydrophilic. Putting it another way, the phase in which the emulsifying agent is more soluble will become the continuous or external phase of the emulsion. Although this theory does not represent a completely accurate depiction of the molecular arrangement of the emulsifier molecules, the concept that water soluble emulsifiers form oil in water emulsions is important.

The interfacial film theory proposes that the emulsifier forms an interface between the oil and water, surrounding the droplets of the internal phase as a thin layer of film adsorbed on the surface of the drops. The film prevents the contact and coalescing

of the dispersed phase; the tougher and more pliable the film, the greater the stability of the emulsion. Naturally, the surfactant must be available to coat the entire surface of each drop of internal phase. Similar to the oriented wedge theory, the formation of an oil in water or a water in oil emulsion depends on the degree of solubility of the emulsifier in the two phases, with water soluble agents encouraging oil in water emulsions and oil soluble emulsifiers promoting water in oil emulsions.

In reality, none of the emulsion theories can individually explain the mechanism by which the many and varied emulsifiers promote emulsion formation and stability. It is more than likely that, even within a given emulsion system, more than one of the theories of emulsification are applicable. For instance, reducing the interfacial tension is critical during initial formation of an emulsion, but the formation of a protective wedge of molecules or film of emulsifier is equally important for continued emulsion stability. Undoubtedly, many emulsifiers are capable of both tasks.

### EMULSION FORMULATION INGREDIENTS

The first step in preparation of an emulsion is the selection of the emulsifier. The emulsifier must be compatible with the formulation ingredients and the active pharmaceutical ingredient. It should be stable, non-toxic, and promote emulsification to maintain the stability of the emulsion for the intended shelf life of the product. The selection of the oil phase for oral preparations depends on the purpose of the product. For example, mineral oil is used as a laxative, and corn oil is used for its nutrient properties. Vegetable oils can be used to dissolve or suspend pharmaceuticals, such as oil-soluble vitamins.

Emulsions are thermodynamically unstable, due to the large increase in surface energy that results from the combination of interfacial tension and large surface area of the dispersed phase and the different densities of the two phases. Thus, emulsions tend to cream—the less dense phase rises and the denser phase falls in the container. Subsequently, the droplets can coalesce with a considerable reduction in surface free energy.

Consequently, considerable research has been conducted on their preparation and stabilization. To prepare suitable emulsions that remain stable, a number of excipients are used in their preparation.

Emulsifiers often have a hydrophilic portion and a lipophilic portion with one or the other being more or less predominant. Griffin devised a method whereby emulsifying or surface-active agents may be categorized on the basis of their hydrophilic-lipophilic balance or HLB value.<sup>70</sup> By this method, each agent is assigned an HLB value or number that is indicative of the substance's polarity, which may vary from 40 for sodium lauryl sulfate to 1 for oleic acid. Although the numbers have been assigned up to 40, the usual range is between 1 and 20. Table 24-6 lists examples of HLB values for common emulsifiers used in pharmaceutical applications. HLB values have also been useful in describing the functional properties of materials. For example, HLB values from 1 to 3 exhibit antifoaming properties, values from 7 to 10 exhibit good wetting properties, values from 13 to 20 act as solubilizers, and values from 13 to 15 function as detergents. Oil in water emulsions have a weighted HLB value ranging from 8 to 16, whereas water in oil emulsions have weighted HLB values ranging from 3 to 8.

Materials highly polar or hydrophilic have been assigned higher numbers than materials that are less polar and more lipophilic. Lipophilic surfactants have an HLB value from 0 to 10 and are known for their antifoaming, water in oil emulsifying, or wetting properties. Hydrophilic surfactants have HLB values ranging from 10 to 20 and form oil in water emulsions. The HLB system also assigns values to oils and oil-like substances. In using the HLB concept in the preparation of an emulsion, one selects emulsifying agents having the same or nearly the same HLB value as the oleaginous phase of the intended emulsion. When needed, two or more emulsifiers may be combined to achieve the proper HLB value.

The ionic nature of a surfactant is an important consideration when selecting a surfactant for an emulsion. Nonionic surfactants are effective over pH range 3–10; cationic surfactants are

**Table 24-6. HLB Values of Common Emulsifiers used in Pharmaceutical Systems**

Agent	HLB	Class
Oleic Acid	1.0	Anionic
Ethylene glycol distearate	1.5	Nonionic
Sorbitan tristearate (Span 65)	2.1	Nonionic
Glyceryl monooleate	3.3	Nonionic
Propylene glycol monostearate	3.4	Nonionic
Glyceryl monostearate	3.8	Nonionic
Sorbitan monooleate (Span 80)	4.3	Nonionic
Sorbitan monostearate (Span 60)	4.7	Nonionic
Diethylene glycol monolaurate	6.1	Nonionic
Sorbitan monopalmitate (Span 40)	6.7	Nonionic
Acacia	8.0	Anionic
Polyoxyethylene lauryl ether (Brij 30)	9.7	Nonionic
Polyoxyethylene monostearate (Myrj 45)	11.1	Nonionic
Triethanolamine oleate	12.0	Anionic
Polyoxyethylene sorbitan monostearate (Tween 60)	14.9	Nonionic
Polyoxyethylene sorbitan monooleate (Tween 80)	15.0	Nonionic
Polyoxyethylene sorbitan monolaurate (Tween 20)	16.7	Nonionic
Pluronic F 68	17.0	Nonionic
Sodium oleate	18.0	Anionic
Potassium oleate	20.0	Anionic
Cetrimonium Bromide	23.3	Cationic
Cetylpyridinium chloride	26.0	Cationic
Poloxamer 188	29.0	Nonionic
Sodium lauryl sulfate	40.0	Anionic

effective over pH range 3–7; and, anionic surfactants require a pH of greater than 8.<sup>69</sup>

Emulsifying agents may be divided into three classes: natural emulsifying agents, finely divided solids, and synthetic emulsifying agents.

*Natural Emulsifying Agents* are substances derived from vegetable sources and include acacia, tragacanth, alginates, chondrus, xanthan, and pectin. These materials form hydrophilic colloids, when added to water, and produce o/w emulsions. Although their surface activity is low, these materials achieve their emulsifying power by increasing the viscosity of the aqueous phase. Examples of emulsifying agents derived from animal sources include gelatin, egg yolk, casein, wool fat, cholesterol, wax, and lecithin. Due to the widely different chemical constitution of these compounds, they have a variety of uses, depending on the specific compound, in both oral and topical preparations. All naturally occurring agents show variations in their emulsifying properties from batch to batch.

*Finely Divided Solids* are the colloidal clays: bentonite (aluminum silicate) and Veegum (magnesium aluminum silicate). These compounds are good emulsifiers and tend to be adsorbed at the interface, increase the viscosity in the aqueous phase, and are often used in conjunction with a surfactant to prepare O/W emulsions. However, both O/W and W/O preparations can be prepared by adding the clay to the external phase. They are used frequently in external preparations, such as lotions or creams.

*Synthetic Emulsifying Agents* are very effective at lowering the interfacial tension between the oil and water phases, because the molecules possess both hydrophilic and hydrophobic properties. These emulsifying agents are available in different ionic types: anionic, such as sodium dodecyl sulfate; cationic, such as benzalkonium chloride; nonionic, such as polyethylene glycol 400 monostearate; and ampholytic, such as long-chain amino acid derivatives.

In addition to the emulsifying agents, viscosity agents are employed, namely the hydrophilic colloids, such as naturally occurring gums, and partially synthetic polymers, such as cellulose derivatives (e.g., methylcellulose, hydroxypropylmethylcellulose, sodium carboxymethylcellulose), or a number of synthetic polymers that may be used, such as carbomer polymers. These materials are hydrophilic in nature and dissolve or disperse in water to give viscous solutions and function as emulsion stabilizers.

Other functional excipients are often utilized in emulsions. High molecular weight alcohols, such as stearyl alcohol, cetyl alcohol, and glyceryl monostearate, are employed primarily as thickening agents and stabilizers for o/w emulsions of certain lotions and ointments used externally. Cholesterol and cholesterol derivatives may also be employed in externally used emulsions and to promote w/o emulsions.

The aqueous phase of the emulsion favors the growth of micro-organisms; due to this, a preservative is added to the product. Some of the preservatives that have been used include chlorocresol, chlorobutanol, mercurial preparations, salicylic acid, the esters of *p*-hydroxybenzoic acid, benzoic acid, sodium benzoate, or sorbic acid. The preservative should be selected with regard for the ultimate use of the preparation and possible incompatibilities between the preservative and the ingredients in the emulsion (e.g., binding between the surfactant and the preservative). Low pH values of 5–6 and low concentrations of water are characteristics also likely to inhibit microbiological growth in emulsions.

Emulsions consist of an oil or lipid phase and an aqueous phase, thus, the preservative may diffuse from the aqueous phase into the oil phase. It is in the aqueous phase that micro-organisms tend to grow. As a result, water soluble preservatives are more effective, because the concentration of the unbound preservative in the aqueous phase assumes a great deal of importance in inhibiting the microbial growth. Esters of *p*-hydroxybenzoic acid appear to be the most satisfactory preservatives for emulsions.

Many mathematical models have been used to determine the availability of preservatives in emulsified systems. One model takes into account the O/W partition coefficient of the preservative, interaction of the preservative with the surfactant, interfacial tension, and membrane permeability. However, due to the number of factors that reduce the effectiveness of the preservative, a final microbiological evaluation of the emulsion must be performed.

Although emphasis concerning preservation of emulsions deals with the aqueous phase, micro-organisms can also reside in the lipid phase. Consequently, it has been recommended that pairs of preservatives be used to ensure adequate concentration in both phases. A combination of esters of *p*-hydroxybenzoic acid can be used to ensure appropriate concentrations in both phases, due to their difference in oil and water solubilities.

The oxidative decomposition of certain excipients, the oil phase, and some pharmaceuticals is possible in emulsions, not only due to the usual amount of air dissolved in the liquid and the possible incorporation of air during the preparation of the product, but also the large interfacial area between the oil and water phase. The selection of the appropriate antioxidant, briefly described at the beginning of the chapter, depends on such factors as stability, compatibility with the ingredients of the emulsion, toxicity, effectiveness in emulsions, odor, taste, and distribution between the two phases.

## PREPARATION OF EMULSIONS

After the purpose of the emulsions has been determined (e.g., oral or topical use), the type of emulsions (O/W or W/O) and appropriate ingredients selected, and the theory of emulsification considered, then experimental formulations may be prepared. One method is suggested by Griffin:<sup>70</sup>

1. Group the ingredients on the basis of their solubilities in the aqueous and nonaqueous phases.
2. Determine the type of emulsion required and calculate an approximate HLB value.
3. Blend a low HLB emulsifier and a high HLB emulsifier to the calculated value. For experimental formulations, use a higher concentration of emulsifier (e.g., 10–30% of the oil phase) than required to produce a satisfactory product. Emulsifiers should be stable chemically, non-toxic, and suitably low in color, odor, and taste. The emulsifier is selected on the basis of these characteristics, as well as the type of equipment used to blend the ingredients and the stability characteristics of the final product. Emulsions should not coalesce at room temperature, when frozen and thawed repeatedly, or at elevated temperatures of up to 50°C. Mechanical energy input varies with the type of equipment used to prepare the emulsion. The more the energy input, the less the demand on the emulsifier. Both process and formulation variables can affect the stability of an emulsion.
4. Dissolve the oil-soluble ingredients and the emulsifiers in the oil. Heat, if necessary, to approximately 5–10°C over the melting point of the highest melting ingredient or to a maximum temperature of 70–80°C.
5. Dissolve the water-soluble ingredients (except acids and salts) in a sufficient quantity of water.
6. Heat the aqueous phase to a temperature that is 3–5°C higher than that of the oil phase.
7. Add the aqueous phase to the oily phase with suitable agitation.
8. If acids or salts are employed, dissolve them in water and add the solution to the cold emulsion.
9. Examine the emulsion and make adjustments in the formulation, if the product is unstable. It may be necessary to add more emulsifier, to change to an emulsifier with a slightly higher or lower HLB value, or to use an emulsifier with different chemical characteristics.

The technique of emulsification of pharmaceutical preparations has been described by Nielloud and Marti-Mestres.<sup>71</sup> The preparation of an emulsion requires work to reduce the internal phase into small droplets and disperse them throughout the external phase. This can be accomplished by a mortar and pestle or a high-speed emulsifier. The addition of emulsifying agents not only reduces this work, but also stabilizes the final emulsion.

Emulsions are prepared by four principal methods.

#### Addition of Internal Phase to External Phase

This is the most satisfactory method for preparing emulsions, as there is always an excess of the external phase present that promotes the type of emulsion desired. If the external phase is water and the internal phase is oil, the water-soluble substances are dissolved in the water and the oil-soluble substances mixed thoroughly in the oil. The oil mixture is added in portions to the aqueous preparation with agitation. To give a better shearing action during the preparation, sometimes all of the water is not mixed with the emulsifying agent, until the primary emulsion with the oil is formed; subsequently, the remainder of the water is added. An example using gelatin Type A is given subsequently.

#### Addition of the External Phase to the Internal Phase, the Dry Gum Technique

Using an O/W emulsion as an example, the addition of the water (external phase) to the oil (internal phase) will promote the formation of a W/O emulsion, due to the preponderance of the oil phase. After further addition of the water, phase inversion to an O/W emulsion should take place. This method is especially useful and successful when hydrophilic agents, such as acacia, tragacanth, or methylcellulose, are first mixed with the oil, affecting dispersion without wetting. Water is added, and eventually an O/W emulsion is formed. This “dry gum” technique is a rapid method for preparing small quantities of emulsion. The ratio 4 parts of oil, 2 parts of water, and 1 part of gum provides maximum shearing action on the oil globules in the mortar. The emulsion can then be diluted and triturated with water to the appropriate concentration. The preparation of Mineral Oil Emulsion described subsequently is an example.

#### Mixing Both Phases after Heating

This method is used when waxes or other substances that require melting are used. The oil soluble emulsifying agents, oils, and waxes are melted and mixed thoroughly. The water soluble ingredients dissolved in the water are warmed to a temperature slightly higher than the oil phase. The two phases are then mixed and stirred until cold. For convenience, but not necessity, the aqueous solution is added to the oil mixture. This method is frequently used in the preparation of ointments and creams. An example of an oral preparation containing a poorly soluble drug is given subsequently.

#### Alternate Addition of the Two Phases to the Emulsifying Agent

A portion of the oil, if an O/W emulsion is being prepared, is added to all of the oil-soluble emulsifying agents with mixing, then an equal quantity of water containing all the water-soluble emulsifying agents is added with stirring, until the emulsion is formed. Further portions of the oil and water are added alternately, until the final product is formed. The high concentration of the emulsifying agent in the original emulsion makes the initial emulsification more likely, and the high viscosity provides effective shearing action, leading to small droplets in the emulsion. This method is often used successfully with soaps.

Examples of some emulsions are given subsequently.

Type A gelatin is prepared by acid-treated precursors and is used at a pH of about 3.2. It is incompatible with anionic emulsifying agents, such as the vegetable gums. The following formula was recommended.

Type A

Gelatin Emulsion	
GELATIN	(TYPE A)8 G
TARTARIC ACID	0.6 G
FLAVOR	Q.S
ALCOHOL	60 ML
OIL	500 ML
PURIFIED WATER, TO MAKE	1000 ML

Add the gelatin and the tartaric acid to about 300 mL of purified water, allow to stand for a few minutes, heat until the gelatin is dissolved, then raise the temperature to about 98°C and maintain this temperature for about 20 minutes. Cool to 50°C, and add the flavor, the alcohol, and sufficient purified water to make 500 mL. Add the oil, agitate the mixture thoroughly, and pass it through a homogenizer or a colloid mill, until the oil is dispersed completely and uniformly. This emulsion cannot be prepared by trituration or by the use of the usual stirring devices.

Type B gelatin is prepared from alkali-treated precursors and is used at a pH of about 8. It may be used with other anionic emulsifying agents but is incompatible with cationic types. If the emulsion contains 50% oil, 5 g of Type B gelatin, 2.5 g of sodium bicarbonate, and sufficient tragacanth or agar should be incorporated into the aqueous phase to yield 1,000 mL of product of the required viscosity.

An emulsion that may be prepared by the mortar and pestle method is the following Mineral Oil Emulsion, USP.

Mineral Oil Emulsion, USP	
MINERAL OIL	500 ML
ACACIA, IN VERY FINE POWDER	125 G
SYRUP	100 ML
VANILLIN	40 MG
ALCOHOL	L60 ML
PURIFIED WATER, TO MAKE	1000 ML

The mineral oil and acacia are mixed in a dry Wedgwood mortar. Purified water (250 mL) is added, and the mixture is triturated vigorously, until an emulsion is formed. A mixture of the syrup, 50 mL of purified water, and the vanillin dissolved in alcohol is added in divided portions with trituration; sufficient purified water is then added to the proper volume; the mixture is mixed well and homogenized.

An Oral Emulsion (O/W) Containing an Insoluble Drug <sup>72</sup>	
COTTONSEED OIL	460 G
SULFADIAZINE	200 G
SORBITAN MONOSTEARATE	84 G
POLYOXYETHYLENE 20 SORBITAN MONOSTEARATE	36 G
SODIUM BENZOATE	2 G
SWEETENER	QS
FLAVOR OIL	QS
PURIFIED WATER	1000 G

Heat the first three ingredients to 50°C and pass through colloid mill. Add the next four ingredients at 50°C to the first three ingredients at 65°C, and stir, while cooling to 45°C. Add the flavor oil and continue to stir, until room temperature is reached.

#### PROPERTIES AND STABILITY OF EMULSIONS

The type of emulsion (O/W or W/O) depends, to some extent, on the phase to volume ratio. The higher the fraction of one phase, the greater likelihood it will form the external phase.

Thus, O/W emulsions are favored, if water forms a greater fraction of the volume than the oil phase. However, it is possible for the internal phase of an emulsion to occupy up to 74% of the volume of the emulsion and still form a stable product.

The consistency of emulsions can be increased by increasing the viscosity of the continuous phase, increasing the fractional volume of the internal phase, reducing the particle size of the internal phase, increasing the proportion of the emulsifying agent, or adding hydrophobic emulsifying agents to the oil phase of the emulsion.

The physical stability of emulsions may be defined by a number of expressions. The first of these, which is called "creaming," is the movement of the droplets either upward or downward, depending upon their density. This gives a product that is not homogenous and can lead to poor content uniformity. Creaming is not a serious problem, because a moderate amount of shaking will redisperse the droplets uniformly. The rate of creaming may be decreased by considering the theory of creaming using Stokes' law. This equation relates the rate of creaming to the size of the droplets, the difference in densities, and the viscosity of the external phase. Thus, the rate of creaming may be decreased by decreasing the size of the droplets and increasing the viscosity of the external phases, both of which were previously discussed. Minimizing the difference between densities is more challenging, due to a number of practical difficulties.

When the droplets aggregate, they come together and act as a single unit, but do not fuse. As a result of the larger size, they tend to cream faster and further provoke physical instability. Aggregation is to some extent reversible and may be controlled by choosing a somewhat different surfactant system and controlling the electrical potential of the droplets. Coalescence of an emulsion is the fusion of the droplets, leading to a decrease in their numbers and, eventually, the complete separation of the two phases, yielding an unsatisfactory product that should be reformulated.

General methods are available for testing and challenging the stability of emulsions, including bulk changes, centrifugal and ultracentrifugal studies, dielectric measurement, surface area measurement, temperature cycling, preservative effectiveness, and accelerated motion studies. Low-shear rheological studies measuring viscoelasticity are suggested as the optimal method of stability testing.

## MULTIPLE EMULSIONS

A recent innovation in emulsion technology is the development of multiple emulsions. The dispersed phase of these emulsions contains even smaller droplets that are miscible with the continuous phase. Thus, the multiple emulsion may be O/W/O, where the aqueous phase is between two oil phases, or W/O/W, where the internal and external aqueous phases are separated by an oil phase. In these systems both hydrophobic and hydrophilic emulsifiers are used, and both have an effect on the yield and stability.<sup>73,74</sup>

It appears that O/W/O emulsions are formed better by lipophilic, nonionic surfactants, using acacia emulsified simple systems, whereas W/O/W multiple emulsions are formed better by nonionic surfactants in a two-stage emulsification procedure. A specific formulation for a W/O/W emulsion may be prepared by forming the primary (W/O) emulsion from isopropyl myristate (47.5%), sorbitan monooleate (2.5%), and distilled water to 100%. This primary emulsion (50%) is added to a polyoxyethylene sorbitan monooleate (2% w/v) solution in water.<sup>74</sup> Other formulations of multiple emulsions include carboxymethylcellulose sodium, microcrystalline cellulose, sorbitan monooleate, and sorbitan trioleate.

Although the technique of preparing these emulsions is more complicated, research indicates potential use of these emulsions for prolonged action, taste-masking, more effective dosage forms, improved stability, parenteral preparations, protection against the external environment, and enzyme entrapment. These emulsions may also be used to separate two

incompatible hydrophilic substances in the inner and outer aqueous phases by the middle oil phase. Some drugs that have been investigated in these types of emulsions are vancomycin<sup>75</sup> and prednisolone.<sup>76</sup>

## MICROEMULSIONS

Coarse pharmaceutical macroemulsions appear white and tend to separate on standing. Microemulsions are translucent or transparent, do not separate, and typically have a droplet diameter from 10 to 200 nanometers. The microemulsions are not always distinguishable from micellar solutions. Both O/W and W/O emulsions are possible, and one may be converted to the other by addition of more internal phase or by altering the type of emulsifier. As the internal phase is added, the emulsion will pass through a viscoelastic gel stage; with further addition, an emulsion of the opposite type will occur.

The most obvious benefit of microemulsions is their stability. The emulsifier should be 20–30% of the weight of the oil used. The W/O systems are prepared by blending the oil and emulsifier with a little heat, if required, and then adding the water. The order of mixing for O/W systems is more flexible. One of the simplest methods is to blend the oil and the emulsifier and pour this into water with a little stirring.

If the emulsifier has been selected properly, microemulsification will occur almost spontaneously, leading to a satisfactory and stable preparation. The details of various preparations and the relationship between microemulsions and micellar solutions have been reviewed by Bourrel.<sup>77</sup> Other authors suggest the preparation of microemulsions is considerably more difficult than the preparation of coarse emulsions. Rosano and colleagues discuss the use of a primary surfactant adsorbed at the interface that influences the curvature of the dispersed phase.<sup>78</sup> The amount of surfactant required may be estimated from the surface area of the droplets and the cross-sectional area of the surfactant molecule. The authors propose the use of a cosurfactant to form a duplex film and the order of mixing is important.

## PROCESSING EQUIPMENT FOR EMULSIONS

The preparation of emulsions requires a certain amount of energy to form the interface between the two phases, and additional work must be done to stir the system to overcome resistance to flow. In addition, heat is often supplied to the system to melt waxy solids and/or reduce viscosity. Consequently, the preparation of emulsions on a large scale requires considerable amounts of energy for heating and mixing. Careful consideration of these processes has led to the development of low energy emulsification equipment that use an appropriate emulsification temperature and selective heating of the ingredients. This process, described by Lin, involves the preparation of an emulsion concentrate subsequently diluted with the external phase at room temperature.<sup>79,80</sup>

Due to the variety of oils used, emulsifier agents, phase to volume ratios, and the desired physical properties of the product, a wide selection of equipment is available for preparing emulsions, and the main classes of equipment are discussed. Homogenization speed and time and rate of cooling may influence the viscosity of the product. Further information may be obtained from the **Bibliography**.

Special techniques and equipment in certain instances will produce superior emulsions, including rapid cooling, reduction in particle size, or ultrasonic devices. A wide selection of equipment for processing both emulsions and suspensions has been described.<sup>71</sup> A number of improvements have been made to make the various processes more effective and energy efficient.

The mortar and pestle may be used to prepare small quantities of an emulsion in the pharmacy or laboratory, and it is one of the simplest and least expensive methods. It may be used for most of the different techniques of preparing emulsions. Final particle size is considerably larger than is achieved by the equipment subsequently described. In addition, it is necessary

for the ingredients to have a certain viscosity prior to trituration to achieve a satisfactory shear. Satisfactory emulsions of low viscosity ingredients and small volumes may be prepared using the appropriate equipment described subsequently.

### Agitators

Ordinary agitation or shaking may be used to prepare the emulsion. This method is frequently employed by the pharmacist, particularly in the emulsification of easily dispersed, low-viscosity oils. Under certain conditions, intermittent shaking is considerably more effective than ordinary continuous shaking. Continuous shaking tends to break up not only the phase to be dispersed, but also the dispersion medium, thus, impairing the ease of emulsification. Laboratory shaking devices may be used for small-scale production.

### Mechanical Mixers

Emulsions may be prepared using one of several mixers that are available. Propeller and impeller type mixers that have a propeller attached to a shaft driven by an electric motor are convenient and portable and can be used for both stirring and emulsification. This type operates best in mixtures that have low viscosity, that is, mixtures with a viscosity of glycerin or less. They are also useful for preparing emulsions. A turbine mixer has a number of blades that may be straight or curved, with or without a pitch, mounted on a shaft. The turbine tends to give a greater shear than propellers. The shear can be increased by using diffuser rings perforated and surrounding the turbine, so the liquid from the turbine must pass through holes. The turbines can be used for both low-viscosity mixtures and medium-viscosity liquids. The degree of stirring and shear by propeller or turbine mixers depends on several factors, such as the speed of rotation, pattern of liquid flow, position in the container, and baffles in the container.

Production sized mixers include high powered propeller, shaft stirrers immersed in a tank or self-contained units with propeller and paddle systems. The latter are constructed so the contents of the tank may be either heated or cooled during the production process. Baffles are often built into a tank to increase mixing efficiency. Examples of two production dispersion mixers are shown in Figures 24-1 and 24-2.

Small electric mixers may be used to prepare emulsions at the prescription counter. They save time and energy and produce

**Figure 24-1.** Standard slurry-type dispersal mixer with vaned-rotor mixing element and slotted draft-tube circulating element.

**Figure 24-2.** Standard paste-type dispersal mixer with cupped-rotor milling element and double-rotating mixing arm circulating element.

satisfactory emulsions, when the emulsifying agent is acacia or agar. The commercially available Waring Blender disperses efficiently by means of the shearing action of rapidly rotating blades. It transfers large amounts of energy and incorporates air into the emulsion. If an emulsion is first produced by using a blender of this type, the formulator must remember that the emulsion characteristics obtained in the laboratory will not necessarily be duplicated by the production-size equipment.

### Rotor Stators

The principle of operation of the rotor stator is the passage of the mixed phases of an emulsion formula between a stator and a high speed rotor revolving at speeds of 2,000–18,000 rpm. The advantages of high shear rotor/stator mixers over simple conventional agitators and mechanical mixers stem from the multistage mixing and shearing action as materials are drawn through the specially designed stator workhead. As illustrated in Figure 24-3, in Stage 1, suction is created from the high-speed rotation of the rotor blades within the mixing workhead, drawing liquid and solid materials up from the bottom of the vessel and into the center of the workhead. Next, centrifugal force drives the materials toward the periphery of the workhead, where they are subjected to a milling action in the precision machined clearance between the rotor blades and the inner wall of the stator (Stage 2). The materials are then forced by intense hydraulic shear, at high velocity, out through the perforations in the stator and circulated back into the vessel (Stage 3). The materials expelled from the head are projected radially at high speed towards the sides of the mixing vessel (Stage 4). At the same time, fresh material is continually drawn into the workhead, maintaining the mixing cycle. The effect of the horizontal (radial) expulsion and suction into the head is to set up a circulation pattern that minimizes aeration caused by the disturbance of the liquid's surface. Figure 24-4 illustrate examples of rotor stator workheads.

Rotor stators are available from small, laboratory scale to very large, commercial scale. An example of a pilot plant rotor stator is shown in Figure 24-5. An inline rotor-stator, which can

**Figure 24-3.** Solid and Liquid Flow through a Rotor Stator (Courtesy of Silverson Machines, Ltd.)

**Figure 24-4.** Types of workheads used in rotor stators. From top to bottom, these include a general purpose disintegrating head (versatile and useful for gels, thickeners, suspensions, solutions and slurries), a slotted disintegrating head (useful for fibrous materials), square hole high shear screen (provides high shear rates), and a standard emulsor head and screen (excellent for emulsions). (Courtesy of Silverson Machines, Ltd.)

be plumbed directly to a vessel or tank and has interchangeable screens and workheads, is shown in Figure 24-6.

The clearance between the rotor and the stator is often very small (from 0.001 inches and up) and requires precision machining and alignment. The emulsion mixture, in passing through and between the rotor and stator, is subjected to the tremendous forces that affect the chemical and physical properties of the emulsion.

The operating principle is the same for all, but each manufacturer incorporates specific features that result in changes in operating efficiency. The shearing forces applied in a rotor stator result in a temperature increase within the emulsion. It may be necessary, therefore, to use jacketed equipment to cool the emulsion during processing. Maa and Hsu have shown that droplet size of emulsions was mainly determined by shear force within the gap between the spinning rotor and stationary

**Figure 24-5.** Pilot Scale Rotor Stator. (Courtesy of Silverson Machines, Ltd.)

rotor.<sup>81</sup> Droplet size decreased with homogenization intensity and duration, increasing viscosity of the continuous phase, and with decreasing viscosity of the dispersed phase.

Rotor stators are also used sometimes for the comminution of solids and for the preparation of suspensions, especially suspensions containing solids not wetted by the dispersion medium.

### Homogenizers

Impeller types of equipment frequently produce a satisfactory emulsion; however, for further reduction in particle size, homogenizers may be employed.<sup>82</sup> Homogenizers may be used in one of two ways:

**Figure 24-6.** Inline Rotor Stator for small production, pilot plant, and research laboratories up to 50 liters. (Courtesy of Silverson Machines, Ltd.)

1. The ingredients in the emulsion are mixed and then passed through the homogenizer to produce the final product.
2. A coarse emulsion is prepared in some other way and then passed through a homogenizer for the purpose of decreasing the particle size and obtaining a greater degree of uniformity and stability.

The mixed phases or the coarse emulsion are subjected to homogenization and are passed between a finely ground valve and seat under high pressure. This, in effect, produces an atomization enhanced by the impact received by the atomized mixture as it strikes the surrounding metal surfaces. They operate at pressures of 1000–5000 psi and produce some of the finest dispersions obtainable in an emulsion.

Figure 24-7 demonstrates the flow through the homogenizing valve, the heart of the high pressure, APV Gaulin homogenizer. The product enters the valve seat at high pressure, flows through the region between the valve and the seat at high velocity with a rapid pressure drop, causing cavitation; subsequently, the mixture hits the impact ring, causing further disruption, and then is discharged as a homogenized product. It is postulated that circulation and turbulence are responsible mainly for the homogenization that takes place. Different valve assemblies, two-stage valve assemblies, and equipment with a wide range of capacities are available.

**Figure 24-7.** Material flow through a homogenizer. (Courtesy of SPX Corporation. Figure is copyrighted material owned by SPX Corporation and is used under license and permission from SPX Corporation. © 2011 SPX Corporation.)

Two-stage homogenizers are constructed so the emulsion, after treatment in the first valve system, is conducted directly to another, where it receives a second treatment. A single homogenization may produce an emulsion that, although its particle size is small, has a tendency to clump or form clusters. Emulsions of this type exhibit increased creaming tendencies. This is corrected by passing the emulsion through the first stage of homogenization at a high pressure (e.g., 3000–5000 psi) and then through the second stage at a greatly reduced pressure (e.g., 1,000 psi). This breaks down any clusters formed in the first step.

For small-scale extemporaneous preparation of emulsions, the inexpensive hand-operated homogenizer is particularly useful. It is probably the most efficient emulsifying apparatus available to the pharmacist and pharmaceutical scientist. The two phases, previously mixed in a bottle, are hand-pumped through the apparatus. Recirculation of the emulsion through the apparatus will improve its quality.

A homogenizer does not incorporate air into the final product. Air may ruin an emulsion, because the emulsifying agent is adsorbed preferentially at the air–water interface, followed by an irreversible precipitation termed “denaturation.” This is particularly prone to occur with protein emulsifying agents. Homogenization may spoil an emulsion, if the concentration of the emulsifying agent in the formulation is less than that required to accommodate the increase in surface area produced by the process.

The temperature rise during homogenization is not very large. However, temperature does play an important role in the emulsification process. An increase in temperature will reduce the viscosity and, in certain instances, the interfacial tension between the oil and the water. There are, however, many instances, particularly in the manufacturing of creams and ointments, where the ingredients will fail to emulsify properly, if they are processed at too high a temperature. Emulsions of this type are processed, first, at an elevated temperature, and then homogenized at a temperature not exceeding 40°C.

Homogenizers have been used most frequently with liquid emulsions, but now they may be used with suspensions, as the metal surfaces are formed from wear-resistant alloys that resist the wear of solid particles contained in suspensions.

### Ultrasonic Devices

The preparation of emulsions by the use of ultrasonic vibrations also is possible. An oscillator of high frequency (100–500 kHz) is connected to two electrodes between which is placed a piezoelectric quartz plate. The quartz plate and electrodes are immersed in an oil bath and, when the oscillator is operating, high-frequency waves flow through the fluid. Emulsification is accomplished by simply immersing a tube containing the emulsion ingredients into this oil bath. Considerable research has been done on ultrasonic emulsification, particularly with regard to the mechanism of emulsion formation. The method has not been proven practical for large-scale production of emulsions, but evaluations are underway.<sup>83</sup>

### Microfluidizers

Microfluidizers have been used to produce very fine particles. The process subjects the emulsion to an extremely high velocity through micro-channels into an interaction chamber; as a result, particles are subjected to shear, turbulence, impact, and cavitation. Two advantages of this type of equipment are lack of contamination in the final product and ease of production scale up.

### LIPOSOMES

Liposomes have been one of the most extensively studied drug delivery systems.<sup>84–87</sup> Liposomes, meaning lipid body, may be broadly described as small vesicles of a bilayer of phospholipid

encapsulating an aqueous space ranging from about 0.03 to 10  $\mu\text{m}$  in diameter. The lipid membrane of a liposome consists of a bilayer-forming amphiphile, cholesterol, and a charge-generating molecule. The lipid membrane encloses a discrete aqueous compartment. This structure presents an overall hydrophilic membrane-like assembly in which the apolar or lipophilic portion of the amphiphilic molecule points inward, whereas the polar or hydrophilic portion points outward of the lamellar structure. These characteristics make liposomes useful as drug delivery systems. The enclosed vesicles can encapsulate water-soluble drugs in the aqueous spaces or lipid-soluble drugs in the membranes. Liposomes have been administered parenterally, topically, and by inhalation.

Liposomes offer several advantages as drug delivery systems: 1) they are biologically inert and completely biodegradable; 2) they can be prepared in various sizes, charge, compositions, and surface morphology; 3) they can encapsulate both water-soluble and water-insoluble drugs, including enzymes, hormones, and antibiotics; 4) encapsulated drugs are less susceptible to degradation; 5) organ-targeted drug delivery is possible, since the entrapped drug is delivered intact to various tissues and cells after the liposome is destroyed; and 6) other tissues and cells of the body are protected from the drug, until they are released by the liposomes, thus, decreasing the drug's toxicity. The primary disadvantage of liposomes is their rapid removal from the blood following intravenous administration by cells of the reticuloendothelial system, particularly by Kupfer cells in the liver. Drug release is slowed by phagocytes through endocytosis, fusion, surface adsorption, or lipid exchange.

Several different amphiphiles have been investigated to create liposomal structures (vesicles). Only the bilayer-forming lipid is the essential part of the lamellar structure and the other components are to impart specific characteristics. For example, cholesterol adds rigidity to the vesicular structure, rendering it less permeable. Phospholipids, such as phosphatidylcholine (lecithin), were the first amphiphiles used to produce bilayer structures to mimic cell membranes.

Liposomes can be prepared into several morphologies, which have been classified according to the vesicular shape. Multilamellar vesicles (MLV) were first prepared by Bangham and have multiple bilayer structures surrounding a relatively small internal core, much like an onion.<sup>88</sup> Oligolamellar vesicles (OLV) have large central aqueous cores surrounded by 2–10 bilayers. Unilamellar vesicles (ULV) have a single bilayer structure surrounding an internal aqueous core. Unilamellar vesicles can be prepared in a variety of sizes: small unilamellar vesicles (20–40 nm), medium unilamellar vesicles (40–80 nm), large unilamellar vesicles (100–1,000 nm), and giant unilamellar vesicles (>1,000 nm).

Drug release in the blood following intravenous administration ranges from a few minutes to several hours, depending on the nature and composition of the lipids, surface properties, and size. In general, smaller unilamellar vesicles show much longer half-lives than multilamellar vesicles and large unilamellar vesicles. Negatively charged liposomes are cleared more rapidly from the circulation than neutral or positively charged liposomes. Circulation can be prolonged by blocking the reticuloendothelial system and allowing the liposomes to interact with vascular endothelial cells and blood cells. These “stealth liposomes” were developed by coating the liposomes with polymers, such as polyethylene glycol, enabling liposomes to evade detection by the body's immune system.

## PREPARATION OF LIPOSOMES

Liposomes have been prepared using a number of techniques, including solvent evaporation, sonication, supercritical fluid techniques, spray drying, extrusion, and homogenization. A combination of these methods is often used, and the drug is added during the formation process. In this method, the lipid is dissolved in an organic solvent, such as acetone or chloroform. The solvent is evaporated, leaving a thin, lipid film on the walls

of the container. An aqueous solution of the drug is added and placed in an ultrasonic bath. The sound waves displace the lipid from the container walls, and they self-assemble into spheres or cylinders, entrapping the aqueous drug solution inside. If the drug is lipophilic, it is incorporated into the lipid phase and will reside within the lipophilic bilayers. Several advances have been made in liposome preparation to better control stability and size.

Liposomal products are now commercially available. Amphotec (distributed by InterMune, manufactured by Ben Venue Laboratories) is Amphotericin B Cholesteryl Sulfate Complex for Injection. It is a sterile, pyrogen-free, lyophilized powder for reconstitution and intravenous (IV) administration. Amphotec consists of a 1:1 (molar ratio) complex of amphotericin B and cholesteryl sulfate. Upon reconstitution, Amphotec forms a colloidal dispersion of microscopic disc-shaped particles. Each 50 mg single dose vial contains amphotericin B, 50 mg; disodium edetate dihydrate, 0.372 mg; lactose monohydrate, 950 mg; and hydrochloric acid, qs. Amphotec is indicated for the treatment of invasive aspergillosis in patients whose renal impairment or unacceptable toxicity precludes the use of amphotericin B deoxycholate in effective doses and in aspergillosis patients in whom prior amphotericin B deoxycholate therapy has failed. The drug is reconstituted with Sterile Water for Injection by rapidly adding the water to the vial; it is shaken gently by hand, rotating the vial until all the solids have dissolved. The fluid may be opalescent or clear.<sup>89</sup> For infusion, it is further diluted in 5% dextrose injection. The product should not be reconstituted with any fluid other than Sterile Water for Injection; do not reconstitute with dextrose or sodium chloride solutions. Also, for further dilution, it should not be admixed with sodium chloride or electrolytes. Solutions containing benzyl alcohol or any other bacteriostatic agent should not be used, as they may cause precipitation. An inline filter should not be used and the infusion admixture should not be mixed with other drugs. If infused using a y-injection site or similar device, flush the line with 5% dextrose injection before and after infusion of Amphotec. After reconstitution, the drug should be refrigerated and used within 24 hours; do not freeze. If further diluted with 5% dextrose injection, it should be refrigerated and used within 24 hours.

Doxil (Ortho Biotech) is doxorubicin hydrochloride encapsulated in stealth liposomes for intravenous administration. The product is provided as a sterile, translucent, red liposomal dispersion in a 10 mL glass, single use vial. Each vial contains 20 mg of doxorubicin HCl at a concentration of 2 mg/mL and a pH of 6.5. The stealth liposome carriers are composed of N-(carbonyl-methoxy polyethylene glycol 2000)-1,2-distearoyl-sn-glycerol-3-phosphoethanolamine sodium salt (MPEG-DSPE), 3.19 mg/mL; fully hydrogenated soy phosphatidylcholine (HSPC), 9.58 mg/mL; and cholesterol, 3.19 mg/mL. Each mL also contains ammonium sulfate, approximately 2 mg; histidine as a buffer; hydrochloric acid and/or sodium hydroxide for pH control; and sucrose to maintain isotonicity. Greater than 90% of the drug is encapsulated in the Stealth liposomes. The stealth liposomes are specially formulated to circulate in the body “undetected” by the mononuclear phagocyte system for a prolonged circulation time of about 55 hours. This is accomplished by pegylation, or binding methoxypolyethylene glycol on the surface of the liposomes. These liposomes are small, in the range of 100 nm in diameter. Doxil must be diluted in 250 mL of 5% dextrose injection prior to administration; once diluted, it should be refrigerated and administered within 24 hours. It should not be mixed with any other diluent or any preservative-containing solution. It should not be used with in-line filters. The product is not a clear solution, but a red, translucent liposomal dispersion. Unopened vials should be stored in a refrigerator, but freezing should be avoided, even though short-term freezing (less than 1 month) does not appear to adversely affect the product.

## SUSPENSIONS

The physical chemist defines the word “suspension” as a two-phase system consisting of an undissolved or immiscible material dispersed in a vehicle (i.e., solid, liquid, or gas). A variety of dosage forms fall within the scope of this definition, but emphasis is placed on solids dispersed in liquids. In more specific terms, the pharmaceutical scientist differentiates between such preparations as suspensions, mixtures, magmas, gels, and lotions. In these preparations, the substance distributed is referred to as the dispersed phase and the vehicle is termed the dispersing phase or dispersion medium. In a general sense, each of these preparations represents a suspension, but the state of subdivision of the insoluble solid varies from particles that settle gradually on standing to particles that are colloidal in nature.

The particles of the dispersed phase vary widely in size, from large, visible particles to colloidal dimensions, which fall between 1.0 nm and 0.5  $\mu\text{m}$  in size. Course dispersions contain particles 10–50  $\mu\text{m}$  in size and include suspensions and emulsions. Fine dispersions contain particles of smaller size, 0.5–10  $\mu\text{m}$ . Magmas and gels represent such fine dispersions. Particles in a coarse dispersion have a greater tendency to separate from the dispersion medium than do the particles of a fine dispersion. Most solids in a dispersion tend to settle to the bottom of the container, because their density is higher than the dispersion medium.

Suspensions have a number of applications in pharmacy. They are used to supply drugs to the patient in liquid form. Many people have difficulty swallowing solid dosage forms; consequently, a liquid preparation has an advantage. In addition, the dose of a liquid form may be adjusted easily to meet the patient's requirements. Thus, if the drug is insoluble or poorly soluble, a suspension may be the most suitable dosage form. If a drug is unstable in an aqueous medium, a different form of the drug, such as an ester or insoluble salt that does not dissolve in water may be used in the preparation of a suspension. Drugs, such as antibiotics, that are unstable in the presence of an aqueous vehicle for extended periods of time are most frequently supplied as dry powder mixtures for reconstitution at the time of dispensing. This type of preparation is designated in the USP by the title “for Oral Suspension.” Suspensions that do not require reconstitution at the time of dispensing are simply designated as an “Oral Suspension.” Table 24-7 presents examples of commercial products.

To improve the stability of an antibiotic, such as ampicillin, formulations are made in such a way that the dispersion medium, water, is added upon dispensing to form a satisfactory suspension. The taste of pharmaceuticals can be improved, if they are supplied in suspension form, rather than solutions; thus, chloramphenicol palmitate is used instead of the more

soluble form, chloramphenicol. Another method to decrease the solubility of the drug is to replace part of the water with another appropriate liquid, such as alcohol or glycerin. Insoluble drugs may be formulated as suspensions for topical use, such as calamine lotion. Other preparations of suspensions, in addition to those noted previously, include parental preparations (Chapter 26), ophthalmic preparations (Chapter 28), aerosol suspensions (Chapter 33), and medicated topicals (Chapter 29).

## PHYSICAL CHARACTERISTICS OF SUSPENSIONS

Formulation of suspensions involves more than mixing a solid in a liquid. Knowledge of the behavior of particles in liquids, suspending agents, wetting agents, polymers, buffers, preservatives, flavors, and colors is required to produce an acceptable and satisfactory suspension. Suspensions should possess several basic chemical and physical properties. The dispersed phase should settle slowly, if at all, and be re-dispersed readily upon shaking. The solid particles should have a narrow particle size distribution, which does not cake on settling, and the viscosity should be such that the preparation pours easily. In addition, the product should have an elegant appearance, be resistant to microbial growth and maintain its chemical stability.

Several factors influence the sedimentation rate of particles in a suspension. Stokes' law relates the diameter of the particles, the density of the particles and the medium, and the viscosity of the medium to the sedimentation rate:

$$\frac{ds}{dt} = \frac{d^2(\rho_p - \rho_M)g}{18\eta}$$

where  $ds/dt$  is the sedimentation rate,  $d$  is the diameter of the particles,  $\rho_p$  is the density of the particles,  $\rho_M$  is the density of the medium,  $g$  is the gravitational constant, and  $\eta$  is the viscosity of the medium.

Stokes' equation was derived for an ideal situation with perfectly spherical particles in a very dilute suspension. It assumes the spherical particles settle without causing turbulence, without particle to particle collision, and without chemical or physical attraction or affinity for the dispersion medium. Obviously, the typical pharmaceutical suspension contains particles that are irregularly shaped with a range of sizes, settling results in both turbulence and collision, and there is a reasonable affinity between the particles and suspension medium. However, the basic concepts of the equation offer an indication of the important variables for suspension of the particle and clues to formulation adjustments to decrease the rate of particle sedimentation.

Clearly, the sedimentation rate of large particles is greater than smaller particles, assuming all other factors remain constant. A slower rate of settling can be achieved by reducing particle size. Density also has a direct relationship with sedimentation rate: dense particles settle more rapidly than less

**Table 24-7. Examples of Commercial Suspensions**

Product Name	Manufacturer	Active Ingredient & Dose	Indication
Carafate	Aventis	1 g sucralfate / 10 mL	Antiulcer
Maalox	Novartis	225 mg aluminum hydroxide and 200 mg magnesium hydroxide / 5 mL	Antacid
Mepron	GlaxoSmithKline	750 mg atovaquone / 5 mL	Antiprotozoal
Mylanta Liquid	J&J-Merck	200 mg Aluminum Hydroxide, 200 mg Magnesium Hydroxide, and 20 mg simethicone / 5 mL	Antacid
Nystatin	Teva	100,000 units mycostatin / mL	Antifungal
Pepto-Bismol Liquid	Proctor & Gamble	262 mg bismuth subsalicylate / 15 mL	Antidiarrheal
Pred-G ophthalmic suspension	Allegan	0.3% gentamicin and 1.0% prednisolone acetate	Topical anti-inflammatory/anti-infective
Viramune	Boehringer Ingelheim	50 mg of nevirapine / 5 mL	Antiviral

dense particles. Most pharmaceutical suspensions are aqueous, and the density of the particles is greater than water, a desirable feature, since, if they were less dense, they would float, making a uniform product difficult to achieve.

The sedimentation rate is indirectly related to the medium viscosity, allowing the pharmaceutical scientist to manipulate settling by adjusting the viscosity of the medium. Settling is reduced by increasing the viscosity of the dispersion medium. One must keep in mind, a very high viscosity is not desirable, because it pours with difficulty and is equally difficult to re-disperse. The viscosity characteristics of a suspension may be altered not only by the vehicle used, but also by the solids content. As the proportion of solid particles is increased in a suspension, so is the viscosity. In most cases, the physical stability of a pharmaceutical suspension is adjusted by the dispersed phase, rather than through the dispersion medium. The dispersion medium supports the adjusted dispersed phase.

The most important consideration in formulation of suspensions is the size of the drug particles. In most pharmaceutical suspensions, the particle diameter is between 1 and 50  $\mu\text{m}$ . The reduction in the particle size is beneficial to the stability of the suspension in that the rate of sedimentation is reduced as the particles are decreased in size. The reduction in particle size produces slow, more uniform rates of settling. However, reduction of the particle size to too great a degree of fineness should be avoided, since fine particles have a tendency to form a compact cake upon settling. The result may be that the cake resists breakup upon shaking, and forms rigid aggregates of particles. Particle shape can also affect caking and product stability.<sup>90</sup>

Actions must be taken to prevent the agglomeration of particles into larger crystals or into masses, to avoid the formation of a cake. A common method to prevent rigid cohesion of small particles is through the intentional formation of a less rigid or loose aggregation of the particles by particle-to-particle bonding forces. An aggregation of this type is called a "floc" or "floccule" in which particles form a lattice structure that resists complete settling and compaction. Floes form a higher sediment volume than unflocculated particles, and the loose structure permits the aggregates to break up easily and redistribute with agitation. There are several methods of preparing flocculated suspensions, the choice depending on the drug and type of product desired. For example, clays, such as bentonite, are commonly used as flocculating agents in oral suspensions. The structure of bentonite and of other clays assists the suspension by helping support the floc once formed. When clays are unsuitable, as in a parenteral suspension, a floc of the dispersed phase can be produced by an alteration in the pH of the preparation, to a region of low drug solubility. Electrolytes can also act as flocculating agents by reducing electrostatic interactions between the particles. Nonionic and ionic surfactants can also induce particle flocculation and increase the sedimentation volume.

Particle growth or Ostwald ripening is also a destabilizing process, resulting from temperature fluctuations during storage. Temperature fluctuations may change particle size distribution and polymorphic form of a drug, if the solubility of the drug is temperature dependent. For example, if the temperature is raised, drug crystals may dissolve and form a supersaturated solution, which favor crystal growth on cooling. As the dissolved drug crystallizes out of solution, it will preferentially occur on the surface of a crystal in the suspension.

## SUSPENSION INGREDIENTS

The external phase is water for oral preparations; however, other polar liquids, such as glycerin or alcohol, may be considered to control solubility, stability, and taste. The selection of the external phase is based on taste, viscosity, density, and stability. Non-polar liquids, such as aliphatic hydrocarbons and fatty esters, may be considered, if the preparation is used for external purposes.

The main ingredients in a suspension are the drug and functional excipients that wet the drug, influence flocculation, control viscosity, adjust pH, and the external medium, usually water. In addition, flavoring, sweetening, and coloring agents and preservatives are employed. A wetting agent is a surfactant with an HLB value between 7 and 9. Surfactants with higher HLB values are sometimes recommended, such as polysorbates and poloxamers. They are employed at a low concentration (0.05–0.5%) to allow the displacement of air from hydrophobic material and permit the liquid, usually water, to surround the particles. If it is desirable to flocculate the particles, then flocculating agents are employed. Low concentrations, less than 1%, of electrolytes, such as sodium or potassium chloride, are employed to induce flocculation. Water soluble salts possessing divalent or trivalent ions may be considered, if the particles are highly charged.

Viscosity producing agents are polymers, including natural gums (acacia, xanthan) and cellulose derivatives, such as sodium carboxymethylcellulose and hydroxypropyl methylcellulose. These excipients are used at low concentrations to function as protective colloids, but, at higher concentrations, they function as viscosity increasing agents. At higher viscosity, the rate of settling of deflocculated particles is decreased, providing additional stability to the flocculated suspension. The choice of an appropriate viscosity agent depends on the use of the product (external or internal), the processing equipment, and the duration of storage. Suspension preparations for internal use exhibiting good flow and suspending properties often contain sodium carboxymethylcellulose 2.5%, tragacanth 1.25%, or guar gum 0.5%. For external applications, Carbopol polymers have been successfully used. Other common viscosity producing agents include acacia, methylcellulose, sodium alginate, or tragacanth.

Ideally, a suspension should be stable over a wide pH range. The chemical and/or physical stability of an active compound may occasionally require the pH of the medium be maintained within a specified range. Buffers must be carefully considered, so they produce their intended effects without interference with other ingredients in the formulation. Buffers can influence the solubility of the active, preservative ionization and its activity and ionic viscosity agents.

## PREPARATION OF SUSPENSIONS

The preparation of suspensions involves several steps; the first is to obtain particles of the proper size, typically in the lower micrometer range. Oral preparations should not feel gritty; topical preparations should feel smooth to the touch; and injectables should not produce tissue irritation. Particle size and distribution should also be considered in terms of bioavailability or, from an *in vitro* perspective, the rate of release. Very small particles, less than 1  $\mu\text{m}$ , will have a higher solubility than larger particles but also have a faster rate of dissolution. Thus, particle size of the dispersed solid in a suspension can influence the rate of sedimentation, flocculation, solubility, dissolution rate, and, ultimately, bioavailability.

Particle size reduction is accomplished by dry milling prior to the incorporation of the dispersed phase into the dispersion medium. Milling is the mechanical process of reducing particle size, which may be accomplished by a number of different types of machines. Impact mills and Hammer mills grind the powders by impact (Figs. 24-8, 24-9, and 24-10). Centrifugally rotating hammers, pins, or blades contact the particles and direct them against a screen, typically in the range of 4–325 mesh. The particles are forced through the screen, which regulates final particle size at the outlet of the milling chamber. The blade and screen act in conjunction to determine final product sizing, typically in the range of 10–50  $\mu\text{m}$ .

Fluid energy or jet mills produce particles under 25  $\mu\text{m}$  through violent turbulence in high velocity air (Fig. 24-11). Compressed air forms a high speed, jet stream, which passes the feed funnel and draws powders into grinding chamber.

**Figure 24-8.** A cross section of an impact mill. (Courtesy of Hosokawa Micron Powder Systems.)

Pulverizing nozzles are installed around the grinding chamber and inject additional high speed air into the grinding chamber in a rotational direction. The centrifugal air flow accelerates particles and reduces particle size by particle-to-particle impaction and friction. The air flow drives large particles toward the perimeter, but small particles move toward the center, where they exit through the outlet.

A ball mill contains a number of steel or ceramic balls in a rotating drum. The balls reduce the particle size to a 20–200 mesh by both attrition and impact. Roller mills have two or more rollers that revolve at different speeds, and the particles are reduced to a mesh of 20–200 by means of compression and a shearing action. (See Chapter 23 (Powders) for a more detailed discussion on particle size reduction of solids.)

In the pharmacy, ceramic mortar and pestle are better at grinding and reducing particle size than glass. After reducing particle size, the drug powder is wetted thoroughly with a small quantity of water miscible solvent, such as glycerin or alcohol, which reduces the interfacial tension. The suspending agent in the aqueous medium is then added. Alternately, the suspending agent can be triturated with the drug particles, using a small quantity of glycerin or alcohol and then brought up to volume with the diluent water and triturated to a smooth uniform product.

On a large scale, the fine drug particles are treated with a small portion of water that contains the wetting agent and allowed to stand for several hours to release entrapped air. At the same time, the suspending agent should be dissolved or dispersed in the main portion of the external phase and allowed to stand until complete hydration takes place. Subsequently, wetted drug particles should be added slowly to the main portion of the dissolved suspending agent. Other excipients, such as electrolytes or buffers, should be carefully introduced. The preservatives, flavoring agents, and coloring agents are added last. Finally, the formulation is processed with homogenizers, ultrasonic devices, or colloid mills to produce a uniform product.

**Figure 24-9.** Multiple rotor options available for an impact mill. (Courtesy of Hosokawa Micron Powder Systems.)

A procedure for the preparation of Trisulfapyrimidines Oral Suspension is subsequently given.

### Trisulfapyrimidines Oral Suspension

Veegum	1.00 g
Syrup USP	90.60 g
Sodium Citrate	0.78 g
Sulfadiazine	2.54 g
Sulfamerazine	2.54 g

Add the Veegum slowly and with continuous stirring to the syrup. Incorporate the sodium citrate into the Veegum–syrup mixture. Premix the sulfa drugs, add to the syrup, stir, and homogenize. Add sufficient 5% citric acid to adjust the pH of the product to 5.6. A preservative and a flavoring agent may be added to the product.

### QUALITY CONSIDERATIONS

The quality of the suspension can be determined in a number of ways. Particle size, particle size distribution, and particle shape are often determined using photo microscopy or laser light diffraction techniques. Physical stability, the degree of settling or flocculation, may be determined using a device to measure the zeta potential. Viscosity may be determined by instruments,

**Figure 24-10.** Material Flow through a Hammer Mill. Hammer mills operate by feeding material uniformly into a chamber in which a rotating blade assembly reduces the particles of the material by cutting or impacting them. The material discharges through a screen, which regulates final particle size at the outlet of the milling chamber. (Courtesy of The Fitzpatrick Company.)

**Figure 24-11.** Schematic of particle size reduction in a fluid energy or jet mill. (Courtesy of Hosokawa Powder Systems.)

such as the Brookfield viscometer, or of the cone and plate configuration. Microbiological, as well as stability testing, according to ICH guidelines should be performed to determine the efficiency of the preservative and the appropriateness of the formulation with respect to time, temperature, and relative humidity.<sup>91</sup>

### EXTEMPORANEOUS PREPARATIONS FROM TABLETS AND CAPSULES

Occasionally, it is necessary to prepare a liquid formulation of a drug to meet certain patient requirements. Consequently, patients who are unable to swallow solid medications and require a different route of administration or different dosing strength present a special need. Thus, the pharmacist may have to extemporaneously compound a liquid product. If the pure drug is available, it should be used to prepare the liquid dosage form. If it is necessary to prepare a liquid dosage form from tablets or capsules, a suspension is formed, if either the drug or one of the excipients in the tablets or capsules is insoluble. Insoluble excipients in these dosage forms include disintegrants, lubricants, glidants, colors, diluents, and coatings. Consequently, although the drug may be soluble in water, many excipients are not. It is preferable to use the contents of capsules, or tablets that are not coated. If coated, tablets with a water soluble coat are preferred to those with functional enteric coatings and the like. In any case, the contents of the capsules or the tablets should be ground finely with a ceramic mortar and pestle and then wetted using alcohol or glycerin.

Preservatives may be included in the liquid formulation to enhance the stability. However, preservatives have been found to cause serious adverse effects in infants. Benzyl alcohol should be omitted from neonatal formulations, because it can cause a gasping syndrome characterized by a deterioration of multiple organ systems and eventually death. Propylene glycol has also been implicated to cause seizures and stupor in some preterm infants. Thus, formulations for neonates should be purposely kept simple, not compounded to supply more than just a few days of medicine.

Finally, it may be desirable to use a hand homogenizer to prepare a more suitable product. Some drugs formulated in this manner include clonidine hydrochloride and simple syrup,<sup>92</sup> cefuroxime axetil in an orange syrup vehicle,<sup>93</sup> and famotidine in cherry syrup.<sup>94</sup> Many other examples may be found in current hospital and community pharmacy journals, such as the *American Journal of Hospital Pharmacy*, *Canadian Journal of Hospital Pharmacy*, *U.S. Pharmacist*, *International Journal of Pharmaceutical Compounding*, and *Drug Development and Industrial Pharmacy*. Frequently, stability data and, occasionally, bioavailability and/or taste data are provided.

To minimize stability problems of the extemporaneously prepared product, it should be placed in air tight, light resistant containers and stored in the refrigerator by the patient.

Because it is a suspension, the patient should be counseled to shake it well prior to use and to be aware of any change that might indicate a stability problem with the formulation.

Tortorici reports an example of an extemporaneous suspension of cimetidine tablets that retained its potency at 40° over 14 days.<sup>95</sup> Twenty-four, 300 mg cimetidine tablets are compounded with 10 mL of glycerin and 120 mL of simple syrup. The tablets are triturated to a fine powder using a mortar, the mixture is levigated with the glycerin, and the simple syrup added. The suspension is mixed well, placed in a blender until smooth, and then refrigerated.

## SUSTAINED RELEASE SUSPENSIONS

Sustained release suspensions represent a very specialized class of preparation. Sustained release, oral suspensions with morphine,<sup>96</sup> non-steroidal anti-inflammatory agents,<sup>97</sup> and other drugs<sup>98</sup> have been described in the literature. However, limited commercial success has been achieved, due to the difficulty in maintaining the stability. Formulation research for sustained release suspensions has focused on the similar technologies used in preparing sustained release tablets and capsules. Celltech licenses the Tussionex Pennkinetic system, which uses a combination of ion exchange resin and particle coating.<sup>99</sup> This novel system exploits the likelihood of complexation between ionic drugs and ion-exchange resins, which are then coated with ethyl cellulose. When administered orally, the coated particles with encapsulated drug adsorbed onto the resin are slowly released by an ion exchange process.

Durect markets the SABER system for sustained release suspension applications. SABER uses sucrose acetate isobutyrate (SAIB), a non-polymeric, non-water soluble high-viscosity liquid carrier material (>5000 cPs. at 37°C), to provide controlled release of active ingredients.<sup>100</sup> The drug is mixed with a small amount of a pharmaceutically acceptable solvent to form a low viscosity solution or suspension, which is then mixed with the high viscosity carrier. The resulting suspension can be administered via injection, orally, or as an aerosol, forming an adhesive, biodegradable depot upon contact with tissues. After administration of the SABER formulation, the solvent diffuses away, leaving a viscous, adhesive matrix of the three components—SAIB, drug, and any additives. The release rate can be easily modified by the ratio of non-polymeric, non-water soluble high-viscosity liquid carrier material present in the formulation. Extended systemic and local delivery for durations of 1 day to 3 months from a single injection has been demonstrated.

## GELS AND MAGMAS

Gels are defined by the USP as:

Semisolid systems consisting of either suspensions made up of small inorganic particles or large organic molecules interpenetrated by a liquid. Where the gel mass consists of a network of small discrete particles, the gel is classified as a two-phase system. In a two-phase system, if the particle size of the dispersed phase is relatively large, the gel mass is sometimes referred to as a magma. Both gels and magmas may be thixotropic, forming semisolids on standing and becoming liquid on agitation.

Single-phase gels consist of organic macromolecules uniformly distributed throughout a liquid in such a manner that no apparent boundaries exist between the dispersed macromolecules and the liquid. Single-phase gels may be made from synthetic macromolecules or from natural gums. The latter preparations are also called mucilages. Although these gels are commonly aqueous, alcohols and oils may be used as the continuous phase. For example, mineral oil can be combined with a polyethylene resin to form an oleaginous ointment base.

Gels can be used to administer drugs topically or into body cavities.

Gels are also defined as semi-rigid systems in which the movement of the dispersing medium is restricted by an interlacing three dimensional network of particles or solvated

macromolecules in the dispersed phase. Physical and/or chemical cross linking may be involved. The interlacing and consequential internal friction is responsible for increased viscosity and the semisolid state.

Some gel systems are clear, and others are turbid, since the ingredients involved may not be completely soluble or insoluble or they may form aggregates, which disperse light. The concentration of the gelling agents is less than 10%, and in 0.5-2.0% range. Gels in which the macromolecules are distributed throughout the liquid in such a manner that no apparent boundaries exist between them and the liquid are called single-phase gels. In instances in which the gel mass consists of floccules of small distinct particles, the gel is classified as a two-phase system and frequently called a magma or a milk. Gels and magmas are considered colloidal dispersions, since they each contain particles of colloidal dimension.

Different types of colloidal dispersions have been given specific names. For instance, “sol” is a general term designating a dispersion of a solid substance in a liquid, a solid, or a gaseous dispersion medium. However, more often than not, it is used to describe the solid liquid dispersion system. A prefix, such as hydro- for water (hydrosol) or alco- for alcohol (alcosol), is used to specify the medium. Similarly, aerosol has similarly been developed to indicate a dispersion of a solid or a liquid in a gaseous phase.

The accepted size range for a substance “colloidal” is when particles fall between 1 nm and 0.5 μm. One difference between colloidal dispersions and true solutions is the larger particle size of the dispersed phase in colloidal systems. The optical properties of the two systems are also different. True solutions do not scatter light and, therefore, appear clear, but colloidal dispersions contain discrete particles scatter light.

## Gelling Agents

Several compendial materials function as gelling agents, including acacia, alginate, bentonite, carbomer, carboxymethylcellulose sodium, cetostearyl alcohol, colloidal silicon dioxide, ethylcellulose, gelatin, guar gum, hydroxyethylcellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose, magnesium aluminum silicate, maltodextrin, methylcellulose, polyvinyl alcohol, povidone, propylene carbonate, propylene glycol alginate, sodium alginate, sodium starch glycolate, starch, tragacanth, and xanthan gum.

Alginate acid is refined from seaweed. It is a tasteless, practically odorless, white to off-white colored, fibrous powder. It is used in concentrations between 1 and 5% as a thickening agent and swells in water to about 200 times its own weight without dissolving. Alginate acid can be cross linked by addition of calcium salts, resulting in substantially higher viscosity. Sodium alginate produces a gel at concentrations up to 10%. Aqueous preparations are most stable between pH values of 4–10; below pH 3, alginate acid is precipitated. Sodium alginate gels for external use should be preserved.

Carbomer resins are high molecular weight, acrylic acid-based polymers. The pH of 0.5% and 1.0% aqueous dispersions are 2.7–3.5 and 2.5–3.0, respectively. There are many carbomer resins, with viscosity ranges available from 0 to 80,000 cPs., depending on the pH to which it is neutralized. In addition to thickening, suspending and emulsifying in both oral and topical formulations, carbomers are also used to provide sustained release properties in both the stomach and intestinal tract for commercial products. Alcohol is often added to carbomer gels to decrease their viscosity. Carbomer gel viscosity is also dependent on the presence of electrolytes and the pH. A rubbery mass forms, if greater than 3% electrolytes are added. Carbomer preparations are primarily used in aqueous systems, although other liquids can be used. In water, a single particle of carbomer will wet very rapidly, but, like many other powders, carbomer polymers tend to form clumps of particles, when haphazardly dispersed in polar solvents. Rapid dispersion of carbomers can be achieved by adding the powder very slowly into the vortex

of the liquid that is very rapidly stirred. A neutralizer is added to thicken the gel after the carbomer is dispersed. Sodium hydroxide or potassium hydroxide can be used in carbomer dispersions containing less than 20% alcohol. Triethanolamine will neutralize carbomer resins containing up to 50% ethanol.

Carboxymethylcellulose (CMC) produces gels when used in concentrations of 4–6% of the medium viscosity grade. Glycerin may be added to prevent drying. Precipitation will occur at pH values less than 2; it is most stable at pH levels between 2 and 10, with maximum stability at pH 7 to 9. It is incompatible with ethanol. Sodium carboxymethylcellulose (NaCMC) is soluble in water and should be dispersed with high shear in cold water, before the particles hydrate and swell. Once the powder is well dispersed, the solution is heated with moderate shear to about 60°C for fastest dissolution. These colloidal dispersions are sensitive to pH, and the viscosity of the product decreases below pH 5 or above pH 10.

Tragacanth gum has been used to prepare gels that are stable at a pH range of 4–8. These gels must be preserved or sterilized by autoclaving. Tragacanth often lumps when added to water, thus, aqueous dispersions are prepared by adding the powder to rapidly mixed water. Also, lumps are also prevented by wetting the gum with ethanol, glycerin, or propylene glycol.

Colloidal silicon dioxide can be used to prepare transparent gels, when used with other ingredients of similar refractive index. Colloidal silicon dioxide adsorbs large quantities of water without liquefying, and its viscosity is largely independent of temperature. Changes in pH affect the viscosity: it is most effective at pH values up to about 7.5. Colloidal silicon dioxide (fumed silica) forms a hydrophobic gel, when combined with 1-dodecanol and n-dodecane. These are prepared by adding the silica to the vehicle and sonicating for about 1 minute to obtain a uniform dispersion, sealing, and storing at about 40°C overnight.

Gelatin gels are prepared by dispersing gelatin in hot water followed by cooling. Alternatively, gelatin can be wetted with an organic liquid, such as ethyl alcohol or propylene glycol, followed by the addition of the hot water and cooling. Magnesium aluminum silicate forms thixotropic gels at concentrations of about 10%. The material is inert and has few incompatibilities but is best used above pH 3.5. It may bind to some drugs and limit their availability.

Methylcellulose forms gels at concentrations up to about 5%. Since methylcellulose hydrates slowly in hot water, the powder is dispersed with high shear at 80–90°C in a portion of water. Once the powder is finely dispersed, the remaining water is added with moderate stirring. Alcohol or propylene glycol is often used to help wet the powders. High electrolyte concentrations will salt out the polymer, ultimately precipitating the polymer.

Poloxamer gels are made from selected forms of polyoxyethylene-polyoxypropylene copolymers in concentrations ranging from 15 to 50%. Poloxamers are white, waxy, free-flowing granules that are practically odorless and tasteless. Aqueous solutions of poloxamers are stable in the presence of acids, alkalis, and metal ions. Polyvinyl alcohol (PVA) is used at concentrations of about 2.5% in the preparation of various jellies, which dry rapidly when applied to the skin. Borax is often used to gel PVA solutions. For best results, disperse PVA in cold water, followed by hot water. It is less soluble in the cold water.

Povidone, in the higher molecular weight forms, can be used to prepare gels in concentrations up to about 10%. It has the advantage of being compatible in solution with a wide range of inorganic salts, natural and synthetic resins, and other chemicals. It has also been used to increase the solubility of a number of poorly soluble drugs.

### Two-Phase Gels

Two-phase gels containing bentonite may be used as a base for topical preparations, such as plaster and ointment. Aluminum

hydroxide gel, USP, is an example of a two phase gel. The USP states that “Aluminum Hydroxide Gel is a suspension of amorphous aluminum hydroxide in which there is a partial substitution of carbonate for hydroxide.” The gel is prepared by the interaction of a soluble aluminum salt, such as a chloride or sulfate, with ammonia solution, sodium carbonate, or bicarbonate. The reactions that occur during the preparation are:

The physical and chemical properties of the gel will be affected by the order of addition of reactants, pH of precipitation, temperature of precipitation, concentration of the reactants, the reactants used, and the conditions of aging of the precipitated gel.

Aluminum Hydroxide Gel is soluble in acidic (or very strongly basic) media. The mechanism in acidic media is:

It is unlikely that the last reaction proceeds to completion, because the activity of the gel is controlled by its insolubility. Further, because a certain quantity of insoluble gel is always available, the neutralizing capability of the gel extends over a considerable period of time.

Aluminum hydroxide gels may also contain peppermint oil, glycerin, sorbitol, sucrose, saccharin, and various preservatives. Sorbitol improves the acid consuming capacity by inhibiting a secondary polymerization that takes place on aging. In addition, polyols, such as mannitol, sorbitol, and inositol, have been shown to improve the stability of aluminum hydroxide and aluminum hydroxycarbonate gels.<sup>101</sup>

### Single-Phase Gels

Single-phase gels are used more frequently in pharmacy for several reasons: semisolid state, high degree of clarity, ease of application, and ease of removal and use. The gels often provide a faster release of drug substance, independent of the water solubility of the drug, as compared to creams and ointments.

Some recent gel formulations include ophthalmic preparations of pilocarpine, carbachol, and betamethasone valerate; topical preparations for burn therapy, anti-inflammatory treatment, musculoskeletal disorders, and acne; peptic ulcer treatment with sucralfate gel; and bronchoscopy, using lidocaine. Gels may be used as lubricants for catheters and bases for patch testing, and sodium chloride gels are used for electrocardiography.

Some gel formulation examples are subsequently provided.

Methylcellulose and Carbomer Gel Base	
METHYLCELLULOSE,	4000 CPS 1.0 %
CARBOMER	934 0.35 %
1 N SODIUM HYDROXIDE SOLUTION	QS TO PH 7
PROPYLENE GLYCOL	16.7 %
METHYL PARABEN	0.015%
PURIFIED WATER	QS 100%

Disperse the methylcellulose in a portion of hot (80–90°C) water. Cool to room temperature, and disperse the Carbomer 934 in the gel, using a bladed impeller. Adjust the pH of the dispersion to 7.0, by adding sufficient 1 N sodium hydroxide solution. Dissolve the methylparaben in the propylene glycol. Mix the methylcellulose, Carbopol 934, and propylene glycol fractions, using caution to avoid incorporating air.

**Sodium Alginate Gel Base**

SODIUM ALGINATE	10 G
GLYCERIN	10 G
METHYL HYDROXYBENZOATE	0.2 G
A SOLUBLE CALCIUM SALT (CALCIUM GLUCONATE)	0.5 G
PURIFIED WATER, TO MAKE	100 ML

Place a portion of water in a beaker and add the glycerin and preservative. Stir this solution with a high speed mixer and add the sodium alginate. The calcium salt is added next, which increases the viscosity. Continue mixing, until the preparation is homogeneous. The preparation should be stored in a tightly sealed, wide mouth jar or tube.

**Carbomer Gel**

CARBOMER	9342 G
TRIETHANOLAMINE	1.65 ML
METHYL PARABEN	0.2 G
PROPYL PARABEN	0.05 G
PURIFIED WATER, TO MAKE	100 ML

The parabens are dissolved in 95 mL of water with the aid of heat and allowed to cool. Carbomer 934 is added in small amounts to the solution using a high speed mixer, until a smooth dispersion is obtained. The preparation is allowed to stand, permitting entrapped air to separate. Then the neutralizing agent, triethanolamine, is added very slowly to avoid entrapping air. Finally, the remaining water is then incorporated.

**LOTIONS**

Lotions are not defined specifically in the USP, but a broad definition describes them as either liquid or semi-liquid preparations that contain one or more active ingredients in an appropriate vehicle. Lotions may contain antimicrobial preservatives and other appropriate excipients, such as stabilizers. Lotions are intended to be applied to the unbroken skin without friction. Lotions are suspensions of solids in an aqueous medium. Some lotions are, in fact, emulsions or solutions.

Even though lotions are applied without friction, the insoluble matter should be divided very finely. Particles approaching colloidal dimensions are more soothing to inflamed areas and effective in contact with infected surfaces. A wide variety of ingredients may be added to the preparation to produce better dispersions or to accentuate its cooling, soothing, drying, or protective properties. Bentonite is a good example of a suspending agent used in the preparation of lotions. Methylcellulose or sodium carboxymethylcellulose, for example, will localize and hold the active ingredient in contact with the affected site and be rinsed off easily with water. A formulation containing glycerin will keep the skin moist for a considerable period of time. The drying and cooling effect of a lotion may be accentuated by adding alcohol to the formula.

Dermatologists frequently prescribe lotions containing anesthetics, antipruritics, antiseptics, astringents, germicides, protectives, or screening agents to treat or prevent various types of skin diseases and dermatitis. Antihistamines, benzocaine, calamine, resorcin, steroids, sulfur, zinc oxide, betamethasone derivatives, salicylic acid, safflower oil, minoxidil, and zirconium oxide are ingredients common in lotions.

Lotions may be prepared by triturating the ingredients to a smooth paste and then adding the remaining liquid phase with trituration. High speed mixers or colloid mills produce better dispersions and, therefore, are used in the preparation of larger quantities of lotion. Calamine Lotion, USP, is the classic example of this type of preparation and consists of finely powdered,

insoluble solids held in more or less permanent suspension by the presence of suspending agents and/or surface-active agents. The formula and the method of preparation of Calamine Lotion, USP, follows.

**Calamine Lotion, USP**

CALAMINE	80 G
ZINC OXIDE	80 G
GLYCERIN	20 ML
BENTONITE MAGMA	250 ML
CALCIUM HYDROXIDE TOPICAL SOLUTION	Q.S. 1,000 ML

Dilute the bentonite magma with an equal volume of calcium hydroxide topical solution. Mix the powder intimately with the glycerin and about 100 mL of the diluted magma, triturating until a smooth, uniform paste is formed. Gradually incorporate the remainder of the diluted magma. Finally, add enough calcium hydroxide topical solution to make 1000 mL, and shake well. If a more viscous consistency in the Lotion is desired, the quantity of bentonite magma may be increased to not more than 400 mL.

Many investigators have studied Calamine Lotion, and this has led to the publication of many formulations, each possessing certain advantages over the others, but none satisfying the collective needs of all dermatologists. Formulations containing hydrated microcrystalline cellulose and carboxymethylcellulose have a slower rate of sedimentation than the official preparation.

Although most lotions are prepared by trituration, some lotions are formed by chemical interaction in the liquid. White Lotion, USP, is an example, and the chemical reaction between Sulfurated Potash and Zinc Sulfate is as follows:

**White Lotion**

ZINC SULFATE	40 G
SULFURATED POTASH	40 G
PURIFIED WATER,	Q.S. 1,000 ML

Dissolve the zinc sulfate and the sulfurated potash separately, each in 450 mL of purified water, and filter each solution. Add slowly the sulfurated potash solution to the zinc sulfate solution with constant stirring. Then add the required amount of purified water, and mix.

Benzyl Benzoate Lotion, USP, is an example of a lotion that is also an emulsion. The formula and method of preparation are:

**Benzyl Benzoate Lotion, USP**

BENZYL BENZOATE	250 ML
TRIETHANOLAMINE	5 G
OLEIC ACID	20 G
PURIFIED WATER	Q.S. 1,000 ML

Mix the triethanolamine with the oleic acid, add the benzyl benzoate, and mix. Transfer the mixture to a suitable container of about 2000 mL capacity, add 250 mL of purified water, and shake the mixture thoroughly. Finally, add the remaining purified water, and again shake thoroughly.

Triethanolamine forms a soap with the oleic acid and functions as the emulsifying agent to form a stable product. This type of emulsifying agent is almost neutral in water and gives a pH of about 8, thus, should not irritate the skin.

Certain lotions tend to separate or stratify on long standing, and they require a label directing they be shaken well before each use. All lotions should be labeled "For External Use Only."

Micro-organisms may grow in certain lotions, if no preservative is included. Care should be taken to avoid contaminating the lotion during preparation, even if a preservative is present.

Milk of Magnesia, USP, is a suspension of magnesium hydroxide containing approximately 80 mg of  $Mg(OH)_2$  per milliliter. The specifications for double strength or triple strength are that these products should contain approximately 160 mg or 240 mg of  $Mg(OH)_2$  per mL, respectively. It has an unpleasant, alkaline taste that can be masked with 0.1% citric acid (to reduce alkalinity) and 0.05% of a volatile oil or a blend of volatile oils. Magnesium hydroxide is prepared by the hydration of magnesium oxide.

For the most part, magmas are intended for internal use, although Bentonite Magma is used primarily as a suspending agent for insoluble substances for local application and occasionally for internal use. All magmas require "Shake Well" and "Avoid Freezing" labels.

## EXTRACTS

Extraction, as the term is used pharmaceutically, involves the separation of medicinally active portions of plant or animal tissues from the inactive or inert components by using selective solvents in standard extraction procedures. The products obtained from plants are relatively impure liquids, semisolids, or powders intended only for oral or external use. These include classes of preparations known as decoctions, infusions, fluidextracts, tinctures, pilular (semisolid) extracts, and powdered extracts. Such preparations popularly have been called galenicals, after Galen, the 2nd century Greek physician.

Extraction continues to be of considerable interest to obtain improved yields of drugs derived from plant and animal sources. For example, extraction of digitalis glycosides has been carried out using super critical carbon dioxide.<sup>102</sup> Other techniques include ultrasonics, rotary-film evaporators, hydro-distillation, liquid chromatography, multiple-solvent extraction, counter-current extraction, and gravitation dynamics.

This discussion is concerned primarily with basic extraction procedures for crude drugs to obtain the therapeutically desirable portion and eliminate the inert material by treatment with a selective solvent, known as the menstruum. Extraction differs from solution in that the presence of insoluble matter is implied in the former process. The principal methods of extraction are maceration, percolation, digestion, infusion, and decoction. The quality of the finished product can be enhanced by standardizing primary extracts and carrying out analytical assays during production on the raw materials, intermediate products, and manufacturing procedures.

The processes of particular importance, insofar as the USP is concerned, are those of maceration and percolation, as described specifically for Belladonna Extract, USP, and Cascara Sagrada Extract, USP. Most pharmacopeias refer to such processes for extraction of active principles from crude drugs. The USP provides general directions for both maceration and percolation under the heading of **Tinctures**.

Techniques of extraction continue to be investigated and applied to obtain higher yields of the active substance from natural sources. Some of these methods include the use of different grinding and shearing processes of plants, use of specific membranes for extraction, and different extraction procedures, such as distillation, digestion, percolation, and microwaves.

### MACERATION

In this process the solid ingredients are placed in a stoppered container with 750 mL of the prescribed solvent and allowed to stand for a period of at least 3 days in a warm place with frequent agitation, until soluble matter is dissolved. The mixture is filtered and, after most of the liquid has drained, the residue on the filter is washed with sufficient quantity of the prescribed solvent or solvent mixture; the filtrates are combined to produce 1000 mL.

### PERCOLATION

The ground solids are mixed with the appropriate quantity of the prescribed solvent to make it evenly and uniformly damp. It is allowed to stand for 15 minutes, then transferred to a percolator and packed. Sufficient prescribed solvent is added to saturate the solids. The top is placed on the percolator, and, when the liquid is about to drip from the apparatus, the lower opening is closed. The solids are allowed to macerate for 24 hours or for the specified time. If no assay is directed, the percolation is allowed to proceed slowly or at the specified rate, gradually adding sufficient solvent to produce 1000 mL of solution. If an assay is required, only 950 mL of percolate are collected and mixed and a portion assayed as directed. The rest of the percolate is diluted with the solvent to produce a solution that conforms to the required standard and then mixed.

### DIGESTION

This is a form of maceration in which gentle heat is used during the process of extraction. It is used when moderately elevated temperature is not objectionable and the solvent efficiency of the menstruum is increased thereby.

### INFUSION

An infusion is a dilute solution of the readily soluble constituents of crude drugs. Fresh infusions are prepared by macerating the solids for a short period of time with either cold or boiling water. The USP has not included infusions for some time.

### DECOCTION

This once popular process extracts water soluble and heat stable constituents from crude drugs, by boiling in water for 15 minutes, cooling, straining, and passing sufficient cold water through the drug to produce the required volume.

### EXTRACTIVE PREPARATIONS

After a solution of the active constituents of a crude drug is obtained by maceration or percolation, it may be ready for use as a medicinal agent, as with certain tinctures or fluidextracts, or it may be processed further to produce a solid or semisolid extract.

### TINCTURES

Tinctures are defined in the USP as alcoholic or hydroalcoholic solutions prepared from vegetable materials or from chemical substances, an example of the latter being Iodine Tincture. Traditionally, tinctures of potent vegetable drugs essentially represent the activity of 10 g of the drug in each 100 mL of tincture, the potency being adjusted following assay. Most other tinctures of vegetable drugs represent the extractive from 20 g of the drug in 100 mL of tincture.

The USP, specifically, describes two general processes for preparing tinctures, one by percolation and the other by maceration. Percolation includes a modification, so tinctures that require assay for adjustment to specified potency, thus, may be tested before dilution to final volume. Belladonna Tincture, USP, is prepared in this manner. Compound Benzoin Tincture, USP, and Sweet Orange Peel Tincture, USP, are prepared by the maceration procedure.

### FLUID EXTRACTS

The USP defines fluidextracts as liquid preparations of vegetable drugs, containing alcohol as a solvent or as a preservative, or both, so made that, unless otherwise specified in an individual monograph, each milliliter contains the therapeutic constituents of 1 g of the standard drug that it represents.

### EXTRACTS

Extracts are defined in the USP as concentrated preparations of vegetable or animal drugs obtained by removal of the active constituents of the respective drugs with suitable menstrua,

evaporation of all or nearly all of the solvent, and adjustment of the residual masses or powders to the prescribed standards. There are three forms of extracts: semiliquids or liquids of syrupy consistency, plastic masses (known as pilular or solid extracts), and dry powders (known as powdered extracts). Extracts, as concentrated forms of the drugs from which they are prepared, are used in a variety of solid or semisolid dosage forms. The USP states that pilular extracts and powdered extracts of any one drug are interchangeable medicinally, but each has its own pharmaceutical advantages. Pilular extracts, called so because they are of a consistency to be used in pill masses and made into pills, are also suited for use in ointments and suppositories. Powdered extracts are better suited for incorporation into a dry formulation, as in capsules, powders, or tablets. Semiliquid extracts, or extracts of a syrupy consistency, may be used in the manufacture of some pharmaceutical preparations.

Most extracts are prepared by extracting the drug by percolation. The percolate is concentrated by distillation under reduced pressure. The use of heat is avoided where possible, due to potential injurious effect on active constituents. Powdered extracts made from drugs that contain inactive oily or fatty matter may have to be defatted or prepared from defatted drug. Pure Glycyrrhiza Extract, USP, is an example of a pilular extract and Belladonna Extract, USP, is an examples of a powdered extract.

### FORTIFIED BEVERAGES

Our increasingly health conscious population has become more accustomed to dietary supplementation. Dietary supplements have, traditionally, been in the form of tablets and capsules that provide vitamins, minerals, herbs, and other naturally occurring ingredients. In the last decade, dietary supplementation has become available in many new forms, including beverages, shakes, powders, bars, and gels. These products are marketed as meal replacement shakes (Slim-Fast), vitamin fortified beverages (VitaminWater, LifeWater, etc.), protein and fiber powders for reconstitution (Muscle Milk), sports/electrolyte replacement drinks (Gatorade), and energy drinks (Redbull, Monster).

Currently, the Food and Drug Administration (FDA) regulates the sale and use of dietary supplements as a distinct subset of foods under the Federal Food, Drug and Cosmetic Act. Congress enacted the Dietary Supplement Health and Education Act of 1994, due to pressure from the dietary supplement industry to curtail FDA regulation and consumer advocacy groups desiring more quality standards. This legislation is intended to balance consumer access and the need for regulation to ensure product safety. The Act essentially confirms the status of all dietary supplements as foods and subjects such products to regulations accordingly.

Several of these products have excellent regulatory compliance records and quality standards, including confirmed expiration dates determined by stability testing. Other products have not had satisfactory compliance records and quality standards. Companies have been guilty of misleading labeling, unsubstantiated marketing claims, and excessive quantities of certain ingredients (e.g., sugar, caffeine). In one instance, a product marketed as a vitamin fortified beverage and a healthy alternative to a daily multivitamin was found to contain 85 g of sugar per serving, about 30% more sugar than a typical soft drink. Clinical nutritionists and consumer advocacy groups have expressed concern that some of these products may be more marketing than substance, suggesting scrutiny of the ingredients and claims associated with them.<sup>103,104</sup> As a result, consumers should carefully review the labels of these products and exercise care in their selection.

### INTRODUCTION

Microorganisms represent a potential threat to human health in various settings. The presence of some microorganisms in foods, pharmaceuticals and even the environment can cause illness and even death. Louis Pasteur established the link between microbes and disease, and his seminal work influenced Joseph Lister to use phenol to reduce contamination risk during invasive surgery in the late 1800s.<sup>1</sup> This knowledge led to the introduction of multiple measures to mitigate the risks associated with microbial contamination and led to the development of sterilization methods, sanitization practices, and other microbial control measures intended to assure product and procedural safety.

In the pharmaceutical and medical device industries, sterile products are produced using two primary methods: terminal sterilization or aseptic processing.<sup>1</sup> Terminal sterilization provides for the clean assembly of the product as a final package, which is then subjected to a lethal process. Aseptic processing rearranges the steps: the product components are individually sterilized and then assembled in an extremely clean environment. This chapter will review the primary methods for the production of sterile products, using either approach, with emphasis on sterilization and sterility assurance related subject matter. Some of the processes described will also afford some measure of destruction/removal of pyrogens (endotoxin), viruses, and prions; however, their removal is not considered in detail with the exception of dry heat depyrogenation.

In addition to the therapeutic goal of all medical products there is a safety requirement; a major component of which in the context of sterile pharmaceuticals and medical devices is “sterility”. Sterility, which has been defined as the absence of life (or inability to reproduce), is an absolute concept. Items are “sterile,” or they are not; there is no middle ground. However, at the present time, there are no nondestructive means to demonstrate sterility. Instead we define processes to attain that goal, subject the materials to these processes, and then estimate the results. For the lethal sterilization processes, whether terminal or in-process, the “sterility” expectation is fulfilled by demonstrating a minimum Probability of a Non-Sterile Unit (PNSU) of not more than one positive unit in 1 000 000 units or  $1 \times 10^{-6}$ .<sup>2,3</sup> It must be understood that the microorganism of concern in any process is the bioburden present prior to treatment. In actual practice this target is often exceeded by a substantial margin

as the industry is inherently conservative about such a critical quality attribute. The focus of the treatment is on the removal/destruction of any bioburden microorganisms that might be present on/in the materials prior to the process. Where liquids are sterilized by filtration, the filters utilized are shown capable of removing a minimum of seven logs of a challenge microorganism specifically cultured for its small size and potential penetration of the filter. In aseptic processing, which relies on prior sterilization of the materials, equipment, and other items, the goal is to prevent the recontamination of those items in the assembly process. Aseptic process simulations are used to demonstrate contamination rates of not more than one unit in 5000 units. The various estimations of performance from these processes are established during the validation efforts with the assumption that routine operations deliver comparable (or superior) results. In most instances everyday manufacturing performance is well in excess of the targeted and demonstrated minimum levels established by the validation efforts. Nevertheless, the level of sterility present after any of these processes is never known with any degree of precision.

### MICROBIAL GROWTH AND DEATH

In considering means to control the microbial content of materials, a basic understanding of the typical microbial life cycle can be useful. In order to increase in number (or replicate), aerobic and facultative microorganisms require essentially what we need: food, water, and air.<sup>2</sup> While nutrient requirements across the spectrum of flora are diverse, the core needs are carbon and nitrogen, liquid moisture, and oxygen. Aseptic processing is performed in cleanrooms, in which the connotation of “clean” means absence of soil and moisture that might support microbial proliferation. The presence of human operators in many aseptic processing environments means that microbial contaminants will be continuously introduced. Appropriate cleanroom designs and operating practices are developed to provide for their prompt removal and adequate protection of the critical environments, such that those which do remain do not result in microbial contamination of sterilized items.

The other side of the microbial life cycle relates to their death. This can be accomplished by removing what they need to increase in number or, more expeditiously, by subjecting the microbes to some degree of stress. The stress can be thermal, chemical, or ionic in nature (filtration is not a lethal process

<sup>1</sup>Where products are manufactured with aseptic processing followed by terminal sterilization, there is little difference in the manner in which either process is controlled compared to when they are performed individually.

<sup>2</sup>Obligate anaerobic microorganisms cannot survive in environments where the level of oxygen is greater than ~ 0.2% and thus are almost never isolated in manned environments.

and accomplishes microbial control by separative means) in which the death rate is accelerated. Sterilization processes deliver these conditions to extreme to rapidly kill the microbes.

While the lethal processes appear to be fundamentally different, the lethal aspect of each is at its core a chemical reaction that generally follows first order kinetics. Bigelow established that when the log number of the microorganisms is plotted against time, an essentially straight line results.<sup>4</sup> This aspect of microbial destruction lies at the very core of all lethal processes as it enables predictive destruction of microorganisms. The inverse slope of this line is the D-value or the time required to reduce the population by one log (or 90%) (See Figure 25-1).

The D-value is influenced by a number of factors, most notably by the conditions that will ultimately result in the microorganism's destruction. When a D-value is reported, it should always indicate the exact conditions under which it was determined.

The semi-logarithmic plot of the Survivor Curve has the difficulty of being undefined mathematically at zero, which is the definition of "sterile". The concept of "Commercial Sterility" was initiated to address this difficulty and the practical nature of assessing sterilization processes that destroy microorganisms within the food industry. This concept expresses sterility as a probability in the region of the survivor curve below one surviving organism. This region has negative values for the log of concentration and is interpreted as non-sterile containers in a group being sterilized (e.g., one non-sterile unit in ten units for a survivor concentration of  $10^{-1}$ , see Figure 25-1). This approach is called Probability of a Non-Sterile Unit (PNSU) or, as applied to all processes (not necessarily containers), Sterility Assurance Level (SAL). The D-value approach can be misused by applying it to curvilinear semi-log survivor curves, or extrapolating the linear portion from a limited range of experimental data. The latter misuse resulted in cases of paralytic polio and death when a vaccine manufacturer in the 1950s extrapolated the linear segment of a Survivor Curve for Poliomyelitis Virus treated with Formalin, published by Salk, *et al.*, to treat commercial quantities of vaccine.<sup>5</sup>

Thermal processes using moist heat have been extensively studied and the D-value has been determined for many important spoilage and resistant microorganisms to facilitate the control of lethal processes. The change in the D-value in response to changes in temperature is an important concern in thermal sterilization processes. The relationship between temperature

**Figure 25-1.** Graphical Representation of D-value from Survivor Curve.

and the D-value is established by the Thermal Death Time Curve and determination of the z-value (See Figure 25-2).

The z-value is the reciprocal slope of the semi-logarithmic plot of the Thermal Death Time Curve and allows for calculation of process lethality for processes where the conditions are not constant, and thus, microbial kill will occur at varying rates during the course of the treatment. A comparable approach is usable for dry heat sterilization albeit with less supportive data. There have been attempts to apply the D- and z-value approach to dry heat depyrogenation; however, these determinations are not universal because the endotoxin utilized in each varied.<sup>3</sup>

The sterilization process is modeled by a step functional isothermal process, in which the temperature is instantaneously raised to a reference temperature, held for "F" minutes, and instantaneously reduced to sublethal levels. The kinetic parameters of D- and z-values can be utilized to mathematically estimate the lethality delivered by an actual thermal process, according to the following calculation. The general form of this equation has been adapted for steam and dry heat processes.

F equation

$$L = \log^{-1} (T - T_b) / z = 10^{(T - T_b) / z} \quad (1)$$

Where:

$T_0$  = temperature in load

$T_b$  = base (or reference) temperature

$z$  = z - value [ $10^\circ\text{C}$ ] Note: units are a temperature difference, not a temperature

$L$  = instantaneous process lethality

When the base temperature is  $121.1^\circ\text{C}$  and the z-value employed  $10^\circ\text{C}$ , the equation can be utilized in conjunction with thermal data to determine the  $F_0$ , or the equivalent sterilization time for a particular process. The subscript "0" was initiated historically in the food industry, where  $250^\circ\text{F}$  and a z of  $18^\circ$  Fahrenheit degrees were more widely used. The use of a standard calculation method allows for the comparison of lethal conditions within load, between loads, and between processes.

$F_0$  equation

$$F_0 = 110^{(T - 121.1) / 10} dt \quad (2)$$

This integral is normally calculated as a summation of contributions over finite temperature measurements

**Figure 25-2.** Graphical Representation of z-value from Thermal Death Time Curve.

<sup>3</sup>Dry heat depyrogenation is supported empirically by verification of endotoxin destruction. Mathematical determinations of dry heat depyrogenation are used for correlation to equipment parameters and not as definitive proof of process performance.

$F_0$  equation

$$F_0 = \sum 10^{(T-121.1)/10} \Delta t \quad (3)$$

Where:

$\Delta t$  = time interval between measurements

$T$  = temperature at each interval

A comparable but less accurate means for estimation of lethality has been developed for dry heat processes. Separate equations are used for sterilization and depyrogenation.

$F_H$  equation sterilization

$$F_H = \sum 10^{(T-170)/20} \Delta t \quad (4)$$

$F_H$  equation depyrogenation

$$F_H = \sum 10^{(T-250)/50} \Delta t \quad (5)$$

Where:

$\Delta t$  = time interval between measurements

$T$  = temperature at each interval

In the case of depyrogenation, differing base temperatures and  $z$ -values can be used.<sup>4</sup> Gillis and Mosely have developed a mathematical model for ETO sterilization that considers gas concentration and temperature conditions, estimates the process lethality, and determines equivalent process time.<sup>6</sup>

Relative humidity was not considered as a contributing factor as the operation range evaluated showed no meaningful impact on lethality. The use of this model is not widespread although it affords a level of understanding for ETO sterilization.

$$U = \sum \left( 10^{\left( \log t + \left( \frac{T_i - T_{REF}}{Z} \right) \right)} \right) \frac{C_i}{C_{REF}} \quad (6)$$

Where:

$U$  = equivalent time

$C$  = concentration

$T$  = temperature

$t$  = time

For the other sterilization processes, there are no current means to convert physical parameter measurements into lethality estimations. Their effectiveness is established using biological indicators, customarily Gram-positive spore formers, as surrogates for the bioburden. The delivered lethality should always be referenced to the bioburden present in order to support demonstration of process performance. This is accomplished by making a determination of the PNSU using equation 7.

PNSU calculation

$$\log N_u = \frac{-F}{D} + \log N_0 \quad (7)$$

Where:

$N_u$  = PNSU or SAL

$D$  = D-value of the microorganism

$F$  = F-value of the process

$N_0$  = initial microbial population (extrapolated from linear segment of survivor curve)

In this calculation the D-value to be utilized is that of the bioburden as it is the target of the process in routine operation, and its destruction must be supported. The log reduction of a microorganism can be estimated for processes where the F value cannot be readily measured by substituting the process time in the equation (see equation 8). Note that the actual initial microbial concentration may be different if there is a significant curvilinear initial segment.

$$\log \text{reduction } \log N_u = \frac{-U}{D} + \log N_0 \quad (8)$$

Where:

$N_u$  = PNSU or SAL

$D$  = D-value of the microorganism

$U$  = Duration of the process

$N_0$  = initial microbial population

This assumes the process is accomplished at the same conditions at which the D-value has been determined, which may not be precisely the case. Nevertheless, Equation 8 provides some means of assessment for these other processes.

While it may appear tempting to rely on the physical measurements to estimate process lethality and provide a more quantitative assessment of the process, the measurements must be acknowledged for their secondary nature. The mathematical models rely first on the response of microorganisms to the process (their D-value), as adjusted with respect to the specific conditions (their  $z$ -value). The physical measurements are assumed to be representative of the sterilizing conditions the microorganism experiences and responds to; however, those conditions are assumed and never precisely known. For this reason, sterilization microbiologists tend to place greater credence on the reaction of the biological challenge system to the process as proof of process efficacy.<sup>7</sup>

Sterilization by filtration processes differ from the other methods in that the mechanism is separative rather than lethal. As a consequence, the parametric measurements of the lethal methods are not applicable to sterilizing filtration. The important filtration process parameters relate to filter integrity, which can be used to substantiate microbial retention. An expanded discussion of sterilizing filtration is provided later in this chapter.

## STERILIZATION CYCLE DEVELOPMENT

The determination of a suitable process (cycle) for sterilization must first consider the expected effect of the process on the materials. Certainly there is no value in defining a process that, while effective in destruction of microorganisms, has substantial adverse quality and/or reliability impact on the items being processed. A balance must often be struck between an extreme process that provides substantial microbial kill and less aggressive conditions that preserve the material's essential quality attributes. With the exception of stainless steel and glass (and even these can be impacted in some instances), the material effects have to be taken into account in cycle development. If the adverse material effects are excessive, a different sterilization process should be selected.

There are three fundamental approaches to the development, validation, and control of a sterilization process: overkill, bioburden/biological indicator (BB/BI), and bioburden.<sup>5</sup> The default choice for cycle approach is the overkill method which is the simplest to establish and control but has the greatest potential adverse impact on the load items. At the other extreme is the bioburden method which has the least impact on materials but requires more rigorous evaluation initially and throughout its operational use. The bioburden/biological indicator approach falls between the other methods with respect to both material impact and operational ease (see Figure 25-3). The BB/BI method is used for the majority of terminally sterilized products and laboratory media, instances where the negative consequences of over-processing need to be avoided.<sup>7</sup> Radiation sterilization is validated using a bioburden approach in part because the radiation resistance of many microorganisms has not been evaluated and non-sporeforming microorganisms have been isolated with substantial resistance to radiation.<sup>8</sup>

<sup>4</sup>See later section on dry heat depyrogenation for additional clarification.

<sup>5</sup>It is essential that the same process control methodology be utilized throughout.

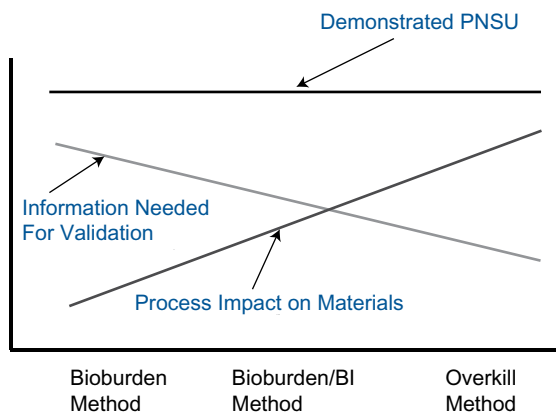

Figure 25-3. Comparison of Validation Approaches.

The methods can be briefly described as follows:

### Overkill Approach

A process where the destruction of a high concentration of a resistant microorganism supports the elimination of bioburden that might be present in routine processing. That objective can be demonstrated by attaining any of the following: a defined minimum lethality, a defined set of process conditions, or confirmation of minimum log reduction of a biological indicator.

### Bioburden / Biological Indicator Approach

A method where the incomplete destruction (or destruction of a modest population) of a resistant biological indicator can be used to demonstrate the capability of the process to reliably destroy any bioburden. This is accomplished using detailed knowledge of the bioburden/biological indicator populations and their relative resistance.

### Bioburden Approach

A method where multiple bioburden isolates from the material are evaluated for resistance to the sterilization method and utilized as biological indicators to demonstrate the lethality of the process. Frequent monitoring of the bioburden population and resistance is mandatory for success.

The methods must be validated consistent with their initial development approach and maintained in the same way. Despite the difference in bioindicator performance with the different methods, each can provide materials that are adequately sterilized. This is because the PNSU for a sterilization process should be calculated using the population and resistance of the bioburden present (see Equation 7 above). The biological indicator serves as a measure of the process (as well as confirmation of lethality in locations and on surfaces where physical measurement is not possible), and not as definitive proof of performance in routine operation.<sup>6</sup>

The overkill method is intended primarily for items where the process's sensitivity to the treatment is such that the potential for over-processing is minimal. The process is demonstrated lethal under reduced conditions with both process monitors and biological indicators present. The routine use of somewhat more aggressive conditions provides an added measure of confidence in the outcome. The BB/BI and bioburden approaches are better suited where material impact places constraints on the conditions that can be used. Their validation is accomplished using the routine process, as it is the added controls on the bioburden that provides the desired process confidence.

There is an adaptation of the overkill method, called the half-cycle method, in which the process dwell period is doubled to

define the extent of the routine process. Originally developed for use with ETO before accurate in-process measures of concentration and relative humidity were available, the doubling of the dwell time was considered sufficient to support the full duration process if the biological indicators were inactivated in the half-cycle. Its use for other processes presupposes no adverse material impact with the extended duration, something that should not be assumed so readily. Lethal factors other than time – such as concentration, temperature, humidity, and others are never adjusted, making it more difficult to support process effectiveness when these parameters vary outside the demonstrated values. The half-cycle method is in widespread use, notwithstanding its limited utility in supporting variations in parameters other than time.<sup>9</sup>

## EQUIPMENT QUALIFICATION

Qualification of sterilization equipment and its associated utility systems must be performed prior to beginning performance qualification. The reproducibility of sterilization cycles is largely dependent on the controls, utilities, and mechanics of the sterilizer and its ability to consistently operate according to expectations. The essential elements of the sterilizer and its supply services should be verified as properly installed and set to their specifications as part of the initial qualification and is often termed the installation qualification. This is followed by basic confirmation of equipment functionality in an operational qualification exercise. These can be performed sequentially or in a more integrated manner. The overall activity is often termed equipment qualification and precedes performance qualification, which entails rigorous evaluation of system performance under load, using independent parameter measurement and/or microbial challenges. An exact separation of the activities is non-critical; provided the appropriate measures are followed their designation as IQ, OQ, or PQ is arbitrary.

Qualification is performed to assure that the sterilizer has been installed and operates according to manufacturer's specifications. Its most important purpose is to establish a baseline for the installation and operation that can be used to assess the impact of subsequent changes or alterations. Any testing performed during the equipment qualification is commonly executed with the sterilizer empty.

Process equipment for sterilization, regardless of the process type, includes at least three major process stages: preparation/pre-treatment of the items to be sterilized; exposure to the sterilizing agent; and post-exposure steps. While these differ with respect to their execution in relation to each phase, there are common considerations:

- Preparation/pre-treatment steps (which can be performed prior to transfer to the sterilizer) encompass such activities as cleaning of the items, wrapping/placement into containers, pre-humidification/pre-conditioning of load items, and removal of air (to facilitate agent penetration).
- Exposure provides the regulation of sterilizing conditions for the required time period. This is variously called the dwell period or exposure time.
- Post-exposure activities include cooling, drying, sterilizing agent removal, and maintenance of sterility for unwrapped surfaces (essential in sterilization-in-place and chemical treatments).

The most important aspect of the equipment is its ability to deliver consistent performance over an extended period of use and the reliability/accuracy of the routine documentation it provides on each sterilization process. This mandates that the equipment be supported by a number of related practices:

<sup>6</sup>When comparing the height of two individuals to determine which is taller, the unit of measurement is not critical. Whether the measurement is made in meters, yards, rods, or fathoms, each measurement system will confirm the same result.

- A formal change control program addressing the sterilization equipment, utility supplies, materials, and procedures.
- Preventive maintenance as established by the equipment manufacturer for maintaining system performance.
- Calibration procedures for the installed instrumentation on sterilization equipment and critical utilities.
- Training of operating, maintenance, and other personnel in the procedures for operation maintenance and calibration.

## CONTAINER AND LOAD MAPPING

In order to establish the process dwell time at the desired conditions, the load items and the load configuration itself must be studied to confirm attainment of the desired condition through the item (and load). This entails the execution of preliminary studies, in which the process conditions are evaluated within the item and the load to determine “worst case” locations for penetration. It is these locations that will define the expected process time to satisfy the sterilization objective.

## COMPONENT MAPPING

Items to be evaluated are reviewed and physical monitoring devices introduced to assess penetration of the items. For thermal processes this is carried out with thermocouples placed in expected “worst case” locations, where, by virtue of mass, complexity, condensate/air retention, etc., heating will be slowest. Biological indicators can be used similarly in gas, liquid, and vapor processes. Radiation-sterilized items can be mapped using dosimeters to determine low-dose locations. Identification of these locations is essential to establish the desired dwell periods in these “worst case” locales. Measurements should be made in as non-obtrusive manner as possible so as to gain the most information with minimal alteration of the item and any external wrapping material and without impacting either positively or negatively the sterilization process. The items should be sealed in a manner comparable to that routinely used. Temperature measurements of load items should be made with the thermocouple junction in contact (or nearly so) with the item's surface. Biological indicator strips can be used; however, wires, dots, and strings with a surface dried spore suspension may be more appropriate in smaller items. The container mapping can be performed in other sterilized units, provided the process used is comparable to that expected in routine use. Once the appropriate “worst case” location has been identified, all subsequent monitoring should be performed at that location with the item wrapped as it was in the component mapping and oriented in the same way, e.g., open end down. Large items may only have their openings covered to facilitate handling.

Component mapping should be a part of all the destructive sterilization processes with the intent of locating the “most difficult to sterilize” location within the item. In gas sterilization this location would be the appropriate location for positioning of biological indicators on or within the device. The practice in radiation sterilization is comparable with dosimeters, positioned where the measured dose might be the lowest. These evaluations can be performed for a complete shipping carton in which a central or middle unit would be studied since these would represent the “most difficult to sterilize” location. These locations are roughly equivalent to the “cold spot” in thermal sterilization.

## LOAD MAPPING

This activity provides for the assessment of the effect of load size, arrangement, and density on penetration across the sterilizing chamber. With load items probed as described above, the load is assembled and the effect of loading on the conditions assessed. Where the load consists of items potentially susceptible to the treatment, it is equally important to identify locations where maximum degradation might occur, in addition to those where minimum sterilization conditions are demonstrated. Those portions

of the load evidencing the most aggressive conditions would be evaluated for adverse effects on the materials, while those demonstrating the least aggressive are more appropriate for monitoring with biological challenges. Load mapping is less of a concern where items are largely unaffected by the sterilization process, such as steam sterilization of stainless steel and glass items. In these situations the differences in the item have substantially more influence on the process than its location in the sterilizer. It has added importance with dry heat processes where the ability of the sterilizing medium to penetrate / heat the items is limited.

Load mapping is expected for non-thermal destructive processes as well, with the effect of load density evaluated during cycle development and validation. In this exercise identification of maximum exposure conditions is valuable in identifying those locations where stability samples should be drawn from.

## BIOLOGICAL INDICATORS

The use of biological indicators in sterilization has evolved. The first sterilization processes in the food industry were developed to eliminate *Clostridium botulinum*, which had been responsible for deaths in improperly processed canned foods. *Clostridium sporogenes*, a non-toxic anaerobic sporeformer with comparable resistance was identified as a suitable substitute for process development, validation, and monitoring. *Bacillus* spp. (and later *Geobacillus* spp.) spores with various levels of resistance (above and below that of the *Clostridia*) were introduced as biological indicators due to their ease of cultivation (they grow best in aerobic media), increased resistance to a variety of sterilization processes, and adaptability for use as suspensions and on various substrates.

The sporeforming *Bacillus* spp. and *Geobacillus* spp. have other characteristics that make them well suited for their use in sterilization process control. They are non-pathogenic; easy to produce, use and test; stable over extended periods; and substantially resistant to various treatments.

The commonly used biological indicators are indicated in Table 25-1. The use of other microbial strains is certainly acceptable. Bioburden microorganisms can be utilized as well for this purpose, and these are most commonly sporeforming microorganisms of the *Bacillus* species.

The purpose of the biological indicator is to directly assess the lethal conditions delivered by the process through their inactivation; however, it must be recognized that the BI serves as a measure of process performance, and while its destruction is generally sought in validation, that is not strictly required as the real concern is destruction of the bioburden during routine processing. Because the BI can be positioned on or in the load items at locations where physical measurements cannot always be made, it offers the most direct evidence of process conditions possible. The calculation of lethality, as discussed earlier, should always be considered as a secondary level assessment because it relies on numerous assumptions, including the linearity of the Survivor and Thermal Death Time Curves, accurate determination of D- and z-values, errors in physical measurement, and inaccuracies associated with spatial separation of physical measurement locations from the targeted surfaces, etc. Precedence should, therefore, be always given to the biological results when compared to physical data.<sup>7</sup>

The limitations of biological indicators in the evaluation and control of radiation sterilization procedures has been recognized for many years.<sup>8</sup> The use of *Bacillus pumilus* for this purpose is no longer considered appropriate as “worst case”. Current practices for radiation sterilization process control rely heavily on actual bioburden monitoring without the necessity for challenge placement within load items.

Dry heat depyrogenation processes are commonly validated using endotoxin indicators; however, there are no standards for their resistance to processing. Suggestions as to D- and z-values for various endotoxin preparations have appeared in the literature; however, the results of these determinations cannot be

**Table 25-1. Common Biological Indicator Microorganisms****Steam sterilization**

- *Geobacillus stearothermophilus* - ATCC 7953/12980\*
- *Bacillus subtilis* - ATCC 5230
- *Bacillus smithii* (*Bacillus coagulans*) - ATCC 51232
- *Clostridium sporogenes* - ATCC 11437/9372

**Dry heat sterilization**

- *Bacillus atrophaeus* (previously *Bacillus subtilis* var. *niger*) - ATCC 49337/9372

**Gas, liquid and vapor sterilization**

- Ethylene Oxide - *Bacillus atrophaeus* - ATCC 49337/9372
- Hydrogen Peroxide - *Geobacillus stearothermophilus* - ATCC 7953/12980
- Chlorine Dioxide - *Bacillus atrophaeus* - ATCC 49337/9372
- Ozone - *Geobacillus stearothermophilus* - ATCC 7953/12908
- Peracetic Acid - *Bacillus atrophaeus* - ATCC 49337/9372

**Radiation**

*Bacillus pumilis* - ATCC 27142 (no longer in current use, see below)

\* *Geobacillus stearothermophilus* is preferred for steam sterilization by direct contact, however its use in terminal sterilization is somewhat problematic because of its somewhat extreme resistance compared to possible bioburden microorganisms.

extended universally. Confirmation of endotoxin elimination must be established empirically, and correlation between  $F_H$  values and destruction of endotoxin is not currently possible.

**PHYSICAL MEASUREMENTS**

As sterilization processes rely on the exposure of items to extreme conditions intended to destroy microorganisms (and endotoxin) on them, physical measurements play an important role. The sterilization process equipment, depending upon its sophistication, will be equipped with instruments measuring (also recording) the essential process parameters. The most commonly measured variables are time, temperature, pressure, sterilizing medium concentration, and relative humidity, while others such as belt speed and agitation/recirculation rates may also be useful. Depending upon the equipment design, the measurements may be variously intended for control (the most critical application), confirmation/monitoring (useful in process evaluation), and informational (safety or convenience). During the validation exercise additional confirmation and information instruments may be added to provide greater information regarding the process conditions. Depending upon their use and type, the calibration frequency and accuracy/precision of these instruments will vary.<sup>10,11</sup> Radiation processes utilize a unique measurement system, the dosimeter that is able to directly measure the delivered radiation dose.

**MOIST HEAT STERILIZATION**

The most widely used sterilization medium is moist heat, which is utilized for in-process sterilization of stainless steel, glass, and elastomeric materials (Dry Goods Sterilization); liquids in sealed containers (Liquid Good Sterilization); and for sterilization of large processing systems (Sterilization-in-Place). As each of these presents some unique challenges to execution, they will be addressed independently after discussion of the elements common to all.

Sterilization processes using moist heat entail the exposure of microorganisms to liquid water at elevated temperatures, which is believed to irreversibly denature cell wall proteins. In the absence of liquid water, the destructive process occurs much more slowly (see dry heat sterilization below). Steam sterilization is thus best accomplished in the presence of saturation conditions where both gas (steam) and liquid (condensate) are present. Saturated steam is defined as a state of  $H_2O$  that has both gas and liquid phases present simultaneously and

has a fixed relationship between temperature and pressure (see Figure 25-4).

The use of saturated steam for sterilization provides an advantage not present with other sterilization methods. When saturated steam comes into contact with a cooler surface, condensation of the gaseous steam phase occurs with concurrent release of energy, which serves to rapidly heat the surface to temperatures where microbial death is more rapid. The heat released is the latent heat of condensation, which must be added to boiling water to effect the phase change to the gaseous state. The heat of condensation is approximately 2240 kJ/kg. This amount of energy is substantially higher on a mass basis than is available when heating is accomplished without a phase change, using either superheated water or steam. Nevertheless, steam sterilization can be accomplished just as expeditiously when the microorganism is exposed to superheated liquid water at elevated temperatures, and this is used to considerable advantage in the sterilization of liquid-filled containers (see below).

**STERILIZATION OF PARTS/HARD/DRY GOODS**

The simplest of steam sterilization process is that utilized for stainless steel and glass items that are often termed parts loads or hard goods loads. Many of the items to be sterilized in parts

**Figure 25-4.** Saturated Steam Curve. Courtesy of Fedegari Autoclavi.

loads have little or no sensitivity to the steam process, and thus these processes are accomplished almost entirely using an overkill approach. Since the items to be sterilized may have an internal void volume, i.e., filters, tubing, fill sets, needle lumens, etc., air removal is necessary to allow for direct steam contact with the surfaces to be sterilized. Older sterilizers may use gravity displacement; however, this results in substantially longer cycle times and is frowned upon by some regulators. Newer sterilizers utilize multiple pre-vacuums (typically 3-6) for more efficient removal of the air and may have *in-situ* air indication devices. Items are placed in the sterilizer with the heavier, larger items (as confirmed to be “worst case,” based upon the component mapping) on the lower shelves. Where the load items are identical (e.g., elastomeric stopper loads), a discernable cold spot within the chamber may be identifiable and cycle dwell time derived from that location. Sterilization dwell periods are established to assure that the “worst case” items (or with identical items the “cold spot” in the sterilizer) attain the desired PNSU. Drying of the items may or may not be required. Items that are predominantly steel will require less drying, while elastomeric items and those with complex internal geometry may require drying under vacuum. International standards (ISO 17665) require specific steam quality and temperature distribution for the sterilizing medium.

A typical batch type steam sterilizer used for this purpose is shown in Figure 25-5. These sterilizers are commonly installed between areas of different classification and are used to supply sterilized items into the higher classified environment for use in subsequent processing.

Sterilization of these load items requires condensate removal throughout, and items within the load should be oriented to permit drainage from them. Items with complex internal geometries (e.g., filling assemblies) and substantial mass (e.g., stopper bowls) present the greatest difficulty in this regard.

Load items are customarily wrapped to reduce the contamination risk in post-sterilization, and this must be accomplished in a manner that does not restrict air/condensate removal and steam penetration. The wrapping need not enclose the item, merely those opening through which air/condensate and steam must pass to attain the sterilization process objective. Specifically designed rigid containers can also be used for this purpose.

The efficacy of hard goods sterilization is demonstrated in validation studies using penetration thermocouples (positioned as described earlier in component mapping) and biological indicators. The biological indicators are customarily either paper strips inoculated with spore suspension sealed in glassine envelopes or other materials inoculated with a *Geobacillus stearothermophilus* spore suspension. Complete destruction of the biological challenge is expected as outlined in the overkill approach to cycle development, validation, and control.

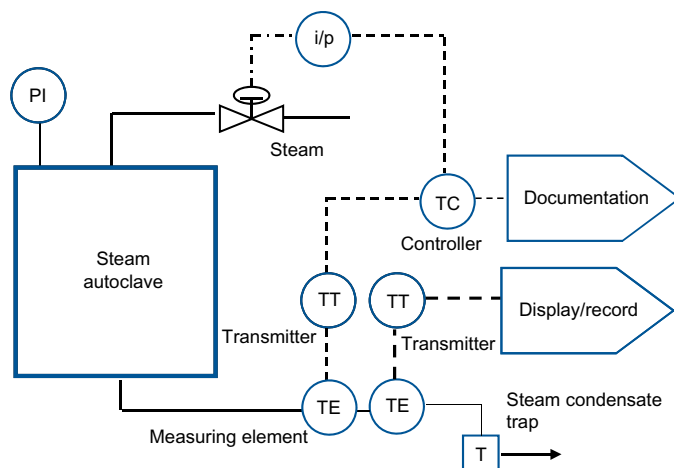

Figure 25-5. Typical Steam Sterilizer for Parts.

Sterilization cycle control is based upon confirmation of exceeding minimum time-temperature or  $F_0$  targets. This is customarily derived from physical data obtained from the sterilizer drain, which is usually the coldest point in the system.

## STERILIZATION OF LIQUIDS IN SEALED CONTAINERS

A seemingly similar process is used for the sterilization of containers filled with aqueous liquids. The outward similarity with parts sterilization is actually misleading. In these processes sterilization of the fluid is accomplished by heating of the container exterior, conduction through the container, and heating of the contents. The heat transferred superheats the aqueous phase and creates a moist heat condition in the container headspace. This type of process is utilized in a variety of situations including terminal sterilization of finished products, sterilization of in-process fluids, sterilization of laboratory media, and decontamination of liquid biological waste. Concerns that are generally common to all but the last of these are avoidance of adverse impact on items and maintaining container integrity throughout processing. Concerns relative to potential over-processing of these materials customarily adds an upper limit to the delivered lethality to ensure that essential product quality attributes are preserved. Heating closed containers to efficient sterilizing temperatures entails a commensurate increase in the internal pressure within the sealed containers, which presents a particular challenge in the post-cycle cooling. The sterilization of each container type is adapted to the specific needs of each and the available equipment.

### Terminal Sterilization of Finished Products

The methods used for the sterilization of products in their final container are often specifically designed for that purpose, and this carries through to the equipment utilized. On the largest scale of operation, the sterilizers are substantial in size and customized for this purpose. The sterilization equipment includes steam-air sterilizers (see Figure 25-6), steam-air-water (see Figure 25-7), immersion sterilizer and continuous sterilizer in addition to the simpler designs used for sterilization by direct contact (see Figure 25-5). Because these units are utilized for sterilizing finished, sealed containers, they are commonly located in unclassified environments with defined flows for non-sterilized and sterilized materials to avoid potential mix-up. The efficient use of these batch sterilizers limits them to the sterilization of a single lot of a single size product container.

The preponderance of available literature on sterilization of aqueous containers (and actually all sterilization practices) is derived from practices originally developed for this process, and while appropriate for this specific process, their adoption across the spectrum of sterilization should be approached with some degree of caution. Many of these concepts were described in some detail in FDA's 1976 draft regulation on Large Volume Parenterals.<sup>12</sup>

In execution of these processes, provision for cooling of the containers at the conclusion of the exposure dwell cycle is often provided, which is intended to reduce the adverse effect of extended heating that might occur during an unassisted cooling. The microbial and chemical quality of the cooling water in direct contact with the containers is an essential consideration. An incident in the early 1970s, in which contaminated cooling water was aspirated into parenteral containers, resulted in the regulatory mandate for validation.<sup>13</sup> This also entails maintenance of container integrity caused by stresses associated with increased differential pressure between the interior and exterior of container to prevent the ingress of cooling water. The use of air external over-pressure to assist in this is common place.

While the overkill sterilization method is preferred for items sterilized by direct contact, it is less commonly utilized in terminal sterilization, in which preservation of material properties is a primary consideration. The BB/BI and bioburden approaches are more appropriate in many applications. The validation of the process entails identification of both “cold” and “hot” spots

Figure 25-6. Steam-Air Sterilizer. Courtesy of Fedegari Autoclavi.

Figure 25-7. Steam-Air-Water Sterilizer. Courtesy of Fedegari Autoclavi.

to ensure that both minimum and maximum limits for sterilization are maintained.

### Sterilization of In-Process Fluids

Formulation and filling processes often require small amounts of sterile aqueous materials for use in formulation, pH/volume adjustment, lubrication, and cooling of equipment. The sterilizers used for this process are typically of the same design as those used for direct sterilization. The only consideration given to their application for this process is the use of slow exhaust in an attempt to mitigate container integrity problems associated with sterilizing sealed containers. These containers are often sterilized in mixed loads with items sterilized by direct contact with the steam. The quantity of material processed in this manner is typically small, and the materials being sterilized generally have little heat sensitivity. The cycle dwell time is established to provide the appropriate exposure to the “worst case” item, regardless of whether it is a wrapped item or a sealed container. The overkill approach is commonly used.

Sterilization of fluids is sometimes necessary prior to the final filling of the distribution container. This may be necessitated by the desire to limit microbial growth during processing or

by the impracticality, or impossibility, of terminal sterilization or aseptic filtration. An example of this is influenza vaccine, in which low temperature sterilization by filtration is performed weeks, sometimes months, prior to final filling. In this case the sterile state is maintained by preservatives, such as formaldehyde and thimerisol.

### Sterilization of Laboratory Media

The testing of many items requires a variety of sterile microbial growth media. Sterile media is available commercially in small containers; however, large users, especially those manufacturers having to validate aseptic filling operations using media fills and fermentation manufacturing, need to sterilize their own prepared media. Media for routine laboratory use may be prepared, filled into suitable bottles, and terminally sterilized in a batch-type autoclave. Larger quantities are prepared in stainless steel steam jacketed manufacturing tanks and sterilized in bulk. The sterilization processes are validated but have the advantage of being self-indicating after storage at ambient temperature. In laboratory settings these are processed in the same sterilizers used for direct sterilization in conjunction with the equipment and utensils necessary for the test. The “worst

case” item defines the process dwell period. In contrast with terminal sterilization processes, the sterilization of varying size containers with different media contents within them is commonplace. Laboratory sterilizers may provide some cooling capability (usually through the jacket) and air-overpressure because media represents their predominant use. The production of sterile media on a commercial scale resembles the terminal sterilization for finished products, with comparable equipment and controls. Over-sterilization of media can result in difficulty with preserving its growth promotion properties (and also makes the detection of growth more difficult), and thus BB/BI and bioburden methods are preferred.

### Decontamination of Liquid Biological Waste

Many biotech manufacturing processes generate biohazards waste materials as a bi-product of the fermentation process. For example, large quantities of egg waste contaminated with influenza virus are generated during the manufacture of vaccine. Additionally, the ubiquitous microbiological laboratory produces biological waste materials as a course of normal operations. These waste materials have to be rendered safe prior to disposal. This is usually accomplished by using sterilization in batch type steam autoclaves with an extreme overkill process. The effectiveness of steam coupled with the disadvantage of chemical agents (replacing a bio-hazard with a chemical hazard) make steam the sterilizing medium of choice for this application. Incineration has been criticized as a decontamination method, especially for polyvinyl chloride (PVC) intravenous bags, where dioxin and acids are produced upon combustion. Knowledge of the materials to be decontaminated, specifically the decontamination kinetics, is necessary. Where possible, D and z values for the thermally vulnerable factor should be determined. This is not always easily obtained. In one instance, the authors recall having to decontaminate rattlesnake venom that had contaminated syringe equipment and bottles at an antivenom manufacturing facility. In this case it was necessary to contact the source producer of the venom to obtain process parameters.

Bio-waste decontamination is a common need in smaller facilities and laboratories where spent media and materials that are potentially contaminated with hazardous biological materials. Maintenance of container integrity is a consideration; however, over-processing is not a concern but rather an intention, and thus the overkill method is always utilized.<sup>14</sup> In the most extreme installations, condensate from the sterilizer chamber is subject to overkill sterilization prior to discharge. Mixed items are commonly sterilized.

### STERILIZATION-IN-PLACE (SIP)

The production of sterile products requires sterile containers to contain the items. On the smallest scales of operation, this entails the availability of sterile vials, bottles, and flexible bags in the compounding and holding of the materials. As the scale of operation increases, fixed vessels are more appropriate as intermediate processing and storage of sterile materials prior to aseptic filling operations. In the preparation of sterile bulk drugs, liposome formulation, and other complex formulations, the process often requires a substantial number of large sterile vessels. Another common need is for the sterilization of lyophilization equipment (chamber and condenser) prior to each batch.

The sterilization of these vessels and chambers is accomplished using direct contact with steam in an overkill process that is adapted from that used in steam autoclaves for individual smaller items. While identical in the core process, destruction of microorganisms by exposure to moist heat at elevated temperatures, there is one substantial difference that changes the

situation rather dramatically. Where a steam sterilizer is employed, the end user generally purchases the unit from an experienced manufacturer that has had considerable experience in the design and fabrication of the sterilizer, as well as in the establishment of process sequences and controls that assure its reliable performance. All purchasers of sterilizers utilize similar cycles and follow essentially similar methods in their cycle definition, control, and operation. The differences in sterilizer usage at each firm largely relate to the contents of the sterilizer and not to its design details.

The use of sterilization-in-place processes forces a major shift in the role of the end user. SIP systems are typically comprised of a vessel (or vessels) designed for use in a specified manner. As the usage changes, the details of the vessel and its inlet/outlet connections will change as well. As the intent with SIP is to sterilize the surfaces of the equipment rather than its contents, the details of the systems design are increasingly important. The variety of process applications requires the end user to develop a physical layout and process sequence amenable to SIP that may be unique unto it. As many systems subject to SIP involve liquid handling, the basics of the vessel are substantially different from a steam sterilizer. The scale of SIP systems can vary substantially as well. The smallest systems might be intended for portable tanks of 100 L or less with minimal additional piping. At the other extreme, a very large SIP system might include multiple large vessels (up to 5000 L) with numerous process filters and valves.<sup>7</sup> This diversity of application entails unique approaches in design and execution.

The conventional starting point in SIP design is identification of the “sterile boundary,” that portion of the process system that is potentially exposed to sterile fluids. The boundaries of the system are commonly associated with filters and block valves. Once the boundary is defined, the design system requires many of the same considerations as sterilization in an autoclave. The most important of these include removal of air, removal of condensate, determination of a process sequence, and maintenance of system integrity post-cycle.

### Air Removal

The presence of air within an SIP system prevents direct steam contact with the target surface. Removal of air from the system is most commonly managed using gravity displacement (there are some firms that endeavor to emulate steam sterilizers and use pre-vacuums). The most challenging areas of the system are process pipe runs that may extend some distance from the main vessel or chamber. Process piping that is remote from the vessel should be opened at the end to facilitate steam penetration. Steam is generally introduced at the top of the system to facilitate the air's downward movement. The steam may be introduced via a sterilizing grade filter, though larger systems may also utilize a direct steam inlet to ensure adequate supply.

### Condensate Removal

In steam sterilizers condensate removal is accomplished by a single low point drain/steam trap, and the sterilizer is carefully leveled upon installation to be sure chamber is properly pitched to that location. The temperature control for the sterilizer chamber is commonly managed from a sensor in this drain line, which is colder than the chamber of the sterilizer. In an SIP system, especially those with a large number of inlet and outlet piping, there may be several low points where condensate could accumulate, and each must be opened to assure its removal. Process pipe should be sloped to facilitate the movement of condensate towards the low points. The SIP system may use steam traps, fixed orifices, or valves at each low point to restrict flow and build adequate steam pressure (and thus

<sup>7</sup>An example would be a bulk antibiotic process train that consisted of 5 major vessels, 10 sets of sterilizing grade filters for solvents and gases, the connecting piping and approximately 150 valves.

temperature). It is preferable to oversize these, as the loss of some steam is preferable to the adverse effect of condensate retention, which risks inadequate sterilization. The removal of air and condensate is accomplished by the same design elements with the only exceptions being vertical lines above the vessel chamber, where condensate flows downward into the vessel proper, while air might be removed at the top of the line farthest from the vessel.

### Process Sequence

When operating a steam sterilizer, the operator merely has to press a button or make a key stroke to initiate a process sequence of multiple steps that will perform the sterilization. Sterilizer manufacturers have defined the steps, their sequence, and details for optimum performance. In an SIP application, it is the end user's responsibility to provide comparable certainty with respect to the execution of the process. Given the diversity of design and complexity, the process execution details may vary substantially.<sup>7</sup> In larger facilities, SIP processes might be automated; however, the initial development of the software can be a trial and error exercise to define the proper timing and sequence of operation to assure reliable sterilization. Complete automation of SIP is uncommon; most automated SIP processes are supported by standard operating procedures requiring operator participation in the execution. The connection of spool pieces, hose connections, and adjustment of manual valves are the operator's responsibility. Fully manual SIP systems are also commonly used, in which the operator follows the SOP defined sequence.

### Post-Sterilization Maintenance

The last portion of any sterilization process, and SIP is no exception, entails the removal of the sterilizing agent and returning the items to a usable state. With wrapped goods or sealed packages, this is rarely a major concern. In an SIP process the now-sterilized system must be protected until ready for use. This is accomplished by purging the system of steam at the conclusion of the dwell period with pressurized air (or other gas), delivered through a sterilizing grade filter. Initially the pressure of the gas must be higher than that of the vessel at sterilizing temperature. The filter is customarily sterilized *in-situ* with the rest of the system to eliminate the need for an aseptic connection. Attention must be paid to ensure that no portion of the system is allowed to become negative to the surrounding environment as that might result in the ingress of contamination. The internal pressure is maintained until the system has cooled to ambient condition, at which time it can be reduced to a level adequate to protect the system until it is used in the process.

### SYSTEM DESIGN

The singular nature of many SIP systems makes the design of the system the most important concern of all with respect to their successful use. The design elements described below represent the more salient aspects of vessel and system design:

- The vessel should be rated for full vacuum and pressure to at least 130°C (and preferably higher).
- Inlet lines to the vessel should be kept short and installed vertically upwards to the extent possible.
- Where a line must extend some distance from the vessel, a bleed is usually required at the end of the line.
- Air and condensate bleeds should be placed at every low point in the system.
- Caution should be exercised in the use of jacket steam as it may result in a superheat condition within the vessel.
- Pipe runs should not be horizontal; the lines should be pitched (approximately 1/50-1/200) to provide for condensate drainage.
- Steam inlets to piping systems should be located at the high points in the system.
- Piping configurations shaped like the letters “W”, “M”, “V”, “U” or “N” should be avoided as each of these will have a low point at which condensate can collect.
- Where flexibility in piping arrangement is required, permanent piping manifolds with appropriate valves or spool pieces to make temporary connections should be employed.
- Avoid flex hoses where possible; where they must be used, ensure they are sloped to drain at one or both ends.

### FILTERS AND STERILIZATION-IN-PLACE

Within the context of SIP, the sterilizing grade filters used for steam, vent, process liquids, or gases require perhaps the greatest attention of all. They are a required part of virtually every installation to obviate the need for a post-sterilization aseptic connection. They are also prone to damage if subjected to excessive heat or pressure differential during the process, something that is rarely a concern with other physical components. The filter housing in larger systems is a small vessel in its own right, and the design considerations outlined above for process vessels apply. The porous nature of sterilizing grade filters makes them more difficult to sterilize as condensate within or adjacent to the membrane can have a deleterious impact on the sterilization efficacy.<sup>15</sup>

The outwardly similar process of sterilization-in-place may rely on the same lethal factors as steam sterilization in an autoclave; however, the uniqueness of system design where SIP is applied mandates an attention to design detail that transcends anything applied to autoclave designs. There are no universal solutions; each system must address the same fundamental concerns in a manner tailored for its unique configuration.

### DRY HEAT PROCESSES

Dry heat processing for sterilization and depyrogenation has been a pharmaceutical process staple for many years. Items sterilized are typically glass containers, either Small Volume Parenteral (SVP) primary packages or laboratory glassware. Manufacturing equipment, consisting of glass or stainless steel items, is also sterilized. The sterilizing medium is hot air, and the predominant heat transfer mechanism is convection. The simplicity of process and abundant, inexpensive sterilizing medium has provided for its longevity. The disadvantages of dry heat relative to pressurized steam are the low thermal capacity of air, absence of latent heat (as provided in moist heat by condensation of the steam), and low surface coefficients for convective heat transfer. Whereas steam provides both sensible and latent heat upon condensation, dry heat has only the sensible heat. Consider how inserting an unprotected hand into boiling water versus into an oven at 100°C would compare, and the difference in heat transfer rates is obvious. Moreover, air heat transfer limitations also make air cooling inefficient. As a consequence, dry heat processes require longer process times to accommodate both the slow “come-up-time” and cooling of the load items. Dry heat equipment usually employs forced convection in which filtered hot air is blown by internal fans across the items to be processed to mitigate to the extent possible the poor heat transfer properties of air. Thermal process evaluation follows that used for autoclaves with the exception that the kinetic property of the thermally vulnerable factor ( $z$ ) is 20°C for sterilization and approximately 50°C for depyrogenation. Note that this parameter, as in steam sterilization process evaluation, is a temperature difference and not a temperature. Also, the corresponding reference temperatures ( $T_b$ ) are 170°C and 250°C, respectively, rather than the 121.1°C used in steam sterilization process evaluation. The corresponding sterilizing value to  $F_0$  estimated for a dry heat process is called “ $F_H$ .” As described by Hitchens, bacteria enter a “self-preservation” state when deprived of conditions conducive to rapid growth.<sup>16</sup> This “resistant capsule” or spore contains the vital part of the bacteria and, when entirely dry, can be heated to a temperature

far above the boiling point of water without killing them. The biological challenge of choice for dry heat processes is the heat resistant bacterial spores of *Bacillus subtilis* at a typical concentration of  $10^6$  spores per challenge location. Typical D-values are substantially different for sterilization and depyrogenation. Dry heat sterilization at  $170^\circ\text{C}$  uses either *Bacillus atrophaeus* or *Bacillus subtilis* that have  $D_{170}$  of approximately 1–2 minutes. Depyrogenation at  $250^\circ\text{C}$  presents a very different picture: vegetative cell  $D_{250}$  values estimated at NMT 0.00005 minutes, with *Bacillus atrophaeus* and *Bacillus subtilis*  $D_{250}$  estimated at 0.002–0.003 minutes, while purified endotoxin is in the range  $D_{250}$  of 0.5 to 2.0 minutes.<sup>8</sup>

The efficacy of dry heat sterilization is dependent upon three primary variables and three secondary variables.<sup>17</sup> The primary variables are time, temperature and water content of the thermally vulnerable factor. The secondary variables are nature of adjacent support, nature of the system containing the thermally vulnerable factor (open or closed), and nature of the sterilizing medium. The secondary variables generally address whether the mode of heat transfer is convection or conduction. The moisture content of the cell appears to have an influence on mode of action of dry heat, which has been widely accepted as a denaturation of essential genetic material used for reproduction. There are two types of dry heat sterilizers, the batch type, consisting of ovens, and the continuous type, consisting of tunnels.

### Dry Heat Ovens

Ovens can be single door or double door; the latter type is used when processing equipment to be sterilized into a classified area. Items to be processed are placed upon trays directly in smaller ovens or on wheel-in tray racks for the larger units. A diagram of the air flows and major components for a typical unit is shown in Figure 25-8. Note that there are no “standard” designs for ovens, and the arrangement of the major mechanical components of the oven may vary from that shown.

**Figure 25-8.** Typical Dry Heat Oven cross section. Courtesy of Fedegari Autoclavi.

Heated air is blown across the trays from one side of the oven to the other and recirculated. Filtered (HEPA) make-up air and filtered exhaust ducts are provided to ensure no contamination along with maintaining a positive air pressure with respect to non-classified areas. Materials of construction are selected to provide ease in cleaning and preclude particulate matter generation, with stainless steel a common choice. Non-stainless steel components, such as motors and conduits, are external to the oven chamber and recirculation ducts. A disadvantage of batch type units is that items are exposed to a different process, based upon their location within the oven chamber. The load items may have aluminum foil covers or wrappings to prevent contamination with particulate matter. Primary glass containers are typically loaded upside down. Older ovens may have broken heating elements, broken insulators, or residue from broken glass containers hidden behind plenum walls that produce particulate matter. These particles are blown around by the high velocity circulation air, which contaminates the load. Effective preventive maintenance programs, along with current monitors on heating elements, are necessary to prevent particle contamination of previously washed load items. Qualification protocols should ensure that effective cleaning and preventive maintenance programs are in place for these units. Typical temperature plots are shown in Figure 25-9.

Unlike some autoclaves, the dwell period start condition is based upon the heating medium temperatures and not load temperatures. The controlling temperature probe (thermocouple or resistance temperature detector) is typically located on the cool side recirculation plenum wall. Note in Figure 25-9 that the minimum load, consisting of a single slowest to heat item, shows the characteristic of having the process timer start well before the load is at temperature, considerably lower than the maximum load at the same point in time. It is essential that validation studies include the minimum load and that it not be an “empty chamber.” Maximum and minimum loads can be used to establish the process for intermediate size loads, provided all components are identical. In mixed loads the load size and configuration must be evaluated for each load. When ordering dry heat ovens, it is important to ensure that they are specified with thermocouple access ports for process development, determination of the cold spot(s), and process validation. Overkill processes (12D, 15D in the EU) are typically used, in which the D-value used is that of the resistant biochallenge rather than an actual naturally occurring bioburden. Glass containers are extruded at  $1200^\circ\text{C}$ , and both bioburden and pyroburden arises from point type contamination after processing, which is difficult to detect with sampling schemes.

**Figure 25-9.** Typical Oven Cycle.

<sup>8</sup>Accurate determination of  $D_{250}$  values for these microorganisms is not possible because their death is so rapid at the elevated temperatures.

## Depyrogenation Tunnels

Depyrogenation tunnels are continuous processing units used for use for primary glass containers, typically installed following a washing operation and providing in-feed directly to an aseptic filling operation. An advantage of the continuous process is that each container sees essentially the same process. Units using wide feed belts do have some variation across the belt, but this is small compared to the typically wider temperature distribution experience with batch ovens. Radiation is also a significant heat transfer mechanism in these units, in addition to laminar air flow. Typical units have three sections consisting of heat-up zone, process or dwell zone, and cooling zone (see Figure 25-10).

Components are slowly conveyed along on a stainless steel belt which exposes them to the three zones. Contamination is prevented by using filtered air and the use of positive pressures relative to adjacent non-classified spaces. The target thermally vulnerable factor in depyrogenation processes is lipopolysaccharide, a fever causing bacterial cell product. Commercially available biochallenge material is available for process validation studies.<sup>18</sup> Unlike bacterial contaminants in steam sterilizers, first order reaction kinetics are not easily applied to these chemical entities and dry heat processes that have wide temperature distributions. A widely used empirical reaction kinetics equation<sup>19</sup> is shown below:

$$\log Y_0 - \log Y = AB10^{Cx} \quad (9)$$

Where  $Y_0$  is the initial concentration,  $Y$  is the concentration after the depyrogenation process, and  $A$ ,  $B$ , and  $C$  are constants for the selected temperature. The parameter  $x$  is the dry heat sterilizing value  $F_H$  described above. A disadvantage of this equation is that for a given temperature, a maximum log reduction of the initial concentration is observed, regardless of the level of the initial concentration or the magnitude of  $F_H$ . For example, for 250°C there is a maximum log reduction of slightly above six. As in ovens, overkill processes are employed; in this case, temperatures above 250°C are used to deliver a process equivalent to 30 minutes at 250°C within the process section. Belt speeds of 45 cm (1.5 ft) per minute are typical.

In summary, dry-heat processes are conducted to provide sterilization and/or depyrogenation. The latter typically

requires 250°C for 30 minutes, or equivalent. Sterilization can be accomplished at 170°C ( $T_b$ ) with process times usually 20 minutes following a come-up time to achieve the process temperature ( $T_1$ ), which usually exceeds the reference temperature. Equipment is selected, validated, and maintained to prevent contamination with particulates and/or microbes during and following processing.

## GAS, LIQUID AND VAPOR STERILIZATION

Sterilization processes entail the exposure of microorganisms to conditions that destroy their viability. A variety of chemical agents are able to kill microbes by chemical reactions, many of which are oxidation related. The number of agents that can accomplish this in a rapid manner is extensive, and many of the agents are lethal in both the gaseous and liquid (water solution) state. Because the killing mechanism with these agents is based upon a chemical reaction between the chemical agent and the microorganism, first order kinetics as described in the Arrhenius equation (see Equation 10).

Arrhenius equation

$$-k = Ae^{-E_A/RT} \quad (10)$$

Where

$k$  = Reaction rate

$A$  = Prefactor

$E_A$  = Activation energy

$R$  = Gas constant

$T$  = Absolute temperature

The rate of kill is predominantly a factor of the agent concentration, with temperature and humidity playing substantially less influential roles.<sup>10</sup> The basis for all of the gaseous agents is ethylene oxide (ETO) where a substantial body of data has been developed, and the practices for ETO have largely defined the methods used for the other gases. Essentially identical approaches can be used for liquid sterilization as these operate in a single phase as well. The fundamentals of vapor processes differ somewhat because of the two-phase aspect of their delivery and action. Nevertheless some parallels to the base ETO process can be useful in those applications. These processes

Figure 25-10. Typical Dry Heat Tunnel. Courtesy of Fedegari Autoclavi.

<sup>9</sup>Studies with ETO sterilization have demonstrated a  $z$  value of approximately 32° C and little difference in microbial resistance across relative humidities between 40-90% (Gillis & Mosely). There is a paucity of data on other agents, which neither supports nor repudiates the ETO experience.

can benefit from mixing or agitation in all phases of the process because mixing serves to improve uniformity.

## Gas Sterilization

### Ethylene Oxide

The most widely used gaseous sterilization agent is ethylene oxide ( $C_2H_4O$ ), which kills by alkylation of the nucleic acid within the microorganism.<sup>20</sup> The range of lethal concentration begins near 300 mg/L and extends to approximately 1200 mg/L as higher levels have not been shown to result in substantially shorter process times.<sup>21</sup> At one time ETO sterilization processes, whether in sterilizers or for lyophilizers, were commonly found in pharmaceutical plants. Recognition that ETO is both a carcinogen and mutagen led many pharmaceutical firms to rely on contract sterilizers for items requiring ETO sterilization. The violently explosive nature of ETO was another consideration in its displacement from pharmaceutical production sites. ETO is widely used for medical device sterilization, and the preferred methods are largely optimized for that application. Device sterilization is accomplished with the device in its final bulk package (ordinarily in pallet configuration), including multiple layers of packaging. Device packaging often entails Tyvek® lidded plastic trays with additional fiberboard/corrugate. In order to effect sterilization of the device, ETO must penetrate all of the layers. For effective kill adequate humidity must also be present. A typical ETO cycle (using 100% ETO) for medical devices would include the following steps:

- Pre-Conditioning – The load items are exposed to elevated humidity (90-95%) to increase moisture levels on the device surface prior to introduction to sterilizer. The pre-conditioning makes the microorganisms more susceptible to ETO. In temperate climates, this step is essential to ensure a consistent process despite seasonal variations in humidity that would otherwise alter process lethality. This step is performed in an area specifically designed (and qualified) for this purpose.
- Re-Conditioning – After transfer from the pre-conditioning area to the sterilizer, reconditioning in the sterilizer may be performed to re-humidify those peripheral portions of the load that may have dropped in humidity while in transit. This would be accomplished by low pressure steam injection. This step is optional.
- Evacuation – To mitigate the explosive potential of ETO sterilization, air is removed from the chamber. Unlike steam sterilization, in which air removal is sometimes carried to excess, the removal of air must be tempered with the desire to maintain adequate humidity within the load. Thus a single pre-vacuum is generally performed as desiccation of the load should be avoided.
- Humidification – The replacement of moisture within the load follows to return the load to the desired state.
- Charge – ETO gas and nitrogen are added to attain the desired concentration and pressure for the process dwell.
- Exposure – The lethal conditions are maintained for the pre-established process dwell period with ETO gas make-up to maintain the target concentration.
- Exhaust – The ETO/nitrogen mixture is removed from the chamber to make the materials safe for handling during the unloading process. The exhaust cycle may include multiple pulses of nitrogen and eventually air.
- Unloading – The sterilizer is unloaded and items transferred to the post-conditioning area. Operating personnel performing this task may need to wear personal protective equipment to minimize their exposure to trace amounts of ETO diffusing from the materials.
- Post-Conditioning – The load is aerated so that levels of ETO (as well as common process byproducts ethylene chlorohydrin and ethylene glycol) can be reduced to levels safe for the intended use. FDA established its expectations for these residuals in 1978.<sup>22</sup> This remains the only

published expectation with respect to acceptable residual levels. The aeration area is typically supplied with 100% fresh air to aid in residue removal. The external aeration stage can last in excess of eight weeks.

## Cycle Development, Validation, and Routine Process Control

The essentially linear death curves associated with ETO sterilization facilitates cycle development. There are two basic approaches utilized to establish the process D-value: fraction negative method and graduated spore strips. These can be applied in either a smaller test chamber or the production sterilizer. In the fraction negative method, a series of short duration test cycles are performed, in which some, but not all, of the biological indicators are inactivated. Graduated BIs exposed to an abbreviated cycle provides a similar assessment of lethality. The results of either of these studies can be utilized to determine the D-value for the microorganism within the load at the tested conditions.<sup>23</sup> The process dwell time that will be established is a multiple of the D-value.

The oldest approach to establishing and validating the process is the half-cycle, in which the D-value is multiplied by 12 to determine the half-cycle process dwell period. The load is challenged in triplicate with multiple biological indicators (from the same lot as evaluated in the D-value study) at locations across the full load. The complete inactivation of the indicators supports the process lethality. The routine sterilization cycle is defined as twice the cycle (thus the name half-cycle) in which the BIs were all killed, with the belief that this additional dwell time is more than adequate to support variations in gas concentration, relative humidity, and temperature during routine processing as compared to the conditions demonstrated in the half-cycle studies (see Figure 25-11).

An alternative approach to cycle development is the bracketing approach in which the process dwell as established by the half-cycle defines one side of the process bracket. The other side is defined by confirmation that materials exposed to increased gas concentration, higher humidity, higher temperature, and longer process dwell are acceptable for use. Useful where process parameters can be more narrowly controlled, this method results in generally shorter process times, which can be important to key material attributes and/or sterilizer capacity (see Figure 25-12).

Figure 25-11. Visual Depiction of Half Cycle Sterilization.

Figure 25-12. Visual Depiction of Bracketing Approach.

Routine process for ETO processes consists of process monitoring of the parameters along with each cycle biological indicator testing. Fully parametric release is also possible, and this is discussed later in this chapter.

### Other Sterilizing Gases

There are a number of gases with demonstrated lethality against microorganisms other than ETO. Many of these gases, including hydrogen chloride (HCl), chlorine ( $\text{Cl}_2$ ), sulfur dioxide ( $\text{SO}_2$ ), and sulfur trioxide ( $\text{SO}_3$ ), are unfortunately too corrosive and/or hazardous for easy application in a pharmaceutical plant.<sup>10</sup> Less chemically aggressive but highly effective are such gases as chlorine dioxide ( $\text{ClO}_2$ ), ozone ( $\text{O}_3$ ), and nitrogen dioxide ( $\text{NO}_2$ ).<sup>24,25,26</sup> Each of these agents was developed and commercialized at least in part as an alternative to ETO, and thus the basic approaches to their use is similar. Pre-humidification prior to chamber loading is not a part of these processes, but each process does have an in chamber humidification step.

#### CHLORINE DIOXIDE

This moderately stable gas is prepared by chemical reaction in proximity to its point of use. It is less penetrating than ETO and appears to be less readily absorbed by materials and thus is easier to remove post-treatment. Chlorine dioxide is lethal in the range 5-30 mg/L at ambient temperature and humidity levels of 60-75% RH. Chlorine dioxide levels can be measured using relatively inexpensive UV sensors, facilitating routine process control. Exhaust from the sterilizer is chemically scrubbed to prevent atmospheric release.

#### OZONE

This unstable gas is manufactured just prior to introduction into the chamber by passing pure oxygen through an electrical field. It is also less penetrating than ETO, and because of its instability, comparatively easy to remove post-cycle. Ozone is effective at concentrations between 2-10% at room temperature and relative humidity levels 80%.

#### NITROGEN DIOXIDE

This gas is effective across the range of 8-21 mg/L at ambient temperature in the presence of humidity.<sup>27</sup>

### Liquid Sterilization

Historically, chemical sterilization was used as a direct additive to vaccine formulations as a super preservative, and formaldehyde was used for this purpose. Formaldehyde is still used, along with the mercury-containing preservative thimerisol in some current vaccine manufacturing, as a supplement to filter sterilization. Purified water systems can be sterilized by hypochlorite or ozone where high temperature sterilization is not possible. Contact time and concentration are the critical process parameters in chemical sterilization. Hydrogen peroxide solutions are used to in-line sterilize packaging components for form fill and seal aseptic filling operations. Sufficient dwell, or contact time, is needed to assure sterility. Following sterilization, the hydrogen peroxide solution must be neutralized and removed. This is accomplished by exposure to ultraviolet light, which may provide an additional lethal effect. Another common application is the use of dilute NaOH solutions for the cleaning (and effectively the sterilization) of chromatography columns.

Sterilization in the liquid phase obeys the same precepts as other sterilization processes and closely resembles gas sterilization. Agents effective as sterilants in aqueous solution include acids, bases, aldehydes, and various oxidizing agents.<sup>14</sup> The more commonly used materials are hydrogen peroxide and glutaraldehyde in various concentrations. These are chosen because of their generally good compatibility with stainless steel, glass, and many plastics easing the selection of process equipment. The process can be as simple as immersion of materials in the tray or an automated system in a closed vessel. Regardless of the system, the microbial destruction occurs in the same linear fashion observed with gas phase sterilization. There is a paucity of kill rate data for liquid chemical sterilization, but the simplicity with which the process can be executed enables it to be generated rather easily. The most resistant microorganisms are believed to be bacterial spores. The only difficulty associated with the use of liquid chemical sterilization is the need to rinse and/or deactivate the chemical agent from the system or item and maintain its sterility before it can be used.

### Vapor Sterilization

The gas and liquid sterilization processes described above operate similarly despite the difference in phase. When the same agent can be delivered as a gas or dissolved in a liquid, there are differences in the lethal rate. There are at least two major reasons for the lethal rate difference: the concentration of the chemical agent is generally higher in the liquid phase, and moisture levels in liquids are always higher. Where data are available on the same material, the kill rate in the liquid phase is typically more rapid. Vapors are loosely defined in the scientific community:

- Barely visible or cloudy diffused matter, such as mist, fumes, or smoke, suspended in the air.<sup>28</sup>
- Any substance in the gaseous state, the condition of which is ordinarily that of a liquid or solid.<sup>29</sup>
- Vapor is a condensable gas.<sup>30</sup>

Clearly vapors are combinations of both gas and liquid phases. At their entry point they may resemble pure gases, but when exposed to lower temperatures, as is commonplace in ambient temperature applications, condensation of the less volatile components of that vapor can be expected. Most sterilizing vapors are solutions of a lethal chemical material in water. There are three vapors of interest to sterilization scientists: hydrogen peroxide, introduced as hot gas slightly above the boiling point of  $\text{H}_2\text{O}_2$  (108°C for a 35% solution in water); peracetic acid, sprayed on as a room temperature liquid into closed chambers:

<sup>10</sup>Note all of these chemicals agent listed are effective as antimicrobials in aqueous solution as well; however, those that form strong acids in solution are rarely used exclusively for that purpose.

and formaldehyde, added as either as a heated gas or evaporated from its solid counterpart paraformaldehyde. Regardless of the vaporous agent, the potential for the presence of two phases in the system to be sterilized must be recognized. The inability to define the sterilizing conditions for 2 phase systems effectively eliminates a D-value determination and the attendant process control opportunities that affords. Vapor sterilization processes have to be established and validated empirically using biological indicators since parametric measurements cannot be relied upon to fully substantiate lethality. Achieving a consistent process with a vapor process mandates that the vapor be well mixed within the chamber to minimize stratification and the consequent concentration variation that the temperature differences between the surfaces and the vapor will create.

As vapors will have the lethal agent present in both phases, it can be useful to visualize the sterilization process in parallel (See Figure 25-13). There are no dimensions on this image since the slopes of the survivor curves are not well defined. It must be understood that the gas and liquid phases within the system are in equilibrium, and the concentration of the lethal material in each phase differs.

Line (A) in Figure 25-13 represents the survivor curve for microorganisms exposed to gas throughout the process with the slowest kill rate, as might be expected due to its lower concentration. Line (B) depicts the more rapid kill attainable in the liquid phase. Lines (C) and (D) represent locations where the microorganism sees both gas and liquid at some time during the process. Considering the entire system, an overall survivor curve considering a large number of microorganisms located throughout the chamber with varying phase exposure would reveal a "band" bounded by lines (A) and (B) rather than a single best-fit line (see Figure 25-14).

If vapor sterilization is to be adequately controlled, the inherent uncertainty of the rate of kill must be understood. The absence of metrics for the X and Y axis in these images is intentional; the rates of kill will vary with respect to several factors including concentration of the agent in the initial solution, rate of agent feed, temperature of the inlet vapor, temperature range across the chamber, and initial humidity level of the chamber. A suggested means for the empirical cycle design, validation, and routine control of vapor sterilization is depicted in Figure 25-15.

The execution of validation studies less lethal (as proof of sterilization efficacy) and more lethal (as proof of material compatibility) than the routine can be used to substantiate its acceptability. This mimics the bracketing approach described

Figure 25-13. Bi-Phase Survivor Curves.

Figure 25-14. Vapor Phase Survivor Curves.

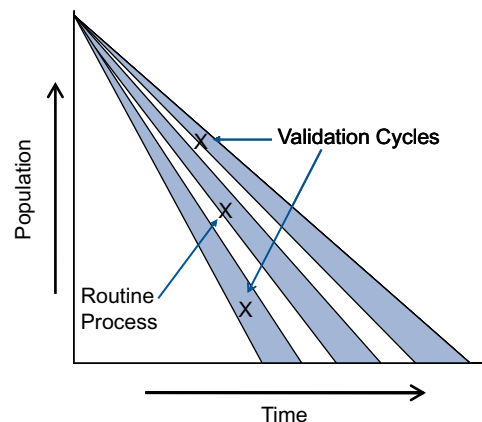

Figure 25-15. Validation Approach for Vapor Sterilization.

above for gas sterilization (see Figure 25-11) and is particularly appropriate for vapor sterilization where D-values are not available.

## RADIATION STERILIZATION

Radiation is often chosen out of necessity and/or convenience as a sterilizing medium in pharmaceutical and medical device manufacturing and is increasingly used for plastic materials. There are three main types used: ionizing gamma ( $\gamma$ ) irradiation from cobalt-60 ( $^{60}\text{Co}$ ), ultraviolet (UV) radiation from lights, and electron beam from cathodes. There are other less used processes, such as microwave, X-ray, and high intensity visible light. The mechanism of sterilization involves the formation of free radicals and excitation of double covalent bonds, causing chemical reactions that degrade the reproductive systems of the target microorganisms. The different forms of radiation differ in the extent of their penetration through materials that will result in different process duration and control. Nevertheless, they achieve sterilization by the same basic principles and are validated in essentially the same way. Recall that it requires a three-inch thickness of lead to stop gamma radiation. Electron beam is much less penetrating, and ultraviolet light can be stopped by almost any thickness of an opaque material. Processing for each sterilizing medium varies to eliminate idiosyncratic disadvantages, such as shadow effects and dose variation, while maximizing penetration.

Out-sourced gamma ray terminal sterilization is attractive because often it can be performed for products already in tertiary packaging (corrugated cardboard shipping containers). Compare this to the costs and inconvenience of operating a sterile filling and packaging facility, and the choice appears obvious. The USP<sup>2</sup> and EU<sup>31</sup> Pharmacopoeia originally recommended doses of 25 kGy and 32 kGy to assure a sterility

assurance level (SAL) of  $10^{-6}$ .<sup>8</sup> However, the major concern with the use of gamma ray sterilization is its effect on the product. The various forms of radiation degrade materials to varying levels dependent upon exposure levels. Dosimeters are made of plastic material (Harwell red Perspex 4034 dosimeters), and the dose is measured by a color change from dark red to darker red, which attests to the degradation effects of the radiation. The processing usually consists of palletized product containers moving into a chamber and remaining stationary or product in carriers, traveling around the source in a train-like conveying system to expose the product from all angles to ensure maximum penetration and increase delivered dose uniformity. Dosing can be highly variable, especially remote from the source. In a recent study Ameri *et al.*, evaluated and compared terminal sterilization of a parathyroid hormone transdermal micro-projection delivery system by gamma or e-beam versus aseptic processing.<sup>32</sup> In developmental work they determined that a 21kGy dose of gamma radiation was necessary to have a SAL of  $10^{-6}$  for and average bioburden of 88.7cfu. They found degradation after three months on stability testing for both irradiation and e-beam terminal sterilization and concluded that aseptic processing was the only feasible procedure that could provide two-year product stability. Even if the active is stable, the other ingredients may be adversely affected. In a recent study by Hegge *et al.*<sup>33</sup> on alginate foams containing curcumin, the active ingredient was exposed to a measured dose of 31kGy. The level of active was not affected; however, the absorption spectra differed from the pre-sterilized product, and a decrease in curcumin release was observed, indicating that the excipients were adversely affected by the treatment.

UV light is utilized primarily as an additional microbial control for water systems in pharmaceutical manufacturing. Some USP Purified Water systems and Water for Injection systems have supplemental UV light treatment units. Wavelengths of 253nm to 264nm are used to control bioburden levels in the recirculation loop. UV is also used to sterilize containers or as a treatment to remove a vaporized hydrogen peroxide sterilization treatment. The advantage of UV is that it can be used for continuous processing. The primary disadvantage of UV is the shadow effects and degradation of the UV source with time. The latter requires diligent preventive maintenance for production systems.

In summary, gamma sterilization is utilized when stability of all components is not an issue or where product cannot withstand heat or be aseptically sterilized and packaged. Electron beam does not have the penetration of gamma, but can be set up for semi-continuous processing. UV is applicable for continuous processing, primarily in water and packaging applications. Stability using any radiation process must be assessed, even if products and components are heat stable. Some materials experience a dramatic drop off in physical/chemical properties that cannot be predicted in accelerated stability studies; therefore, real-time data are much preferred.

### STERILIZATION BY FILTRATION

Filtration removes particles from fluids. Unlike the other sterilization processes described in this chapter, sterilizing filtration relies on physical removal of microorganisms from the material to be sterilized; it does not kill or destroy the microorganisms. Sterilizing filtration is defined as the ability to remove a minimum of  $1 \times 10^7$  per  $\text{cm}^2$  of *P. diminuta* (currently classified as *B. diminuta*) when the filter is challenged under specified conditions.<sup>34</sup> Filtration is used where solutions may be degraded by other sterilization processes, such as autoclaving. Careful selection of the filter and filtration conditions is necessary to ensure that the process will yield a sterile filtrate.

### History

Filtration as a mechanism for sterilizing pharmaceutical solutions was developed in the early part of the last century because of the need to sterilize heat-sensitive products. Three technologies were pursued: porcelain filter cartridges, asbestos-cellulose layers, and microporous membranes.<sup>35</sup> Filters made of porcelain and of asbestos-cellulose layers function as depth filters; that is, particles are retained by entrapment within the filter matrix. The primary retention mechanism of microporous membranes is sieve retention, wherein the particles are too large to fit through the pores of the filter. Porcelain filter cartridges were used to sterilize antibiotics; however, the filters were difficult to clean, and there were concerns about cross-contamination. Additionally, integrity testing that could be related to microbial retention was not possible. Seitz EK (*entkeimung* “germ removal”) asbestos-cellulose filters were used through the mid-1970s until the FDA’s Good Manufacturing Practice (GMP) regulations prohibited the use of asbestos and fiber-releasing filters in parenteral manufacture.<sup>36,37</sup> As with porcelain filter cartridges, definitive integrity testing was not possible. Filters in the form of collodion membranes were manufactured by filter users in the early 1900s. This led to the development by Zsigmondy (Sartorius-Werke, Göttingen, Germany) of the first commercially successful membrane filter in 1929. Reliable integrity testing of these membrane filters was possible, allowing sterilizing filtration processes to be validated, another requirement of the GMP regulations. Flat-stock membranes have largely been replaced in sterilizing filtration applications by pleated cartridges, increasing throughput and minimizing handling concerns for fragile membrane materials. The use of single-use systems in the manufacture of high-value and highly potent pharmaceutical and biopharmaceutical products has facilitated the increasing use of pre-sterilized capsule filters (Figures 25-16 and 25-17).

### Types of Filters and Membrane Materials

Filters for sterilizing pharmaceutical solutions are available in a variety of configurations and membrane materials. While

**Figure 25-16.** Cartridge filter used with a single-use production system. Courtesy of Sartorius Stedim Biotech.

<sup>11</sup>This recommendation was removed from current USP 34 NF 29.

**Figure 25-17.** Capsule filter. Courtesy of Pall Corporation.

**Figure 25-18.** Cartridge filters. Courtesy of Pall Corporation.

flat-stock membranes continue to be used for small-scale filtration and bacterial retention studies, cartridge filters generally are used for production-scale sterilizing filtration because cartridge filters, either singly or in cartridge arrays, have the necessary flux and capacity to avoid the necessity of replacing them during the filtration process, potentially compromising the sterility of the filtration train (Figure 25-18).

Membranes with pore size ratings of 0.2  $\mu\text{m}$  are typically used for sterilizing filtration, although 0.1  $\mu\text{m}$ - and 0.45  $\mu\text{m}$ -rated filters are sometimes used—0.1  $\mu\text{m}$ -rated filters for long-duration filtration of products that may contain small, water-borne microorganisms such as *Pseudomonas* sp., while 0.45  $\mu\text{m}$ -rated filters can be used where the filtration conditions require high flux and filtration capacity and where it has been demonstrated that the pre-filtration bioburden can be consistently removed under the validated filtration conditions.

Microporous membranes are composed of various polymers, including cellulose acetate, polysulfone, polyethersulfone,

polyethylene, polypropylene, polyvinylidene fluoride, and polyamide. Each of these membrane materials has properties that lend its use to a particular application.<sup>38</sup> For example, cellulose acetate exhibits low adsorption and high flow rates, but it has limited pH compatibility; polyamide (Nylon® 66) has good mechanical strength and broad pH compatibility, but it has high nonspecific protein adsorption and low hot water resistance; polyethersulfone exhibits high flow rates and throughput and broad pH compatibility, but it has limited solvent compatibility and moderate to low nonspecific adsorption, depending on surface modifications; and polyvinylidene fluoride has low nonspecific adsorption and good solvent compatibility, but only moderate flow rate and throughput, and because it is made hydrophilic by surface treatment, the membrane may lose hydrophilic properties during the filtration process. Studies should be conducted to ensure that the chosen membrane material is compatible with the product to be filtered, has the necessary flow rate and capacity, and is able to withstand the filtration conditions, including flow rate and pressure differential. The membrane and its housing should not adversely affect the product by introducing leachables or by adsorbing product components beyond established limits. Examples of filters and filter configurations are shown in Figures 25-19 and 25-20.

### Retention Mechanisms

Filtration removes microorganisms from a liquid by two primary mechanisms: sieve retention and adsorption.

Sieve retention involves the capture of a microorganism that is too large to pass through a filter pore. It relies on physical blockage of particles that are larger than the pores they encounter. Although sieve retention is generally independent of filtration conditions and the microbial challenge level, factors such as fluid composition and filtration conditions can affect sieve retention. High ionic strength and osmolarity can draw water from

**Figure 25-19.** Large capacity, multiple cartridge, filter housing. Courtesy of Pall Corporation.

**Figure 25-20.** Assembling a cartridge filter and its housing. Courtesy of Sartorius Stedim Biotech.

microbial cells, reducing their size. High pressures and flow rates can “squeeze” microorganisms through the filter’s pores.

Adsorption retention is a charge-related phenomenon wherein microbial cells are captured by the surfaces they encounter without being physically restrained. Examples of the forces involved include electrical attractions, such as valence and ion-exchange, van der Waals forces, and hydrogen bonding. Adsorption is influenced by the composition of the membrane, the properties of the filtered fluid, the filtration conditions, and the number and type of microorganisms present in the fluid.

It is important to consider both mechanisms when developing and validating sterilizing filtration processes.

### Validation

Good manufacturing practice regulations require validation of any sterilization process. Sterilizing filtration is validated in several stages, and it involves verification of microbial retention and determining that the filter does not contribute leachables to the product beyond established limits and that the filter does not unacceptably absorb formulation components.

Filter manufacturers ensure that membranes of a particular pore-size rating and composition are able to retain a microbial challenge of  $1 \times 10^7$  per  $\text{cm}^2$  of effective filtration area. This standardized testing is accomplished using ASTM F 838-05<sup>39</sup> which specifies the use of *B. diminuta* as the challenge microorganism and details the process conditions and apparatus to be employed. Successfully passing this test enables filter manufacturers to correlate integrity test results with microbial retention and to set integrity test specifications to be used for in-process production control and quality assurance purposes.

Filter manufacturers usually conduct a series of tests to determine the extractable and leachable elements of the microporous membranes and other filtration components, such as O-rings, gaskets, and housing materials.

Filter users must also validate the sterilizing filtration process to ensure it is capable of removing all microorganisms from the process stream under actual conditions of use and to establish a correlation between microbial retention and the integrity test value of the filter under actual conditions of use. Typically, *B. diminuta* at a level of  $1 \times 10^7$  per  $\text{cm}^2$  of effective filtration area in the product is used for this challenge. It is known that filtration efficacy can be affected by many factors, including the type and number of microorganisms to be removed, the properties of the liquid to be filtered, the membrane material, and the filtration process parameters. The surface tension, pH, and ionic strength of the liquid to be filtered can strongly influence microbial retention, while aspects of the filter that can impact the filtration include filter area, nominal pore size, pore-size distribution, filter membrane thickness, porosity, membrane polymer, filter pleat density, non-woven support layers, electrostatic charge, and hydrophilic nature of the filter membrane. The filtration process parameters influencing microbial retention include temperature, flow rate, differential pressure, and pressure pulsations. If the challenge organism is not viable in the product, simulated product (e.g., adjust pH, remove preservative) can be used for the validation testing. Another option is to use product indigenous bioburden microorganisms for the validation testing. In addition to microbial retention testing, leachable and adsorption studies are conducted with the product of interest to ensure the filtration process does not alter the product beyond acceptable established limits. PDA Technical Report No. 26 contains comprehensive information on appropriate validation strategies for sterilizing filtration.<sup>40</sup>

### Integrity Testing

The integrity test values established during validation of the filtration process are used prior to and after filtration to ensure the filter is integral and capable of retaining microorganisms under the intended conditions of use. Bubble point and diffusive flow are two commonly used integrity tests (Figures 25-21 and 25-22).

**Figure 25-21.** Automated integrity test unit. Courtesy of Pall Corporation.

**Figure 25-22.** Performing an automated integrity test on a cartridge filter. Courtesy of Sartorius Stedim Biotech.

The bubble point occurs when a gas displaces a wetting liquid from the largest membrane pores as gas pressure is slowly increased, resulting in bulk gas flow through those pores. The flow is evidenced by a steady stream of bubbles through a column of water on the downstream side of the membrane. There is a direct correlation between microbial retention and bubble point. Numerous studies have demonstrated that when the microbial reduction ratio is plotted against the bubble point a line of constant slope results.<sup>41</sup> The bubble point is independent of the membrane surface area; however, diffusive flow through high surface area filters can mask the true bubble point. The bubble point test is easy to perform on small to medium-scale filters, the test time is short, and temperature effects are minor. Manual bubble point testing requires manipulation of downstream side of filter and is subjective.

Diffusive flow testing measures gas flow through a wetted filter at a constant pressure, usually about 80% of the bubble point. Diffusive flow is proportional to the differential pressure of the test gas, the diffusivity of the test gas in the wetting liquid, the thickness of the wetting liquid, the porosity, void volume, of the membrane, and the effective filtration area.

Unlike the bubble point, diffusive flow testing does not measure gas flow through only the largest set of wetted pores; therefore, diffusive flow does not correlate directly with microbial retention. However, bacterial challenge tests with a series of filters having decreasing diffusion rates show that a point exists where sterile filtrates occur. Diffusive flow testing is highly sensitive, especially for larger surface area membranes. Larger pores or flaws may be detected by thinning of the liquid layer. It is useful for membranes with small pore sizes (i.e., 0.1  $\mu\text{m}$  and smaller), because of the high pressures required for bubble-point testing. Diffusive flow testing measures flow across the total pore volume, which may mask a flaw, especially in high surface-area multiple-cartridge arrays. It is also highly sensitive to temperature.

## EQUIVALENCE IN STERILIZATION

The submission of an application for a pharmaceutical or biological product defines the methods by which that product is to be manufactured. There is a clear understanding that significant deviations from the approved process are to be avoided, and where substantial, submitted for regulatory review.<sup>42</sup> In order to maintain compliance, firms must assure that sterilization processes are performed in a manner consistent with the originally filed procedure. Therapeutic equivalence is an expectation within ANDA regulation whereby changed products are compared to their prior state to determine whether the changes alter their effectiveness *in-vivo*. Within the ANDA regulatory framework, there is no detailed content on the impact of equipment changes on the product, nor is there any mention of sterilization processes or equipment.

Firms operating multiple pieces of identical equipment used for sterilization, or being sterilized as well as those operating even a single piece, must be able to support their (or its) operational equivalence. Where resources are not a constraint, firms would perform all of the initial qualification/validation work necessary for identical equipment during the initial effort. Further, they would repeat the entire exercise (not merely a portion of it) periodically to support that their sterilization processes are unchanged. This seems clearly excessive. The other extreme would be a firm that claimed that non-identical sterilization equipment can be considered equivalent and that validation in one piece supports the use of the other. A firm endeavored to utilize such an approach and received a warning letter from FDA that establishes the principles of equivalence in current use.<sup>43</sup> In essence the sterilizing equipment must be of the same size, control, fabrication, and operating principle. This expectation is tighter than is expected of non-sterilization processes in which substantially greater flexibility is afforded.<sup>42</sup>

There is a simplifying aspect of sterilization for many processes in the  $F_0$  or  $F_H$  determinations, commonly made during initial and ongoing validation studies. These terms are defined as equivalent sterilization time related to the base conditions for temperature and z-value of 10°C and as such is uniquely appropriate for use in equivalence studies for thermal sterilization processes.<sup>44</sup> Where the lethality values for thermal sterilization are comparable to those attended in identical equipment (or the same equipment at a different time), then the operational equivalence of the equipment has been established. In defining the acceptance criteria for equivalence determination, the measurement error and ordinary variation of operation must be considered, “given the material and procedural variation, uncertainties of sampling, and inherent variability in the analytical methods that even a non-varying piece of equipment will demonstrate variation in performance that are unavoidable because of limitations in the measurements applied to it.”<sup>44</sup>

## OTHER STERILIZATION METHODS

This chapter has reviewed the more commonly used sterilization methods, but there are other available processes that are microbially lethal. The decisions of which methods to include and which to omit was largely based upon their prevalence in the literature. Other lethal processes, some of which are derivatives of the method included, can be grouped into categories ranked by their market availability.

### AVAILABLE NOW

- X-rays
- High Intensity Visible Light
- Microwave Sterilization
- Hydrogen Peroxide plasma
- HTST (High Temperature--Short Time)
- Semi-continuous  $\text{H}_2\text{O}_2$  tunnels

## EFFECTIVE WITH LIMITED OR NO COMMERCIAL SUPPORT

- Steam / Hydrogen Peroxide mixture
- Sulfur Dioxide
- High Pressures (>4,000-6,000 bar) (Batch or continuous process)
- Pulsed electrical field
- Cold plasma discharge
- Ultrasonification
- He/O<sub>2</sub> Plasma
- Hydrogen Bromide

## POSSIBLY EFFECTIVE

- Supercritical fluid treatments (by itself or with a sanitizing agent)
- Pulsing magnetic fields

Some of these methods have close parallels in the processes described, and in those instances the described practices can serve as a guide. For those employing novel mechanisms, the path to implementation is more difficult. The general principles to be considered are constant regardless of the particular process, but certainly novel processes will need a substantial investment of time and expertise before they can be applied.

## PARAMETRIC RELEASE OF STERILIZED MATERIALS

The sterility test was introduced in the 1930s as a means for confirming that sterile materials were safe for human use.<sup>45</sup> When the sterility test was first introduced, the process equipment was primitive by today's standards, lot sizes were much smaller and operations were heavily dependent on personnel. In this context, a laboratory test provided a measure of safety for what were potentially contaminated materials. Over the years this evolved to the present day sterility test as defined in the pharmacopeia and applied to both terminally sterilized and aseptically produced products.<sup>46,47</sup> As technology changed, the capability of processes for sterile products improved substantially, and the sterility test became something of an anachronism, especially as it related to terminally sterilized products.<sup>48</sup> Parametric release can be defined as, "A sterility release procedure based upon effective control, monitoring, and documentation of a validated sterilization process cycle in lieu of release based upon end-product sterility testing."<sup>49</sup> Recognition that the sterility test did not afford adequate assurance of sterility led Baxter Healthcare to make the first application for parametric release to the FDA in 1991.<sup>50</sup> FDA was undoubtedly cautious, and it took nearly four years for approval of that submission. FDA issued a compliance policy guide, establishing its expectations for subsequent submissions.<sup>51</sup> Later submissions by Hospira and B. Braun were approved with less delay.<sup>52</sup> The EMEA (now EMA) published a position paper on parametric release in 2000 that addressed the subject at a very high level, followed by a definitive guidance document and Annex 17 of the EU CGMP's.<sup>53,54,55</sup> In 2010 FDA issued submission guidance on parametric release summarizing its overall expectations.<sup>56</sup> Regrettably all of the regulatory documents on the subject lack clarifying detail that would enable practitioners to readily develop parametric release programs. Fortunately those firms that utilize parametric release for their terminally sterilized products have been generally open with respect to what they have provided. Essentially, the firms have individually established a list of critical factors derived from their

validation programs, which are used as the arbiters of sterility for each sterilizer load. The universal applicability of these lists is questionable, given the diversity of equipment designs. A detailed consensus document on the subject is lacking.

## ASEPTIC PROCESSING

The production of sterile materials is divided into two major categories: terminally sterilized, using one or the other of the methods described earlier in this chapter, or aseptic processing, in which individually sterilized items are assembled in a pristine environment into the final product.<sup>10</sup> Sterilization processes employ conditions that are lethal to microorganisms but also potentially detrimental to important properties of the product, container, or closure system. Aseptic processing allows the use of methods specifically suited for the individual component, minimizing the adverse impact on each (See Figure 25-23).

The difficulty lies in maintaining sterility of equipment and items from the point of sterilization through the sealing of the product container. The contamination risks associated with the aseptic assembly of sterile products mandate a strong regulatory (and weaker operational) preference that terminal sterilization be used wherever possible.<sup>57,58</sup> The core of this expectation lies in the essentially universal belief that personnel are responsible for nearly all of the contamination isolated in an aseptic processing environment.<sup>59</sup> The central role of personnel in contamination, whether directly as the source or indirectly as the means for dissemination across the processing environment, has shaped the supportive element necessary for success: facilities, equipment, materials, procedures, and monitoring, as well as specific aspects associated directly with the presence of the operator (See Figure 25-24).

In the last 20 years, numerous technologies for aseptic processing have been introduced that endeavor to mitigate the contamination risk associated with personnel. These technological advances endeavor to alter the contamination vectors that result in loss of sterility. While the improvements may appear unrelated, their objective is singular – improvement in aseptic processing performance by reducing the impact of personnel. The core concepts behind this are common:<sup>60</sup>

- Interventions are to be avoided at all times in aseptic processing.
- Interventions always mean increased risk to the patient.

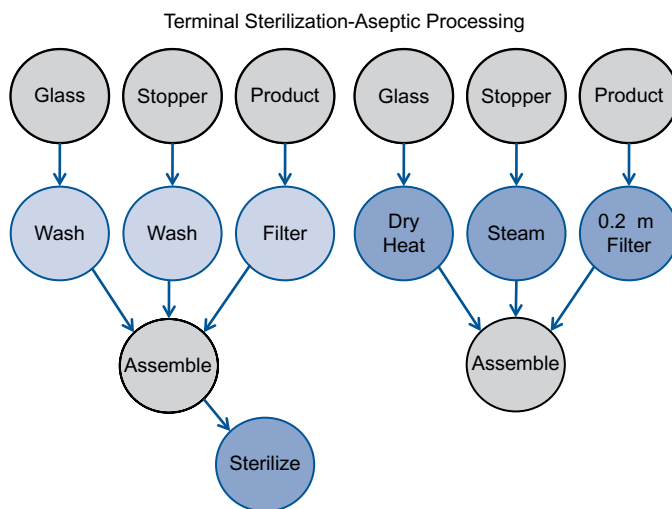

Figure 25-23. TS & AP Process Flow.

<sup>12</sup>The focus of the following discussion will be on the aseptic aspects; compounding and preparation areas must also be present, but aseptic processing is the focus of this discussion.

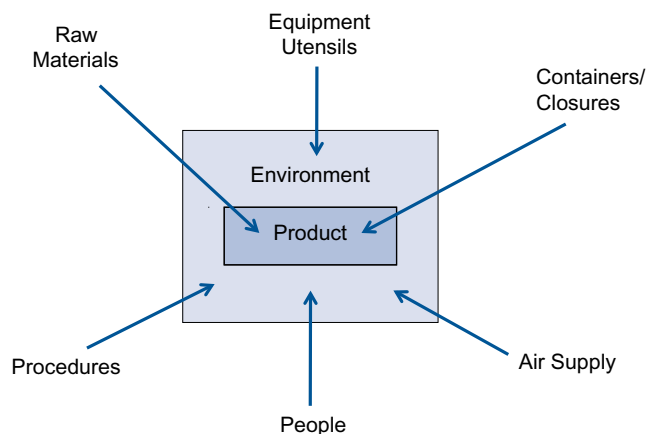

Figure 25-24. Contributions to Contamination in Aseptic Processing.

- There is no truly safe intervention.
- The “perfect” intervention is the one that doesn’t happen.

These ideas should remain central to the thinking of anyone involved with aseptic processing and are of substantially greater importance in older processing technologies that predate the newer approaches. Where technology is lacking, the operator is more intimately involved in the process, and the contamination risk will always be greater. The underlying goal for every aseptic process should be to minimize or eliminate personnel interaction with sterile items. The means to accomplish this is through careful design, selection, and operation of the aseptic process. An emerging term for these interrelated activities is “Sterility by Design”.<sup>61</sup>

### FACILITY, ENVIRONMENT, AND AIR SYSTEMS

The facility provides the structure within which the aseptic process will be performed. At the building level it incorporates separate production, utility, laboratory, warehousing, office, and other areas. These should be arranged in a manner that provides for the flow of materials, personnel, and waste through the operating areas in a manner that minimizes the potential for cross-contamination.<sup>61</sup> Some of the essential design considerations and operating practices for the core aseptic processing areas for sterile products are classified, beginning with ISO 8 in preparations areas and ranging to ISO 5 in the aseptic filling zone are the following:

- The classified environments should use materials of construction that are resistant to the intended agents, a minimum of horizontal surfaces and ledges, coved corners, flush windows, and other design details that facilitate cleaning and decontamination.
- The heating ventilating and air conditioning system should provide adequate air changes, air flows, temperature and relative humidity control, and pressurization to prevent the ingress of contamination.
- Air flow patterns within and between rooms and different classified zones should facilitate the removal and/or exclusion of contamination from critical environments.
- The classified areas should be supplied with HEPA filters (ceiling mounted in ISO 5 and 6) that are periodically tested for integrity.
- Differential pressures between different rooms and zones should be monitored and alarmed to support the integrity of the aseptic processing area.
- The entire aseptic area should be continuously maintained in a “clean” state and cleaned and decontaminated on a frequent basis. Isolators and RABS enclosures should

be treated with sporicidal agents on a periodic basis (these technologies lend themselves to longer intervals than ordinary manned environments).

- A minimum of equipment and materials should be retained in the aseptic portion of the facility to facilitate cleaning and decontamination.

Manned Aseptic Processing – Aseptic formulation and filling of aseptic formulations (and many terminally sterilized products) is performed in an ISO 5 environment, which is accessed from a manned ISO 6/7 background environment.<sup>8</sup> A means of physical separation is provided between the ISO 5 and ISO 6/7 environments for product protection. The operator’s presence in the ISO 5 zone should be minimized. Partial barrier and air over-spill separates the ISO 5 environment from aseptically-garbed personnel. The non-product contact surfaces are manually cleaned and decontaminated.

Restricted Access Barrier System (RABS) Aseptic Filling – RABS are aseptic processing systems (ISO 5) intended to substantially reduce human borne contamination by the use of separative devices and defined mechanical features and operating procedures. Their capability varies with the operational practices employed. They are most effective when operated in a closed mode in which all activities are performed with the doors closed. Opening the door reduces the separation of personnel from sterilized items, and their performance may be only slightly better than a manned cleanroom (see above). Air over-spill protects the ISO 5 environment from the background environment (ISO 6-7), where aseptically-gowned personnel are present. The non-product contact surfaces are manually or automatically cleaned and decontaminated with the doors closed.

Isolator Based Aseptic Processing – Isolators are enclosed aseptic processing environments in which the filling process is performed. The ISO 5 isolator is never opened for access to the system by personnel during processing. All items enter and exit using systems and methods that prevent the ingress of contamination. The internal surfaces are decontaminated using an automated system. The background environment is ISO 8, and aseptically gowning of personnel is not necessary.

The majority of new, large-scale aseptic processing facilities are using either closed RABS or isolation technology since these have proven to be highly successful in preventing the ingress of contamination.

### Equipment

Aseptic processing before the introduction of the HEPA filter relied heavily on operators. There would be some basic equipment, but personnel were responsible for material movement.<sup>62</sup> The availability of HEPA filtration in the mid-1950s allowed for a large, protected area, in which equipment incorporating a modest amount of automation could be installed. Over time equipment improvements were gradually introduced, which increased reliability and sophistication, serving to reduce operator interaction with the equipment and components. The desirable features of filling equipment include the following:

- The product contact surfaces of the equipment can be readily sterilized by a validated method.
- Sterilization-in-place (see above) and clean-in-place should be utilized wherever possible.
- The product contact equipment should be assembled to the fullest extent possible prior to sterilization. Product contact equipment should be sterilized in sealed container and introduced in a manner that retains at least one layer of protection until entry into the ISO 5 zone.
- All equipment should be sterilized/depyrogenated using a just-in-time approach to reduce hold times and facilitate maintenance of the facility.

<sup>13</sup>The production of sterile suspensions, ointments, powders, and other complex formulations often requires the use of an ISO 5 environment.

- Filling equipment should be selected for high reliability, ease of change over, and adjustment. Remote adjustment of equipment parameters should be utilized.
- Tool-free changeover of the filler from one format to another.
- The filler and associated equipment should be largely tolerant of container-closure miss-feeds, jams, and other problems to minimize the need for operator interventions.
- The process equipment (and to some extent facility) should use PAT and other feedback systems for ease of control, operation, and improved documentation.
- Non-product contact portions of the equipment should be easily decontaminated and non-invasive of the critical zone. Equipment surfaces should be resistant to the potential corrosive action of sanitizing and decontamination agents.

More sophisticated equipment, including robotics, offers the means for dramatic reductions in the need for personnel intervention with sterile equipment, containers, closures, and other sterile items.

### Containers and Closures

A core activity in aseptic processing is the assembly/filling of the product into its primary container. In the majority of instances this is a multiple component system in which the items are prepared and sterilized, using method specific for that type of item. In small-scale processing, much of the handling is performed by gowned personnel; however, commercial manufacturing generally entails equipment prepared as described in the previous section. The aseptic processing considerations relating to containers and closures include the following:

- The containers, closures and other primary components should be prepared and sterilized/depyrogenated using validated processes. The preparation processes should assure ease of handling, avoiding the need for interventions related to breakage, clumping, difficulties in feed, etc., that would require corrective interventions. Items should be sterilized/depyrogenated using a just-in-time approach. Inventories of materials in the aseptic environment should be minimized.
- Where possible, items should be introduced in a manner that retains at least one layer of sterilized, protective covering or wrap until entry into the critical zone.
- Containers, closures, and components should be selected for reliability of handling in the processing equipment.
- Containers /closures should be of appropriate quality. Higher AQLs for elimination of defects can result in a reduction in interventions.

Some of these same principles can be applied to utensils, environmental monitoring equipment, and other items to mitigate contamination concerns associated with them.

### Excipients and Active Ingredients

Aseptic processing centers around the product being manipulated, and care must be taken to assure that the means for its introduction are properly established. The methods vary widely with the type of product being handled. Liquid solutions are the easiest to introduce, with sterilizing grade filters typically located close to the point of filling. Methods for introduction of sterile powders, whether for use in a suspension or as the final formulation, are more complex, usually entailing the removal of protective layers. Some of the concerns associated with their use are the following:

- Product materials must be prepared and sterilized using validated methods. The use of sterilization-in-place systems to the maximum extent possible is recommended.

- Product delivery in a closed container should be made directly into the ISO 5 critical zone. Any aseptic connections should be in that zone.
- Where product is supplied to the critical zone in sterile container (e.g., sterile powders), it should be introduced in a manner that retains at least one layer of sterilized, protective covering or wrap until entry into the critical zone.
- The package design for sterile materials must consider the aseptic processing risk of contamination at both the manufacturing site where bulk subdivision is performed and the fill-finish site where drug product containers are filled.<sup>63</sup>

### Operating Procedures

The operation and handling of the items described above must be defined in procedures, providing adequate detail to ensure that personnel can execute the task properly.<sup>64,65,66</sup>

- The procedures central to the aseptic process should be critically reviewed to eliminate and/or simplify aseptic processes. The level of detail may need to be substantial as subtle variations can have a significant adverse impact. Interventions performed during aseptic processing must be recognized as increasing the risk of contamination dissemination.
- All interventions should be performed using sterilized utensils whenever possible.
- Intervention procedures should be established in detail for all inherent interventions and more broadly for corrective interventions (where some flexibility is necessary due to their greater diversity).
- Environmental monitoring is an inherent intervention, and means for its execution must be treated in the same manner as interventions involving product, containers, and closures.

### Personnel

The personnel performing the aseptic process are the one element where the least amount of control is available. Their rate of movement, diligence in gowning, adherence to aseptic technique, and other factors can never be controlled precisely. They are, after all, humans and not machines or robots. If the other aspects of the aseptic process are well structured, the operator's role becomes less central to success. Ideally, the other elements are so well considered that the process will be successful even on their worst day. The reality is that operators play a central role in most aseptic processing operations, and their behavior has the greatest impact on contamination levels. These considerations are somewhat altered when isolators are used and aseptic gowning is eliminated; however, the requirements for aseptic technique apply in those systems without alteration.

- Personnel working in aseptic processing must receive initial and periodic formal training in CGMP, aseptic processing, microbiology, aseptic gowning, aseptic assembly/set-up (for those personnel that perform that tasks, aseptic technique, and job-specific tasks).
- Personnel entering aseptic environments should be initially and periodically evaluated and assessed for their proficiency in aseptic gowning. Less extensive monitoring on each exit from the aseptic core is commonplace as a means of assessing daily performance
- Personnel should be initially and periodically assessed for their proficiency in aseptic technique. Those individuals performing the set-up of the line must be highly capable. The proficiency checks of personnel can rely on off-line evaluations rather than actual media fill participation (see below). Gloves on enclosures should be monitored at the end of the batch or campaign.

- Personnel should conform to the highest standards of aseptic technique at all times. The presence of supervisory personnel with the environment is perhaps the best means to accomplish this.
- The gown materials should be cleaned and sterilized using validated methods. A fresh gown should be used for each entry into the aseptic area.
- Gloves on enclosures should be replaced periodically, decontaminated/sterilized and integrity-tested. Sleeves and half-suits tend to be more robust with replacement intervals somewhat longer than those defined for gloves.
- Manual filling should be recognized as a throwback to an earlier time and no longer used for aseptic processing. Isolators should be utilized for low-volume products requiring continuous, and thus excessive, operator intervention.<sup>62</sup>

The focus of attention on the aseptic processing operator must never waiver. Their performance is all-important. Extraordinary measures with respect to any of the other influences on the process can be negated by inadequate personnel behavior. Isolators reduce some of this concern but do not eliminate it.

### Monitoring, Testing and Capability Demonstration

The successful execution of a sterilization process is demonstrated on a daily basis by the review of records generated by the equipment that verifies that the process met the operational requirements.<sup>12</sup> In the context of aseptic processing, while there are some real-time measurements taken (i.e., pressure differentials, particle counts, temperature, etc.), what are considered the more explicit evidence of successful operation, microbial monitoring results, are not available until sometime after the process has been completed. Sterility testing is a compendial and regulatory requirement for aseptically manufactured sterile products, but the sample limitations are so severe that it should not be used as confirmation of aseptic process acceptability. Process simulations or media fills are means for addressing how well an aseptic process operates; however, there are numerous reasons that they are not considered definitive proof.

In-process microbiological samples are considered the primary evidence of aseptic processing acceptability. There are similar expectations established by both FDA and EMA with respect to the levels of microorganisms tolerated in aseptic environments.<sup>57,67</sup> The sampling programs encompass air, surface, and personnel, with near zero limits in ISO 5 environments. While the goal of zero contamination is laudable, the reality is that that condition is not absolutely necessary for success in aseptic processing.<sup>61</sup> No manned system, included those using closed RABS, can be truly be considered “sterile”; after all, the process is termed “aseptic”. Mandating rejection, extensive investigation, and corrective actions when a single CFU is detected suggests something that is not currently possible: that a manned aseptic environment can be devoid of microorganisms. A more rational approach has been incorporated into USP; however, its long term impact is unknown.<sup>68</sup> Nevertheless, monitoring must be performed, excursions from expected values looked into, and changes made to satisfy an unrealistic expectation and meet the regulatory levels. The design considerations outlined above can certainly assist in accomplishing that objective. The realities of microbial monitoring should be considered, regardless of the ultimate objective, and the following insights might prove useful in properly considering how monitoring, sterility testing, and process simulation results of aseptic processing operations can be considered:

- Despite any denigration of its utility, microbial monitoring of aseptic processing should be performed.
- The monitoring equipment and procedures, whether for viable or non-viables of any aseptic system, must not subject the product to increased risk of contamination. No monitoring is preferable to monitoring that risks contamination of sterile materials.
- All environmental monitoring activities, especially those performed in ISO 5 environments, must be recognized as interventional activity.
- Monitoring procedures are potential means for the introduction of adventitious contamination unrelated to the environment, material, or surface being sampled.
- Viable monitoring, even that of so-called “critical” areas and surfaces, is not an “in-process sterility test” and should never be used in that manner.
- The results of environmental monitoring, sterility testing, and process simulation should not be considered as “proof” of either sterility or non-sterility.
- Microbial monitoring can never recover all microorganisms present in an environment, nor on a surface.
- Significant excursions from the routine microbial monitoring results, with respect to number and type of microorganisms, should be investigated.
- Detection of low numbers of microorganisms in manned cleanrooms, including closed RABS, should be considered a rare but not unusual event.
- Sterility tests are not definitive proof of the acceptability of any batch; the sample size is too small for that purpose. It can only detect gross contamination.
- Process simulations are demonstrations of capability but cannot definitely establish the sterility of any material.
- Process simulations in excess of 5000–10 000 units are of relatively limited value; their greatest utility is in the evaluation of aseptic set-up practices.

Aseptic processing requires near absolute control bioburden in the processing environment. The goal is simple in concept; however, it is extremely difficult to attain. There are inherent risks related to aseptic processing since the sterile state must be maintained over an extended period of time with, in most cases, direct human intervention. Global regulatory agencies have properly expressed a clear preference for terminal sterilization wherever possible.<sup>57,58</sup> There are numerous products that cannot be terminally sterilized, and thus aseptic processing will be necessary. The global industry has understood the inherent limitations associated with aseptic processing, and extensive improvements have been made to reduce the contamination potential.<sup>69</sup> The emerging technologies for aseptic processing suggest that future production methods will be substantially safer than those in current use.<sup>59</sup> The greater issue lies with the least capable aseptic processing facilities and operations; these are in far greater need of improvement than the more contemporary examples.

### CONCLUSION

Sterilization and aseptic processing are essential practices for healthcare product manufacture and many healthcare services. The execution of these processes in an appropriate manner is essential for patient safety. Products that are sterile but non-stable, due to excessive conditions during sterilization, are unusable. Products that are stable but unsafe as a result of inadequate robust aseptic processing are equally inappropriate. Achieving suitably safe and stable products for administration as parenterals, ophthalmics, or by inhalation requires careful consideration of many factors, including the method of sterilization, its effects on the materials, and how those materials are handled post-sterilization.

<sup>14</sup>There are other less direct elements such as change control, calibration, preventive maintenance, training, etc., but prima facie are the sterilizer generated records.

Parenteral (Gk, *para enteron*, beside the intestine) dosage forms differ from all other drug dosage forms, because they are injected directly into body tissue through the primary protective systems of the human body, the skin, and mucous membranes. They must be exceptionally pure and free from physical, chemical, and biological contaminants. These requirements place a heavy responsibility on the pharmaceutical industry to practice current good manufacturing practices (cGMPs) in the manufacture of parenteral dosage forms and on pharmacists and other health care professionals to practice good aseptic practices (GAPs) in dispensing parenteral dosage forms for administration to patients.

Certain pharmaceutical agents, particularly peptides, proteins, and many chemotherapeutic agents, can only be given parenterally, because they are inactivated in the gastrointestinal tract when given by mouth. Parenterally-administered drugs are relatively unstable and generally highly potent drugs that require strict control of administration to the patient. Due to the advent of biotechnology, parenteral products have grown in number and usage around the world.

This chapter focuses on the unique characteristics of parenteral dosage forms and the basic principles for formulating, packaging, manufacturing, and controlling the quality of these unique products. The references and bibliography at the end of this chapter contain the most up-to-date texts, book chapters, and review papers on parenteral product formulation, manufacture, and quality control.

### OVERVIEW OF UNIQUE CHARACTERISTICS OF PARENTERAL DOSAGE FORMS

Parenteral products are unique from any other type of pharmaceutical dosage form for the following reasons:

- All products must be sterile.
- All products must be free from pyrogenic (endotoxin) contamination.
- Injectable solutions must be free from visible particulate matter. This includes reconstituted sterile powders.
- Products should be isotonic, although strictness of isotonicity depends on the route of administration. Products administered into the cerebrospinal fluid must be isotonic. Ophthalmic products, although not parenteral, must also be isotonic. Products to be administered by bolus injection by routes other than intravenous (IV) should be isotonic, or at least very close to isotonicity. IV infusions must be isotonic.
- All products must be stable, not only chemically and physically like all other dosage forms, but also 'stable' microbiologically (i.e., sterility, freedom from pyrogenic and visible particulate contamination must be maintained throughout the shelf life of the product).
- Products must be compatible, if applicable, with IV diluents, delivery systems, and other drug products co-administered.

## FORMULATION PRINCIPLES

Parenteral drugs are formulated as solutions, suspensions, emulsions, liposomes, microspheres, nanosystems, and powders to be reconstituted as solutions. This section describes the components commonly used in parenteral formulations, focusing on solutions and freeze-dried products. General guidance is provided on appropriate selection of the finished sterile dosage form and initial approaches used to develop the optimal parenteral formulation.

## VEHICLES

### WATER

Since most liquid injections are quite dilute, the component present in the highest proportion is the vehicle. The vehicle of greatest importance for parenteral products is water. Water of suitable quality for compounding and rinsing product contact surfaces, to meet United States Pharmacopeia (USP) and other compendia specifications for Water for Injection (WFI), may be prepared either by distillation or by reverse osmosis. Only by these two methods is it possible to separate various liquid, gas, and solid contaminating substances from water. These two methods for preparation of WFI and specifications for WFI are also discussed in this chapter. With the possible exception of freeze-drying, there is no unit operation more important and none more costly to install and operate than that for the preparation of WFI.

### WATER-MISCIBLE VEHICLES

A number of solvents that are miscible with water have been used as a portion of the vehicle in the formulation of parenterals. These solvents are used to solubilize certain drugs in an aqueous vehicle and to reduce hydrolysis. The most important solvents in this group are ethyl alcohol, liquid polyethylene glycol, and propylene glycol. Ethyl alcohol is used in the preparation of solutions of cardiac glycosides and the glycols in solutions of barbiturates, certain alkaloids, and certain antibiotics. Such preparations are given intramuscularly. There are limitations with the amount of these co-solvents that can be administered, due to toxicity concerns, greater potential for hemolysis, and potential for drug precipitation at the site of injection.<sup>1</sup> Formulation scientists needing to use one or more of these solvents must consult the literature (e.g., Mottu F *et al.* 2000)<sup>2</sup> and toxicologists to ascertain the maximum amount of co-solvents allowed for their particular product. Several references provide information on concentrations of co-solvents used in approved commercial parenteral products.<sup>3–8</sup>

### NON-AQUEOUS VEHICLES

The most important group of non-aqueous vehicles is the fixed oils. The USP provides specifications for such vehicles, indicating that the fixed oils must be of vegetable origin so they will metabolize, will be liquid at room temperature, and will not become rancid readily. The USP also specifies limits for the free fatty acid content, iodine value, and saponification value (oil heated with alkali to produce soap, i.e., alcohol plus acid salt). The oils most commonly used are corn oil, cottonseed oil, peanut oil, and sesame oil. Fixed oils are used as vehicles for certain hormone (e.g., progesterone, testosterone, deoxycorticosterone) and vitamin (e.g., Vitamin K, Vitamin E) preparations. The label must state the name of the vehicle, so the user may beware in case of known sensitivity or other reactions to it.

## SOLUTES

Care must be taken in selecting active pharmaceutical ingredients and excipients to ensure their quality is suitable for parenteral administration. A low microbial level will enhance the effectiveness of either the aseptic or the terminal sterilization

process used for the drug product. Likewise, nonpyrogenic ingredients enhance the nonpyrogenicity of the finished injectable product. It is now a common GMP procedure to establish microbial and endotoxin limits on active pharmaceutical ingredients and most excipients. Chemical impurities should be virtually nonexistent in active pharmaceutical ingredients for parenterals, because impurities are not likely to be removed by the processing of the product. Depending on the chemical involved, even trace residues may be harmful to the patient or cause stability problems in the product. Therefore, manufacturers should use the best grade of chemicals obtainable and use its analytical profile to determine that each lot of chemical used in the formulation meets the required specifications.

Reputable chemical manufacturers accept the stringent quality requirements for parenteral products and, accordingly, apply good manufacturing practices to their chemical manufacturing. Examples of critical bulk manufacturing precautions include:

- Using dedicated equipment or properly validated cleaning to prevent cross-contamination and transfer of impurities;
- Using WFI for rinsing equipment;
- Using closed systems, wherever possible, for bulk manufacturing steps not followed by further purification; and
- Adhering to specified endotoxin and bioburden testing limits for the substance.

## ADDED SUBSTANCES

The USP includes in this category all substances added to a preparation to improve or safeguard its quality. An added substance may:

- Increase and maintain drug solubility. Examples include complexing agents and surface active agents. The most commonly used complexing agents are the cyclodextrins, including Captisol. The most commonly used surface active agents are polyoxyethylene sorbitan monolaurate (Tween 20) and polyoxyethylene sorbitan monooleate (Tween 80).
- Provide patient comfort by reducing pain and tissue irritation, as do substances added to make a solution isotonic or near physiological pH. Common tonicity adjusters are sodium chloride, dextrose, and glycerin.
- Enhance the chemical stability of a solution, as do antioxidants, inert gases, chelating agents, and buffers.
- Enhance the chemical and physical stability of a freeze-dried product, as do cryoprotectants and lyoprotectants. Common protectants include sugars, such as sucrose and trehalose, and amino acids, such as glycine.
- Enhance the physical stability of proteins by minimizing self-aggregation or interfacial induced aggregation. Surface active agents serve nicely in this capacity.
- Minimize protein interaction with inert surfaces, such as glass and rubber and plastic. Competitive binders, such as albumin, and surface active agents are the best examples.
- Protect a preparation against the growth of microorganisms. The term 'preservative' is sometimes applied only to those substances that prevent the growth of microorganisms in a preparation. However, such limited use is inappropriate, being better used for all substances that act to retard or prevent the chemical, physical, or biological degradation of a preparation.
- Although not covered in this chapter, other reasons for adding solutes to parenteral formulations include sustaining and/or controlling drug release (polymers), maintaining the drug in a suspension dosage form (suspending agents, usually polymers and surface active agents), establishing emulsified dosage forms (emulsifying agents, usually amphiphilic polymers and surface active agents), and preparation of liposomes (hydrated phospholipids).

Although added substances may prevent a certain reaction from taking place, they may induce others. Not only may visible incompatibilities occur, but hydrolysis, complexation, oxidation, and other invisible reactions may decompose or otherwise inactivate the therapeutic agent or other added substances.<sup>9</sup> Therefore, added substances must be selected with due consideration and investigation of their effect on the total formulation and the container-closure system.

### ANTIMICROBIAL AGENTS

The USP states that antimicrobial agents in bacteriostatic or fungistatic concentrations must be added to preparations contained in multiple-dose containers. The European Pharmacopoeia requires multiple-dose products to be bacteriocidal and fungicidal. They must be present in adequate concentration at the time of use to prevent the multiplication of microorganisms inadvertently introduced into the preparation, while withdrawing a portion of the contents with a hypodermic needle and syringe. The USP provides a test for Antimicrobial Preservative Effectiveness to determine that an antimicrobial substance or combination adequately inhibits the growth of microorganisms in a parenteral product.<sup>10</sup> Because antimicrobials may have inherent toxicity for the patient, the USP prescribes maximum volume and concentration limits for those commonly used in parenteral products (e.g., phenylmercuric nitrate and thimerosal 0.01%, benzethonium chloride and benzalkonium chloride 0.01%, phenol or cresol 0.5%, and chlorobutanol 0.5%).

The above limit is rarely used for phenylmercuric nitrate, most frequently employed in a concentration of 0.002%. Methyl *p*-hydroxybenzoate 0.18% and propyl *p*-hydroxybenzoate 0.02%, in combination, and benzyl alcohol 2% are also used frequently. Benzyl alcohol, phenol, and the parabens are the most widely used antimicrobial preservative agents used in injectable products. Although the mercurials are still allowed to be used in older products, they are not used for new products, due to concerns regarding mercury toxicity. In oleaginous preparations, no antibacterial agent commonly employed appears to be effective. However, it has been reported that hexylresorcinol 0.5% and phenylmercuric benzoate 0.1% are moderately bactericidal. A few therapeutic compounds have been shown to have antibacterial activity, thus, obviating the need for added agents.

Antimicrobial agents must be studied with respect to compatibility with all other components of the formula. In addition, their activity must be evaluated in the total formula. It is not uncommon to find a particular agent effective in one formulation but ineffective in another, possibly due to the effect of various components of the formula on the biological activity or availability of the compound; for example, the binding and inactivation of esters of *p*-hydroxybenzoic acid by macromolecules, such as Polysorbate 80, or the reduction of phenylmercuric nitrate by sulfide residues in rubber closures. A physical reaction encountered is that bacteriostatic agents are sometimes removed from solution by rubber closures.

Protein pharmaceuticals, because of their cost and/or frequency of use, are preferred to be available as multiple dose formulations (e.g., Human Insulin, Human Growth Hormone, Interferons, Vaccines, etc.). However, several proteins are reactive with antimicrobial preservative agents (e.g., Tissue Plasminogen Activator, Sargramostim, and Interleukins) and, therefore, are only available as single dosage units. Phenol and benzyl alcohol are the two most common antimicrobial preservatives used in peptide and protein products. Phenoxyethanol is the most frequently used preservative in vaccine products.

Single-dose containers and pharmacy bulk packs that do not contain antimicrobial agents are expected to be used promptly after opening or discarded. The ICH/CPMP guidelines ([http://www.ema.europa.eu/docs/en\\_GB/document\\_library/Scientific\\_guideline/2009/09/WC500003476.pdf](http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2009/09/WC500003476.pdf)) require that products without preservatives be used immediately, although some package inserts define immediate use as within 3 hours after entering the primary package, or a longer usage period must be

justified. Large-volume, single-dose containers may not contain an added antimicrobial preservative. Therefore, special care must be exercised in storing such products after the containers have been opened to prepare an admixture, particularly those that support the growth of microorganisms, such as total parenteral nutrition (TPN) solutions and emulsions. It should be noted that, although refrigeration slows the growth of most microorganisms, it does not prevent their growth.

Buffers are used to stabilize a solution against chemical degradation or, especially for proteins, physical degradation (i.e., aggregation and precipitation) which might occur if the pH changes appreciably. Buffer systems should have as low a buffering capacity as feasible, so as not to significantly disturb the body's buffering systems when injected. In addition, the buffer type and concentration on the activity of the active ingredient must be evaluated carefully. Buffer components are known to catalyze degradation of drugs. The acid salts most frequently employed as buffers are citrates, acetates, and phosphates. Amino acid buffers, especially histidine, have become buffer systems of choice for controlling solution pH of monoclonal antibody solutions.

**Anitoxidants** are frequently required to preserve products, due to the ease with which many drugs, including proteins with methionine or cysteine amino acids conformationally exposed, are oxidized. Sodium bisulfite and other sulfurous acid salts are used most frequently. Ascorbic acid and its salts are also good antioxidants. The sodium salt of ethylenediaminetetraacetic acid (EDTA) has been found to enhance the activity of antioxidants, in some cases, by chelating metallic ions that would otherwise catalyze the oxidation reaction.

Displacing the air (oxygen) in and above the solution, by purging with an inert gas, such as nitrogen, can also be used as a means to control oxidation of a sensitive drug. Process control is required for assurance that every container is deaerated adequately and uniformly. However, conventional processes for removing oxygen from liquids and containers do not absolutely remove all oxygen. The only approach for completely removing oxygen is to employ isolator technology, where the entire atmosphere can be recirculating nitrogen or another non-oxygen gas.

Tonicity Agents are used in many parenteral and ophthalmic products to adjust the tonicity of the solution. Although it is the goal for every injectable product to be isotonic with physiologic fluids, this is not an essential requirement for small volume injectables administered intravenously. However, products administered by all other routes, especially into the eye or spinal fluid, must be isotonic. Injections into the subcutaneous tissue and muscles should also be isotonic to minimize pain and tissue irritation. The agents most commonly used are electrolytes and mono- or disaccharides.

Cryoprotectants and Lyoprotectants are additives that serve to protect biopharmaceuticals from adverse effects, due to freezing and/or drying of the product during freeze-dry processing. Sugars (non-reducing), such as sucrose or trehalose, amino acids, such as glycine or lysine, polymers, such as liquid polyethylene glycol or dextran, and polyols, such as mannitol or sorbitol, all are possible cryo- or lyoprotectants. Several theories exist to explain why these additives work to protect proteins against freezing and/or drying effects.<sup>11,12</sup> Excipients that are preferentially excluded from the surface of the protein are the best cryoprotectants, and excipients that remain amorphous during and after freeze-drying serve best as lyoprotectants.

### GENERAL GUIDANCE FOR DEVELOPING FORMULATIONS OF PARENTERAL DRUGS

The final formulation of a parenteral drug product depends on understanding the following factors that dictate the choice of formulation and dosage form.

1. Route of administration—Injections may be administered by such routes as intravenous, subcutaneous, intradermal, intramuscular, intraarticular, intralesional, and intrathecal. The type of dosage form (solution,

suspension, etc.) determines the particular route of administration employed. Conversely, the desired route of administration places requirements on the formulation. For example, suspensions would not be administered directly into the bloodstream, due to the danger of insoluble particles blocking capillaries. Solutions administered subcutaneously require strict attention to tonicity adjustment, otherwise irritation of the plentiful supply of nerve endings in this anatomical area would give rise to pronounced pain. Injections intended for intraocular, intraspinal, intracisternal, and intrathecal administration require stricter standards of such properties as formulation tonicity, component purity, and limit of endotoxins, due to the sensitivity of tissues encountered to irritant and toxic substances.

2. If the route of administration must be intravenous, then only solutions or microemulsions can be the dosage form. If the route of administration is subcutaneous or intramuscular, then the likely type of dosage form is a suspension or other microparticulate delivery system.
3. Pharmacokinetics of the drug—Rates of absorption (for routes of administration other than intravenous or intra-arterial), distribution, metabolism, and excretion for a drug have some effect on the selected route of administration and, accordingly, the type of formulation. For example, if the pharmacokinetic profile of a drug is very rapid, modified release dosage formulations may need developed. The dose of drug and the dosage regimen are affected by pharmacokinetics, so the size (i.e., concentration) of the dose will also influence the type of formulation and amounts of other ingredients in the formulation. If the dosage regimen requires frequent injections, then a multiple dose formulation must be developed, if feasible. If the drug is distributed quickly from the site injection, complexing agents or viscosity inducing agents may be added to the formulation to retard drug dissolution and transport.
4. Drug solubility—If the drug is insufficiently soluble in water at the required dosage, then the formulation must contain a co-solvent or a solute that sufficiently increases and maintains the drug in solution. If relatively simple formulation additives do not result in a solution, then a dispersed system dosage form must be developed. Solubility also dictates the concentration of drug in the dosage form.
5. Drug stability—If the drug has significant degradation problems in solution, then a freeze-dried or other sterile solid dosage form must be developed. Stability is sometimes affected by drug concentration that, in turn, might affect size and type of packaging system used. For example, if concentration must be low, due to stability and/or solubility limitations, then the size of primary container must be larger, and this might preclude the use of syringes, cartridges, and/or smaller vial sizes. Obviously, stability dictates the expiration date of the product that, in turn, determines the storage conditions. Storage conditions might dictate choice of container size, formulation components, and type of container. If a product must be refrigerated, then the container cannot be too large, and formulation components must be soluble and stable at colder conditions.
6. Compatibility of drug with potential formulation additives and packaging systems—It is well-known that drug-excipient incompatibilities frequently exist.<sup>9</sup> Initial preformulation screening studies are essential to ensure that formulation additives, although possibly solving one problem, will not create another. Stabilizers, such as buffers and antioxidants, although chemically stabilizing the drug in one way, may also catalyze other chemical degradation reactions. Excipients and certain drugs can form insoluble complexes. Impurities in excipients can cause drug degradation reactions. Peroxide impurities in polymers

may catalyze oxidative degradation reactions with drugs, including proteins, which are oxygen sensitive.

7. The use of silicone to lubricate vial rubber closures, syringe rubber plungers to coat the inner surface of glass syringes, and cartridges potentially can induce protein aggregation. Therefore, compatibility studies need to be designed to determine the potential for a new biopharmaceutical drug adversely affected by the presence of silicone applied to certain packaging surfaces. The increased popularity of laminated rubber closures and plungers has been due to the elimination of the need for applying silicone to these materials. Silicone coating is still required for glass syringes and cartridges, which provide new opportunities for the use of plastic syringes with biopharmaceuticals that further minimize the potential for incompatibilities between biopharmaceuticals and packaging systems.
8. Desired type of packaging—Selection of packaging (i.e., type, size, shape, color of rubber closure, label, and aluminum cap) is often based on marketing preferences and competition. Knowing the type of final package early in the development process aids the formulation scientist in being sure the product formulation will be compatible and elegant in that packaging system.

Table 26-1 provides steps involved in the formulation of a new parenteral drug product. This can also be viewed as a list of questions, of which the answers will facilitate decisions on the final formulation that should be developed.

**Table 26-1. Main Steps Involved in the Formulation of a New Parenteral Drug Product**

1. Obtain physical properties of active drug substance
a. Structure, molecular weight
b. "Practical" solubility in water at room temperature
c. Effect of pH on solubility
d. Solubility in certain other solvents
e. Unusual solubility properties
f. Isoelectric point for a protein or peptide
g. Hygroscopicity
h. Potential for water or other solvent loss
i. Aggregation potential for protein or peptide
2. Obtain chemical properties of active drug substance
a. Must have a 'validatable' analytical method for potency and purity
b. Time for 10% degradation at room temperature in aqueous solution in the pH range of anticipated use
c. Time for 10% degradation at 5°C
d. pH stability profile
e. Sensitivity to oxygen
f. Sensitivity to light
g. Major routes of degradation and degradation products
3. Initial formulation approaches
a. Know timeline(s) for drug product
b. Know how drug product will be used in the clinic
i. Single dose vs multiple dose
ii. If multiple dose, will preservative agent be part of drug solution/powder or part of diluent?
iii. Shelf life goals
iv. Combination with other products, diluents
c. From knowledge of solubility and stability properties and information from anticipated clinical use, formulate drug with components and solution properties known to be successful at dealing with these issues, then perform accelerated stability studies.

i. High temperature storage
ii. Temperature cycling
iii. Light and/or oxygen exposure
iv. For powders, expose to high humidities
d. May need to perform several short-term stability studies as excipient types and combinations are eliminated
e. Selection of primary container and closure
i. Be aware of potential for tubing glass to be subject to glass delamination (glass lamellae); work with glass supplier to select type of glass
ii. Most rubber closure formulations are coated rubber to minimize leachables and do not require siliconization
f. Design and implement an initial manufacturing method of the product
g. Finalize formulation
i. Need for tonicity adjusting agent
ii. Need for antimicrobial preservative
h. Approach to obtain sterile product
i. Terminal sterilization
ii. Sterile filtration and aseptic processing

## ADMINISTRATION

Injections may be classified in six general categories:

1. Solutions ready for injection
2. Dry, soluble products ready to be combined with a solvent just prior to use
3. Suspensions ready for injection
4. Dry, insoluble products ready to be combined with a vehicle just prior to use
5. Emulsions
6. Liquid concentrates ready for dilution prior to administration

When compared with other dosage forms, injections possess select advantages. If immediate physiological action is needed from a drug, it can usually be provided by the intravenous injection of an aqueous solution. Modification of the formulation or another route of injection can be used to slow the onset and prolong the action of the drug. The therapeutic response of a drug is controlled more readily by parenteral administration, since the irregularities of intestinal absorption are circumvented. Also, since the drug is administered by a professionally trained person, it confidently can be expected that the dose is accurately administered. Drugs can be administered parenterally, when they cannot be given orally, due to the unconscious or uncooperative state of the patient or due to inactivation or lack of absorption in the intestinal tract. Among the disadvantages of this dosage form are the requirement of asepsis at administration, the risk of tissue toxicity from local irritation, the real or psychological pain factor, and the difficulty in correcting an error, should one be made. In the latter situation, unless a direct pharmacological antagonist is immediately available, correction of an error may be impossible. One other disadvantage is that daily or frequent administration pose difficulties, as patients must either visit a professionally trained person or learn to self-inject. However, the advent of home health care as an alternative to extended institutional care and availability of new medications from biotechnology to treat chronic diseases have mandated the development of programs for training lay persons to administer these dosage forms.

## PARENTERAL COMBINATIONS

Most dosage forms, when released to the marketplace by the manufacturer, are consumed by the patient without any significant manipulation of the product. For example, tablets and

capsules are ingested in the same form they were when released by the manufacturer. For many parenteral drug products, this is not the case. For example, products in vials must be withdrawn into a syringe prior to injection and often combined with other products in infusion solutions prior to administration. Freeze-dried products, first, have to be reconstituted with a specific or non-specific diluent prior to being withdrawn from the vial. Specifically, it is common practice for a physician to order the addition of a small-volume therapeutic injection (SVI), such as an antibiotic, to large-volume injections (LVIs), such as 1000 mL of 0.9% sodium chloride solution, to avoid the discomfort, for the patient, of a separate injection. Certain aqueous vehicles are recognized officially, due to their valid use in parenterals. Often, they are used as isotonic vehicles to which a drug may be added at the time of administration. The additional osmotic effect of the drug may not be enough to produce any discomfort when administered. These vehicles include Sodium Chloride Injection, Ringer's Injection, Dextrose Injection, Dextrose and Sodium Chloride Injection, and Lactated Ringer's Injection.

Although the pharmacist is the most qualified health professional to be responsible for preparing such combinations, as is clearly stated in the hospital accreditation manual of the Joint Commission on Accreditation of Healthcare Organizations,<sup>13</sup> interactions among the combined products can be troublesome even for the pharmacist. In fact, incompatibilities can occur and cause inactivation of one or more ingredients or other undesired reactions. Patient deaths have been reported from the precipitate formed by two incompatible ingredients. In some instances, incompatibilities are visible as precipitation or color change, but, in other instances, there may be no visible effect.

The many potential combinations present a complex situation even for the pharmacist. To aid in making decisions concerning potential problems, a valuable compilation of relevant data has been assembled by Trissel<sup>14</sup> and is updated regularly. Further, the advent of computerized data storage and retrieval systems has provided a means to organize and gain rapid access to such information. (Further information on this subject may be found in Chapter 27—Pharmaceutical Compounding – USP <797> Sterile Preparations.)

As studies have been undertaken and more information has been gained, it has been shown that knowledge of variable factors, such as pH and the ionic character of the active constituents, aids substantially in understanding and predicting potential incompatibilities. Kinetic studies of reaction rates may be used to describe or predict the extent of degradation. Ultimately, a thorough study should be undertaken of each therapeutic agent in combination with other drugs and IV fluids, not only of generic, but also of commercial preparations, from the physical, chemical, and therapeutic aspects.

Ideally, no parenteral combination should be administered, unless it has been studied thoroughly to determine its effect on the therapeutic value and safety of the combination. However, such an ideal situation may not exist. Nevertheless, it is the responsibility of the pharmacist to be as familiar as possible with the physical, chemical, and therapeutic aspects of parenteral combinations and to exercise the best possible judgment as to whether or not the specific combination extemporaneously prescribed is suitable for use in a patient.

## GENERAL CONSIDERATIONS

An inherent requirement for parenteral preparations is that they be of the very best quality and provide the maximum safety for the patient. Constant adherence to high moral and professional ethics on the part of the responsible persons is most vital to achieving the desired quality in the products prepared.

## TYPES OF PROCESSES

The preparation of parenteral products may be categorized as small-scale dispensing, usually one unit at a time, or large-scale manufacturing in which hundreds of thousands of units may

constitute one lot of product. The former category illustrates the type of processing done in early clinical phase manufacturing or in institutions, such as hospital pharmacies. The latter category is typical of the processing done in the later clinical phase and commercial manufacturing in the pharmaceutical industry. Wherever they are made, parenteral products must be subjected to the same basic practices of GMPs and good aseptic processing essential for the preparation of a safe and effective sterile product of highest quality, however, the methods used must be modified appropriately for the scale of operation.

The small-scale preparation and dispensing of parenteral products might use sterile components in their preparation. Therefore, the overall process focuses on maintaining, rather than achieving, sterility in the process steps. In the hospital setting, the final product might have a shelf life measured in hours. However, the extensive movement of patients out of the hospital to home care has modified hospital dispensing of parenteral products, wherein multiple units are made for a given patient and a shelf life of 30 days or more is required. Such products are sometimes made in hospital pharmacies, but increasingly in centers set up to provide this service. A discussion of such processing can be found in the USP general chapter <1206>.

This chapter emphasizes the preparation of parenteral products from non-sterile components in the highly technologically advanced plants of the pharmaceutical industry, using cGMP principles. In the pursuit of cGMP, consideration should be given to:

1. Ensuring that the personnel responsible for assigned duties are capable and qualified to perform them.
2. Ensuring that ingredients used in compounding the product have the required identity, quality, and purity.
3. Validating critical processes to be sure the equipment used and the processes followed ensure that the finished product has the qualities expected.
4. Maintaining a production environment suitable for performing the critical processes required, addressing such matters as orderliness, cleanliness, asepsis, and avoidance of cross contamination.
5. Confirming, through adequate quality-control procedures, that the finished products have the required potency, purity, and quality.
6. Establishing, through appropriate stability evaluation, that the drug products retain their intended potency, purity, and quality, until the established expiration date.
7. Ensuring that processes are always carried out in accord with established, written procedures.
8. Providing adequate conditions and procedures for the prevention of mix-ups.
9. Establishing adequate procedures, with supporting documentation, for investigating and correcting failures or problems in production or quality control.
10. Providing adequate separation of quality-control responsibilities from those of production to ensure independent decision making.

The pursuit of cGMP is an ongoing effort that must flex with new technological developments and new understanding of existing principles. Due to the extreme importance of quality in health care of the public, US Congress has given the responsibility of regulatory scrutiny over the manufacture and distribution of drug products to the FDA. Therefore, the operations of the pharmaceutical industry are subject to the oversight of the FDA and, with respect to manufacturing practices, to the application of the cGMPs. (These regulations are discussed more fully in Chapter 3—Quality Assurance and Control.)

In concert with the pursuit of cGMPs, the pharmaceutical industry has shown initiative and innovation in the extensive

technological development and improvement in quality, safety, and effectiveness of parenteral dosage forms in recent years. Examples include developments in:

- modular facility design and construction—smaller rooms, easier to clean, sanitize, and maintain;
- application of disposable technologies for compounding, mixing, and filling—reduce potential for cross-contamination;
- closure cleaning, siliconization (if applicable), and sterilization—all-in-one systems for rubber closures;
- sterilization technologies—well-defined sterilization validation principles, multiple approaches to sterilization cycles;
- filling technologies—greater speed, precision, and handling of viscous solutions;
- aseptic processing technology, including barrier isolator technology and restricted access barrier systems;
- freeze-drying technologies—automated loading and unloading, advances in process monitoring;
- control of particulate matter—greater diligence in cleaning methodologies, in-coming inspections, more experience with sources, causes, and minimization of particulate matter in facilities, on equipment and packaging, and personnel practices; and
- Automation—weight checking, inspection technologies, labeling and finishing operations.

## GENERAL MANUFACTURING PROCESS

The preparation of a parenteral product may encompass four general areas:

1. Procurement and accumulation of all components in a warehouse area, until released to manufacturing;
2. Processing the dosage form in appropriately designed and operated facilities;
3. Packaging and labeling in a quarantine area, to ensure integrity and completion of the product; and
4. Controlling the quality of the product throughout the process.

Procurement encompasses selecting and testing according to specifications of the raw-material ingredients and the containers and closures for the primary and secondary packages. Microbiological purity, in the form of bioburden and endotoxin levels, has become standard requirements for raw materials.

Processing includes cleaning containers and equipment to validated specifications, compounding the solution (or other dosage form), filtering the solution, sanitizing or sterilizing the containers and equipment, filling measured quantities of product into the sterile containers, stoppering (either completely or partially for products to be freeze-dried), freeze-drying, terminal sterilization (if possible), and final sealing of the final primary container.

Packaging normally consists of the labeling and cartoning of filled and sealed primary containers. Control of quality begins with the incoming supplies, being sure that specifications are met. Careful control of labels is vitally important, as errors in labeling can be dangerous for the consumer. Each step of the process involves checks and tests to ensure the required specifications at the respective step are being met. Labeling and final packaging operations are becoming more automated.

The quality control unit is responsible for reviewing the batch history and performing the release testing required to clear the product for shipment to users. A common FDA citation for potential violation of cGMP is the lack of oversight by the quality control unit in batch testing and review and approval of results.

## COMPONENTS

Components of parenteral products include the active ingredient, formulation additives, vehicle(s), and primary container and closure. Establishing specifications to ensure the quality of each of these components of an injection is essential. Secondary packaging is relevant more to marketing considerations, although some drug products might rely on secondary packaging for stability considerations, such as added protection from light exposure for light-sensitive drugs and antimicrobial preservatives.

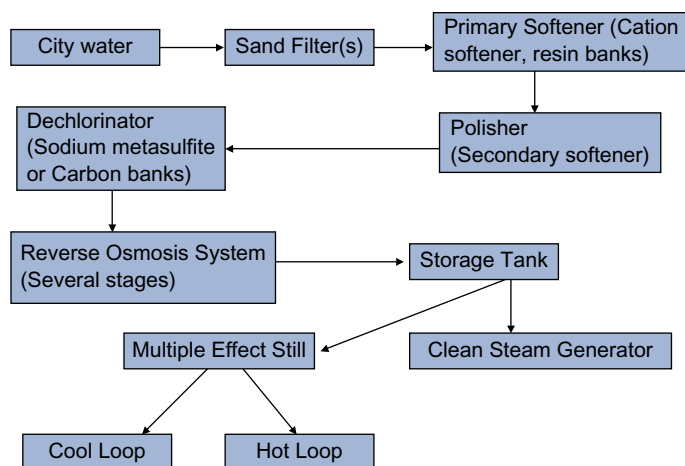

The most stringent chemical-purity requirements will normally be encountered with aqueous solutions, particularly if the product is sterilized at an elevated temperature where reaction rates will be accelerated greatly. Dry preparations pose relatively few reaction problems but may require definitive physical specifications for ingredients that must have certain solution or dispersion characteristics when a vehicle is added.

Containers and closures are in prolonged, intimate contact with the product and may release substances into, or remove ingredients from, the product. Rubber closures are especially problematic (sorption, leachables, air and moisture transmission properties), if not properly evaluated for compatibility with the final product. Assessment and selection of containers and closures are essential for final product formulation, to ensure the product retains its purity, potency, and quality during the intimate contact with the container throughout its shelf life. Administration devices (e.g., syringes, tubing, transfer sets) that come in contact with the product should be assessed and selected with the same care as are containers and closures, even though the contact period is usually brief.

## WATER FOR INJECTION (WFI)

### PREPARATION

The source water can be expected to be contaminated with natural suspended mineral and organic substances, dissolved mineral salts, colloidal material, viable bacteria, bacterial endotoxins, industrial or agricultural chemicals, and other particulate matter. The degree of contamination varies with the source and will be markedly different, whether obtained from a well or from surface sources, such as a stream or lake. Hence, the source water must be pretreated by one or a combination of the following treatments: chemical softening, filtration, deionization, carbon adsorption, or reverse osmosis purification. Figure 26-1 shows a schematic of a typical process used to convert potable water to Water for Injection.

**Figure 26-1.** A schematic of a typical process used to convert potable water to Water for Injection.

Water for Injection can be prepared by distillation or by membrane technologies (i.e., reverse osmosis or ultrafiltration). The EP (*European Pharmacopeia*) only permits distillation as the process for producing WFI. The USP and JP (*Japanese Pharmacopeia*) allow all these technologies to be applied.

Distillation is a process of converting water from a liquid to its gaseous form (steam). Since steam is pure gaseous water, all other contaminants in the feedwater are removed. A conventional still consists of a boiler (evaporator), containing feed water (distilland); a source of heat to vaporize the water in the evaporator; a headspace above the level of distilland, with condensing surfaces for refluxing the vapor, thereby returning nonvolatile impurities to the distilland; a means for eliminating volatile impurities (demister/separation device) before the hot water vapor is condensed; and a condenser for removing the heat of vaporization, thereby converting the water vapor to a liquid distillate.

The specific construction features of a still and the process specifications have a marked effect on the quality of distillate obtained from a still. Several factors must be considered in selecting a still to produce WFI:

1. The quality of the feed water will affect the quality of the distillate. For example, chlorine in water, especially, can cause or exacerbate corrosion in distillation units, and silica causes scaling within. Controlling the quality of the feed water is essential for meeting the required specifications for the distillate.
2. The size of the evaporator will affect the efficiency. It should be large enough to provide a low vapor velocity, thus, reducing the entrainment of the distilland either as a film on vapor bubbles or as separate droplets.
3. The baffles (condensing surfaces) determine the effectiveness of refluxing. They should be designed for efficient removal of the entrainment at optimal vapor velocity, collecting and returning the heavier droplets contaminated with the distilland.
4. Redissolving volatile impurities in the distillate reduces its purity. Therefore, they should be separated efficiently from the hot water vapor and eliminated by aspirating them to the drain or venting them to the atmosphere.
5. Contamination of the vapor and distillate from the metal parts of the still can occur. Present standards for high-purity stills are that all parts contacted by the vapor or distillate should be constructed of metal coated with pure tin, 304 or 316 stainless-steel, or chemically resistant glass.

The design features of a still also influence its efficiency of operation, relative freedom from maintenance problems, or extent of automatic operation. Stills may be constructed of varying size, rated according to the volume of distillate that can be produced per hour of operation under optimum conditions. Only stills designed to produce high-purity water may be considered for use in the production of WFI. Conventional commercial stills designed for the production of high-purity water are available from several suppliers.

There are two basic types of WFI distillation units—the vapor compression still and the multiple effect still.

### Compression Distillation

The vapor-compression still, primarily designed for the production of large volumes of high-purity distillate with low consumption of energy and water, is illustrated diagrammatically in Figure 26-2. To start, the feed water is heated from an external source in the evaporator to boiling. The vapor produced in the tubes is separated from the entrained distilland in the separator and conveyed to a compressor that compresses the vapor and raises its temperature to approximately 107°C. It then flows to the steam chest, where it condenses on the outer surfaces of the tubes containing the distilland; the vapor is, thus, condensed

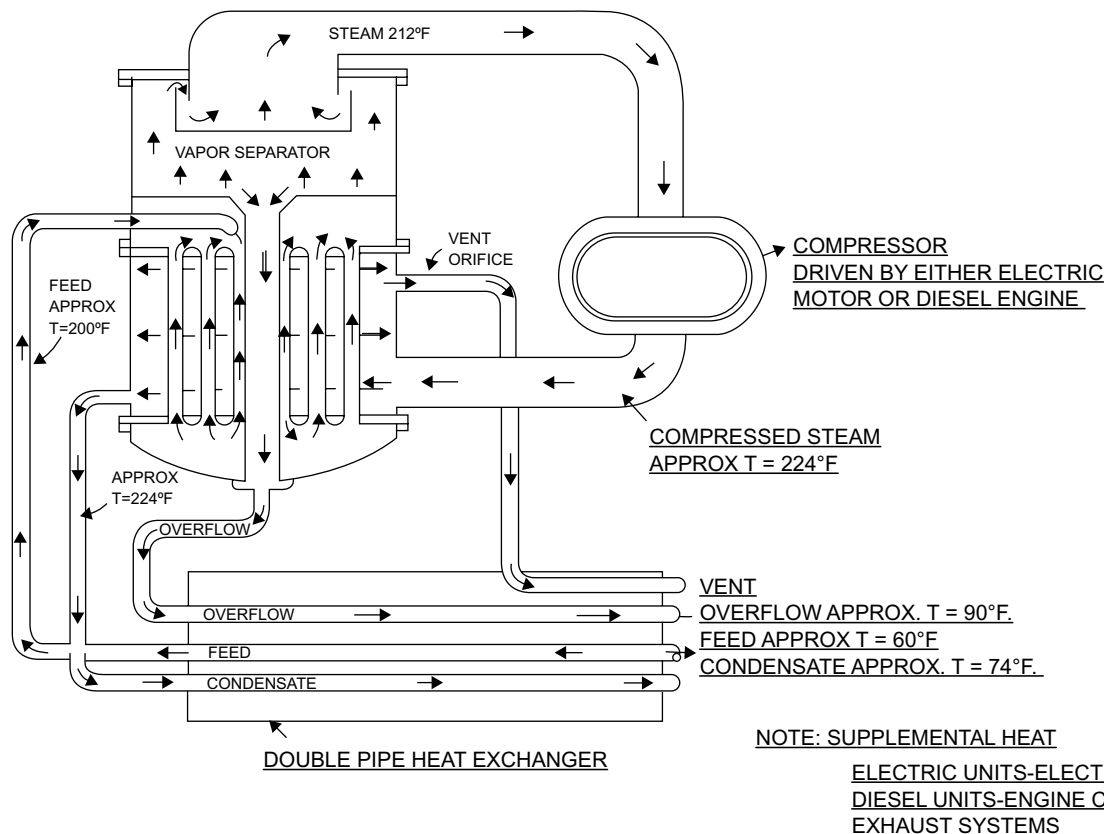

Figure 26-2. Vapor compressor still.

and drawn off as a distillate, while giving up its heat to bring the distilland in the tubes to the boiling point. Vapor-compression stills are available in capacities from 50 to 2800 gal/hr.

### Multiple-Effect Stills

The multiple-effect still is also designed to conserve energy and water usage. In principle, it is simply a series of single-effect stills or columns running at differing pressures where phase changes of water take place. A series of up to seven effects may be used, with the first effect operated at the highest pressure and the last effect at atmospheric pressure. Figure 26-3 shows a schematic drawing of a multiple-effect still. Steam from an external source is used in the first effect to generate steam under pressure from feed water; it is used as the power source to drive the second effect. The steam used to drive the second effect condenses as it gives up its heat of vaporization and forms a distillate. This process continues until the last effect, when the steam is at atmospheric pressure and must be condensed in a heat exchanger.

The capacity of a multiple-effect still can be increased by adding effects. The quantity of the distillate will also be affected by the inlet steam pressure; thus, a 600-gal/hr unit designed to operate at 115 psig steam pressure could be run at approximately 55 psig and would deliver about 400 gal/hr. These stills have no moving parts and operate quietly. They are available in capacities from about 50 to 7000 gal/hr.

### Reverse Osmosis (RO)

As the name suggests, the natural process of selective permeation of molecules through a semipermeable membrane separating two aqueous solutions of different concentrations is reversed. Pressure, usually between 200 and 400 psig, is applied to overcome osmotic pressure and force pure water to permeate through the membrane. Membranes, usually composed of

cellulose esters or polyamides, are selected to provide an efficient rejection of contaminant molecules in raw water. The molecules most difficult to remove are small inorganic molecules, such as sodium chloride. Passage through two membranes in series is sometimes used to increase the efficiency of removal of these small molecules and decrease the risk of structural failure of a membrane to remove other contaminants, such as bacteria and pyrogens.

Several WFI installations utilize both RO and distillation systems for generation of the highest quality water. Since feedwater to distillation units can be heavily contaminated and, thus, affect the operation of the still, water is first run through RO units to eliminate contaminants. (For additional information, see the book by Collentro.)<sup>15</sup>

Whichever system is used for the preparation of WFI, validation is required to be sure that the system, consistently and reliably, produces the chemical, physical, and microbiological quality of water required. Such validation should start with the determined characteristics of the source water and include the pretreatment, production, storage, and distribution systems. All of these systems together, including their proper operation and maintenance, determine the ultimate quality of the WFI.

### Storage and Distribution

The rate of production of WFI is not sufficient to meet processing demands; therefore, it is collected in a holding tank for subsequent use. In large operations, the holding tanks may have a capacity of several thousand gallons and be a part of a continuously operating system. In such instances, the USP requires that the WFI be held at a temperature too high for microbial growth, normally a constant 80°C.

The USP also permits the WFI to be stored at room temperature but for a maximum of 24 hours. Under such conditions,

**Figure 26-3.** Multiple-effect water for injection distillation. Schematic (A) and (B) a space saving and energy efficient combination still and steam generator capable of delivering 750kg/hr (1650lb/hr) of pharmaceutical grade steam and 2200 liters/hr (580 gal/hr) of Water For Injection. (Courtesy of Getinge.)

the WFI is collected as a batch for a particular use with any unused water discarded within 24 hours. Such a system requires frequent sanitization to minimize the risk of viable microorganisms being present. The stainless-steel storage tanks in such systems are usually connected to a welded stainless-steel distribution loop, supplying the various use sites with a continuously circulating water supply. The tank is provided with a hydrophobic membrane vent filter capable of excluding bacteria and nonviable particulate matter. Such a vent filter is necessary to permit changes in pressure during filling and emptying. The construction material for the tank and

connecting lines is usually electropolished 316L stainless steel with welded pipe. The tanks also may be lined with glass or a coating of pure tin. Such systems are very carefully designed and constructed and often constitute the most costly installation within the plant.

When the water cannot be used at 80°C, heat exchangers must be installed to reduce the temperature at the point of use. Bacterial retentive filters should not be installed in such systems, due to the risk of bacterial buildup on the filters and the consequent release of pyrogenic substances.

## Purity

Although certain purity requirements have been alluded to, the USP and EP monographs provide the official standards of purity for WFI and Sterile Water for Injection (SWFI).

The chemical and physical standards for WFI have changed in the past few years. The only physical/chemical tests remaining are the new total organic carbon (TOC), with a limit of 500 ppb (0.5 mg/L), and conductivity, with a limit of 1.3  $\mu\text{S}/\text{cm}$  at 25°C or 1.1  $\mu\text{S}/\text{cm}$  at 20°C. The former is an instrumental method capable of detecting all organic carbon present, and the latter is a three-tiered instrumental test measuring the conductivity contributed by ionized particles (in microSiemens or micromhos) relative to pH. Since conductivity is integrally related to pH, the pH requirement of 5 to 7 in previous revisions has been eliminated. The TOC and conductivity specifications are now considered adequate minimal predictors of the chemical/physical purity of WFI. However, the wet chemistry tests are still used when WFI is packaged for commercial distribution and for SWFI.

Biological requirements continue to be, for WFI, not more than 10 colony-forming units (CFUs)/100 mL and less than 0.25 USP endotoxin units/mL. The SWFI requirements differ in that, since it is a final product, it must pass the USP Sterility Test.

WFI and SWFI may not contain added substances. Bacteriostatic Water for Injection (BWFI) may contain one or more suitable antimicrobial agents in containers of 30 mL or less. This restriction is designed to prevent the administration of a large quantity of a bacteriostatic agent that would probably be toxic in the accumulated amount of a large volume of solution, even though the concentration was low.

The USP also provides monographs giving the specifications for Sterile Water for Inhalation and Sterile Water for Irrigation. The USP should be consulted for the minor differences between these specifications and those for SWFI.

## CONTAINERS AND CLOSURES

Injectable formulations are packaged into containers made of glass or plastic. Container systems include ampoules, vials, syringes, cartridges, bottles, and bags (Fig. 26-4).

Ampoules are all glass, whereas bags are all plastic. The other containers can be composed of glass or plastic and must include

**Figure 26-4.** Various types of packaging for parenterals. (Courtesy of Gerresheimer.)

rubber materials, such as rubber stoppers for vials and bottles and rubber plungers and rubber seals for syringes and cartridges. Irrigation solutions are packaged in glass bottles with aluminum screw caps.

Table 26-2 provides a generalized comparison of the three compatibility properties—leaching, permeation, and adsorption—of container materials most likely involved in the formulation of aqueous parenterals. Further, the integrity of the container/closure system depends on several characteristics, including container opening finish, closure modulus, durometer and compression set, and aluminum seal application force. (Container-closure integrity testing is discussed in the Quality Assurance and Control section.)

## CONTAINER TYPES

### GLASS

Glass is employed as the container material of choice for most SVIs. It is composed, principally, of silicon dioxide, with varying amounts of other oxides, such as sodium, potassium, calcium, magnesium, aluminum, boron, and iron. The basic structural network of glass is formed by the silicon oxide tetrahedron. Boric oxide will enter into this structure, but most of the other oxides do not. The latter are only loosely bound, are present in the network interstices, and are relatively free to migrate. These migratory oxides may be leached into a solution in contact with the glass, particularly during the increased reactivity of thermal sterilization. The oxides dissolved may hydrolyze to raise the pH of the solution and catalyze or enter into reactions. Additionally, some glass compounds will be attacked by solutions and, in time, dislodge glass flakes into the solution. Such occurrences can be minimized by the proper selection of the glass composition.

### Types

The USP provides a classification of glass:

- Type I, a borosilicate glass;
- Type II, a soda-lime treated glass;
- Type III, a soda-lime glass; and
- NP, a soda-lime glass not suitable for containers for parenterals.

Type I glass is composed, principally, of silicon dioxide (~81%) and boric oxide (~13%), with low levels of the non-network-forming oxides, such as sodium and aluminum oxides. It is a chemically resistant glass (low leachability), also having a low thermal coefficient of expansion (CoE) ( $32.5 \times 10^{-7} \text{ cm}/\text{cm}^\circ\text{C}$  for 33 expansion glass;  $51.0 \times 10^{-7} \text{ cm}/\text{cm}^\circ\text{C}$  for 51 expansion glass). In comparison, soda-lime glass has a thermal CoE of expansion of  $8.36 \times 10^{-5} \text{ cm}/\text{cm}^\circ\text{C}$ . The lower the thermal CoE, the more dimensionally stable the glass against thermal expansion stress that can result in cracking.

Types II and III glass compounds are composed of relatively high proportions of sodium oxide (~14%) and calcium oxide (~8%). This makes the glass chemically less resistant. Both types melt at a lower temperature, are easier to mold into various shapes, and have a higher thermal coefficient of expansion. Although there is no one standard formulation for glass among manufacturers of these USP type categories, Type II glass has a lower concentration of the migratory oxides than Type III. In addition, Type II has been treated under controlled temperature and humidity conditions, with sulfur dioxide or other dealkalizers to neutralize the interior surface of the container. Although it remains intact, this surface increases substantially the chemical resistance of the glass. However, repeated exposures to sterilization and alkaline detergents break down this dealkalized surface and expose the underlying soda-lime compound.

The glass types are determined from the results of two USP tests: the Powdered Glass Test and the Water Attack Test. A

**Table 26-2. Comparative Compatibility Properties of Container Materials**

	Leaching		Permeation		Adsorption (Selective) Extent <sup>a</sup>
	Extent <sup>a</sup>	Potential Leachables	Extent <sup>a</sup>	Potential Agents	
Glass					
Borosilicate	1	Alkaline earth and heavy metal oxides	0	N/A	2
Soda-lime	5	Alkaline earth and heavy metal oxides	0	N/A	2
Plastic polymers					
Low density	2	Plasticizers, antioxidants	5	Gases, water vapor, other molecules	2
High density	1	Antioxidants	3	Gases, water vapor, other molecules	2
PVC	4	HCl, especially plasticizers, antioxidants, other stabilizers	5	Gases, especially water vapor and other molecules	2
Polyolefins	2	Antioxidants	2	Gases, water vapor	2
Polypropylene	2	Antioxidants, lubricants	4	Gases, water vapor	1
Rubber polymers					
Natural and related synthetic	5	Heavy metal salts, lubricants, reducing agents	3	Gases, water vapor	3
Butyl	3	Heavy metal salts, lubricants, reducing agents	1	Gases, water vapor	2
Silicone	2	Minimal	5	Gases, water vapor	1

<sup>a</sup> Approximate scale of 1 to 5, with 1 as the lowest.

proposal to revise USP <660> Containers-Glass had been published (*Pharmaceutical Forum*, 37(2), March-April, 2011) in which the USP would adopt the EP's methodology for the glass grains test to replace the USP powdered glass test and the water attack test would be deleted. The latter is used only for Type II glass and is performed on the whole container, due to the dealkalized surface; the former is performed on powdered glass, which exposes internal surfaces of the glass compound. The results are based on the amount of alkali titrated by 0.02 N sulfuric acid, after an autoclaving cycle with the glass sample in contact with a high-purity distilled water. Thus, the Powdered Glass Test challenges the leaching potential of the interior structure of the glass, whereas the Water Attack Test challenges only the intact surface of the container.

Selecting the appropriate glass composition is a critical facet of determining the overall specifications for each parenteral formulation. Glass can be the source/cause of leachables/extractables, particulates (glass delamination or glass lamellae formation), adsorption of formulation components, especially proteins, and cracks/scratches.

**Leachables/Extractables**—If the product is sensitive to the presence of ions, such as boron, sodium, potassium, calcium, iron, and magnesium, great care must be taken in selecting the appropriate glass container, as these ions may leach from the glass container and interact with the product, reducing chemical stability, inducing formation of particulate, or altering pH of solution. Drug formulations and thermal history can impact dissolution rates of glass and induce the leaching of significant quantities of glass metals. The presence of formulation components that can act as metal chelating agents, such as EDTA and citrate, is of special concern. Formulation studies involving accelerated aging (increased temperatures) should monitor changes in solution pH, metal content, and particulate formation, in addition to drug product stability (purity and potency). Leachables from the glass barrel, such as tungsten (used for the formation of the barrel) and silicone (used for lubrication of the syringe), were shown to have significant impact on the protein stability.<sup>16</sup>

The following rules apply with respect to glass leachables:

- Relatively low levels of leachables at pH 4-8.
- Relatively high levels of leachables at pH > 9.
- Major extractables are silicon and sodium.
- Minor extractables include potassium, barium, calcium, and aluminum.
- Trace extractables include iron, magnesium, and zinc.
- Treated glass gives less extractables, if pH < 8.

**Delamination**—Delamination, or glass particulate formation, is caused by chemical attack on the glass matrix by the formulation solution, resulting in weakening of the glass and eventual dislodgement of flakes from the glass surface.<sup>17</sup> These fragments can be subvisible in size and, thus, difficult to detect. Delamination is of particular concern in tubing vials, and susceptibility may be driven by many of the same heat history factors that influence alkali leaching potential (as measured by compendial methods as a pH shift), although measures to reduce alkali leaching (ammonium sulfate treatment) may be completely ineffective in reducing delamination susceptibility.

Certain components or characteristics of the pharmaceutical product formulation may enhance the potential for delamination of the product container. Formulations with elevated pH (particularly >8), high sodium chloride content, or containing specific buffer components, known to attack or solubilize components, of the glass matrix (phosphate, citrate, tartrate, EDTA) are of potential concern. In some cases, delamination may be reduced or eliminated by careful control of process parameters during the glass forming processes; lower heat levels during the conversion process may be critical. Ammonium sulfate-treated glass containers are also known to be more susceptible to delamination.

Although compendial chemical resistance testing may be predictive of delamination potential, in some cases, experience indicates that additional testing with the actual formulation or a surrogate is required to properly evaluate container selection. For example, a product that undergoes terminal sterilization

could be evaluated by multiple sterilization cycles in the formulation matrix, followed by filtration and microscopic examination of the filters for subvisible particles of delaminated glass. For sterile-fill applications, it is recommended that the glass containers be filled with formulation placebo (all components except the unstable API) at the pH release limit(s) for the product and be challenged with a single autoclave cycle or an accelerated aging study at 55°C for at least 4 weeks, followed by filtration and microscopic examination for glass particles.

**Adsorption**—Adsorption of drug to solution contact surfaces and consequent loss of potency of delivered solution is a primary concern of container/solution compatibility and must be rigorously and formally evaluated during solution/container evaluation and stability studies. Glass containers are fairly inert surfaces, for most small drug products at relatively high concentrations, but pose a higher risk for therapeutic proteins and other smaller drug products formulated at low concentrations. Since adsorption is a surface phenomenon, increasing the surface area to volume ratio increases the risk of losses due to adsorption. Thus, small volume products carry higher risk for loss of potency due to adsorption and should be carefully evaluated for drug loss.<sup>18</sup>

**Cracks and Scratches**—Small cracks and scratches on glass containers can best be minimized by implementation of quality agreements between parenteral product manufacturers and glass container manufacturers. Not only does the glass container manufacturer need strict control procedures to minimize cracks and scratches from the time the container is formed until it reaches the finished product manufacturer, but there also needs to be high quality, 100% inspection practices by both glass and final product manufacturers. Also, local quality inspection procedures and practices need to have clearly understood definitions and a library of examples for what is defined as a crack and scratch. Cracks are considered unacceptable, whereas scratches are more of an esthetic indication of product elegance.

Type I glass will be suitable for all products, although sulfur dioxide treatment is sometimes used for even greater resistance to glass leachables. Because cost must be considered, one of the other, less-expensive types may be acceptable. Type II glass may be suitable, for example, for a solution that is buffered, has a pH below 7, or is not reactive with the glass. Type III glass is usually suitable for anhydrous liquids or dry substances. However, some manufacturer-to-manufacturer variation in glass composition should be anticipated within each glass type. Therefore, for highly chemically sensitive parenteral formulations, it may be necessary to specify both USP Type and specific manufacturer.

Schott developed a technology, called Plasma Impulse Chemical Vapor Deposition (PECVD), that coats the inner surface of Type I glass vials with an ultrathin film of silicon dioxide.<sup>19</sup> This film forms a highly efficient diffusion barrier that practically eliminates glass leachables. Such treated glass is especially useful for drug products having high pH values, formulations with complexing agents, or products showing high sensitivity to pH shifts.

### Physical Characteristics

Commercially available containers vary in size from 0.5 to 1000 mL. Sizes up to 100 mL may be obtained as ampoules and vials, and larger sizes as bottles. The latter are used for intravenous and irrigating solutions. Smaller sizes are also available as syringes and cartridges. Ampoules, syringes, and cartridges are drawn from glass tubing. The smaller vials may be made by molding or from tubing. Larger vials and bottles are made only by molding. Containers made by drawing tubing are optically clearer and have a thinner wall than molded containers (Fig. 26-4). Compared to molded glass, tubing glass also has better wall and finish dimensional consistency and no seams, is easier to label, weighs less, facilitates inspection, and has lower tooling costs. Tubing glass is preferable to molded glass for freeze-dried products, due to more efficient heat transfer from the shelf into the product. Molded containers are uniform in external dimensions, stronger,

and heavier. Also, molded glass is not as susceptible to leachables and delamination, because the glass formation temperatures to vaporize and condense the alkali components of the glass are not as high as for tubing container manufacture.<sup>20</sup> Easy-opening ampoules that permit the user to break off the tip at the neck constriction, without the use of a file, are weakened at the neck, by scoring or applying a ceramic paint with a different coefficient of thermal expansion. An example of a modification of container design to meet a particular need is the double-chambered vial, designed to contain a freeze-dried product in the lower, and solvent in the upper chamber. Other examples are wide-mouth ampoules with flat or rounded bottoms to facilitate filling with dry materials or suspensions and various modifications of the cartridge for use with disposable dosage units.

Glass containers must be strong enough to withstand the physical shocks of handling and shipping and the pressure differentials that develop, particularly during the autoclave sterilization cycle. They must be able to withstand the thermal shock resulting from large temperature changes during processing, for example, when the hot bottle and contents are exposed to room air at the end of the sterilization cycle. Therefore, a glass with a low coefficient of thermal expansion is necessary. The container must also be transparent to permit inspection of the contents.

Preparations that are light-sensitive must be protected, by placing them in amber glass containers or by enclosing flint glass containers in opaque cartons labeled to remain on the container during the period of use. It should be noted that the amber color of the glass is imparted by the incorporation of potentially leachable heavy metals, mostly iron and manganese, which may act as catalysts for oxidative degradation reactions. Silicone coatings are sometimes applied to containers to produce a hydrophobic surface, for example, as a means of reducing the friction of a rubber-tip of a syringe plunger.

The size of single-dose containers is limited to 1000 mL by the USP, and multiple-dose containers to 30 mL, unless stated otherwise in a particular monograph. Multiple-dose vials are limited in size to reduce the number of punctures for withdrawing doses and the accompanying risk of contamination of the contents. As the name implies, single-dose containers are opened or penetrated with aseptic care, and the contents used at one time. These may range in size from 1000-mL bottles to 1-mL or less ampoules, vials, or syringes. The integrity of the container is destroyed when opened, so that the container cannot be closed and reused.

A multiple-dose container is designed so that more than one dose can be withdrawn at different times, the container maintaining a seal between uses. It should be evident that, with full aseptic precautions, including sterile syringe and needle for withdrawing the dose and disinfection of the exposed surface of the closure, there is still a substantial risk of introducing contaminating micro-organisms and viruses into the contents of the vial. Due to this risk, the USP requires that all multiple-dose vials contain an antimicrobial agent or be inherently antimicrobial, as determined by the USP Antimicrobial Preservatives-Effectiveness tests. There are no comparable antiviral effectiveness tests, nor are antiviral agents available for such use. In spite of the advantageous flexibility of dosage provided by multiple-dose vials, single-dose, disposable container units provide the clear advantage of greater sterility assurance and patient safety.

Due to concerns for user safety and glass particulate matter occurring when glass is broken, glass sealed ampoules are no longer glass containers of choice for new SVIs in the United States.

### RUBBER CLOSURES

To permit introduction of a needle from a hypodermic syringe into a multiple-dose vial and provide for resealing as soon as the needle is withdrawn, each vial is sealed with a rubber

**Figure 26-5.** Examples of rubber closures for vials and syringes. (Photo Copyright 2011, West Pharmaceutical Services, Inc., Used with Permission).

closure held in place by an aluminum cap (Fig. 26-5). This principle is also followed for single-dose containers of the cartridge type, except that there is only a single introduction of the needle to make possible the withdrawal or expulsion of the contents.

Rubber closures are composed of multiple ingredients plasticized and mixed together at an elevated temperature on milling machines. The elastomer primarily used in rubber closures, plungers, and other rubber items used in parenteral packaging and delivery systems is synthetic butyl or halobutyl rubber. Natural rubber is also used, but, if it is natural rubber latex, then the product label must include a warning statement, due to the potential for allergic reactions from latex exposure.

The plasticized mixture is placed in molds and vulcanized (cured) under high temperature and pressure. During vulcanization the polymer strands are cross-linked by the vulcanizing agent, assisted by the accelerator and activator, so that motion is restricted and the molded closure acquires the elastic, resilient character required for its use. Ingredients not involved in the cross-linking reactions remain dispersed within the

**Table 26-3.** Examples of Ingredients Found in Rubber Closures

Ingredient	Examples
Elastomer	Natural rubber (latex)
	Butyl rubber
	Neoprene
Vulcanizing (curing agent)	Sulfur
	Peroxides
Accelerator	Zinc dibutyldithiocarbamate
Activator	Zinc oxide
	Stearic acid
Antioxidant	Dilauryl thiodipropionate
Plasticizer/lubricant	Paraffinic oil
	Silicone oil
	Carbon black
Fillers	Clay
	Barium sulfate
	Inorganic oxides
Pigments	Carbon black

compound and, along with the degree of curing, affect the properties of the finished closure. Table 26-3 provides examples of rubber-closure ingredients.

The physical properties considered in the selection of a particular formulation include elasticity, hardness, tendency to fragment, and permeability to vapor transfer. The elasticity is critical in establishing a seal with the lip and neck of a vial or other opening and in resealing after withdrawal of a hypodermic needle from a vial closure. The hardness should provide firmness, but not excessive resistance to the insertion of a needle through the closure, and minimal fragmentation of pieces of rubber should occur as the hollow shaft of the needle is pushed through the closure. Although vapor transfer occurs to some degree with all rubber formulations, appropriate selection of ingredients makes it possible to control the degree of permeability. Physicochemical and toxicological tests for evaluating rubber closures are described in section <381> in the USP.

The ingredients dispersed throughout the rubber compound may be subject to leaching into the product contacting the closure. These ingredients (Table 26-3) pose potential compatibility interactions with product ingredients, if leached into the product solution, and these effects must be evaluated. Further, some ingredients must be evaluated for potential toxicity.

The example of pure red cell aplasia, an immunogenic reaction caused by leachables from a rubber closure in a erythropoietin prefilled syringe formulation, highlights the criticality of appropriate container-closure and the study of such leachables and extractables, even as a function of stability shelf life.<sup>21</sup>

To reduce the problem of leachables, laminates have been applied to the product contact surfaces of closures, with various polymers, the most successful being Teflon® (DuPont polytetrafluoroethylene [PTFE]) and Flurotec® (West/Daikyo copolymer of tetrafluoroethylene and ethylene). Polymeric coatings have been developed that are claimed to have more integral binding with the rubber matrix, however, details of their function are trade secrets. Although rubber coatings do reduce the potential for extractables/leachables and eliminate the need for applied silicone treatment, they may have potential disadvantages of not flowing as easily during high speed filling operations and may not have the same container-closure integrity as uncoated stoppers with vial openings.

The physical shape of some typical closures may be seen in Figure 26-5. Most of them have a lip and a protruding flange that extends into the neck of the vial or bottle. Many disk closures

are being used now, particularly in the high-speed packaging of antibiotics. Slotted closures are used on freeze-dried products to permit the escape of water vapor, since they are inserted only partway into the neck of the vial until completion of the drying phase of the cycle. Also, the top design of the freeze-dry closure is important to minimize sticking of the closure to underneath the dryer shelf after stoppering the vial. Stoppers normally have a small protruding circle at the center of the top of the stopper. Gaps provided within the protruding circle minimize the tendency of the stopper to stick to the freeze-dryer shelf.

The plunger type of rubber is used to seal one end of a syringe or cartridge. At the time of use, the plunger expels the product by a needle inserted through the closure at the distal end of the package. Intravenous solution closures often have permanent holes for adapters of administration sets; irrigating solution closures are usually designed for pouring.

Rubber closures must be 'slippery' to move easily through a rubber closure hopper and other stainless steel passages, until they are fitted onto the filled vials. Traditionally, rubber materials are 'siliconized' (silicone oil or emulsion applied onto the rubber) to produce such lubrication. However, advances in rubber closure technologies have introduced closures that do not require siliconization, due to a special polymer coating applied to the outer surface of the closure. Examples are the Daikyo/West closures (Flurotec) and the Helvoet (Omniflex) closures.

## PLASTIC

Thermoplastic polymers have been established as packaging materials for sterile preparations, such as large-volume parenterals, ophthalmic solutions, and, increasingly, small-volume parenterals. For such use to be acceptable, a thorough understanding of the characteristics, potential problems, and advantages for use must be developed. Three principal problem areas exist in using these materials:

1. Permeation of vapors and other molecules in either direction through the wall of the plastic container;
2. Leaching of constituents from the plastic into the product; and
3. Sorption (absorption and/or adsorption) of drug molecules or ions on the plastic material.

Permeation, the most extensive problem, may be troublesome by permitting volatile constituents, water, or specific drug molecules to migrate through the wall of the container to the outside and, thereby, be lost. This problem has been resolved, for example, by the use of an overwrap in the packaging of IV solutions in PVC bags to prevent loss of water during storage. Reverse permeation in which oxygen or other molecules may penetrate to the inside of the container and cause oxidative or other degradation of susceptible constituents may also occur. Leaching may be a problem, when certain constituents in the plastic formulation, such as plasticizers or antioxidants, migrate into the product. Thus, plastic polymer formulations should have as few additives as possible, an objective characteristically achievable for most plastics used for parenteral packaging. Sorption is a problem on a selective basis, that is, sorption of a few drug molecules occurs on specific polymers. For example, sorption of insulin and other proteins, vitamin A acetate, and warfarin sodium has been shown to occur on PVC bags and tubing, when these drugs were present as additives in IV admixtures. Table 26-2 gives a brief summary of some of these compatibility relationships.

One of the principle advantages of using plastic packaging materials is that they are not breakable, as is glass; also, there is a substantial weight reduction. The flexible bags of polyvinyl chloride or select polyolefins, currently in use for large-volume intravenous fluids, have the added advantage that no air interchange is required; the flexible wall simply collapses as the solution flows out of the bag.

Most plastic materials have the disadvantage of not being as clear as glass, and, therefore, inspection of the contents is

impeded. However, recent technologies have overcome this limitation, evidenced by plastic resins, such as CZ (polycyclopentane, Daikyo Seiko) and Topas COC (cyclic olefin copolymer, Ticona). In addition, many of these materials soften or melt under the conditions of thermal sterilization. However, careful selection of the plastic used and control of the autoclave cycle has made thermal sterilization of some products possible, large-volume injectables, in particular. Ethylene oxide or radiation sterilization may be employed for the empty container with subsequent aseptic filling. However, careful evaluation of the residues from ethylene oxide or its degradation products and their potential toxic effect must be undertaken. Investigation is required concerning potential interactions and other problems that may be encountered when a parenteral product is packaged in plastic.

Future trends in primary packaging for parenterals will continue to see significant growth in the application of plastic vials and syringes and the manufacturing of such packaging by form- (or blow-) fill-seal technologies. (For further details, see Chapter 35 (Pharmaceutical Packaging) and the review book chapter by Vilivalam and DeGrazio.<sup>22</sup>

## NEEDLES

Historically, stainless steel needles have been used to penetrate the skin and introduce a parenteral product inside the body. The advent of needleless injection systems has obviated the need for needles for some injections (e.g., vaccines) and is gaining in popularity over the conventional syringe and needle system. However, needleless injections are more expensive, can still produce pain on injection, are, potentially, a greater source of contamination (and cross-contamination from incessant use), and may not be as efficient in dose delivery.

Needles are hollow devices composed of stainless steel or plastic. Needles are available in a wide variety of lengths, sizes, and shapes. Needle lengths range from ¼ inch to 6 inches. Needle size is referred to as its gauge (G), or the outside diameter (OD) of the needle shaft. Gauge ranges are 11 to 32 G, with the largest gauge for injection usually being no greater than 16 G. 16 G needles have an OD of 0.065 inches (1.65 mm), whereas 32 G have an OD of 0.009 inches (0.20 mm). Needle shape includes regular, short bevel, intradermal, and winged. Needle shape is defined by one end of a needle enlarged to form a hub with a delivery device, such as a syringe, or other administration device. The other end of the needle is beveled, meaning it forms a sharp tip to maximize ease of insertion.

The route of administration, type of therapy, and whether the patient is a child or adult dictate the length and size of needle used. Intravenous injections use 1–2 inch 15–25 G needles. Intramuscular injections use 1–2 inch 19–22 G needles. Subcutaneous injections use ¼–5/8 inch 24–25 G needles. Needle gauge for children rarely is larger than 22 G, usually 25–27G. Winged needles are used for intermittent heparin therapy. Many different types of therapies (e.g., radiology, anesthesia, biopsy, cardiovascular, ophthalmic, transfusions, tracheotomy, etc.) have their own peculiar types of needle preferences.

Needles are purchased either alone (e.g., Luer-Lok) to be attached to syringes, cartridges, and other delivery systems, or, for syringes, can be part of the syringe set (stake needle). Syringes with needles may also have needle protectors (for example, see [http://www.bd.com/vacutainer/pdfs/blood\\_transfer\\_device\\_with\\_safetyglide\\_needle\\_VS5985.pdf](http://www.bd.com/vacutainer/pdfs/blood_transfer_device_with_safetyglide_needle_VS5985.pdf)) to avoid potential dangers of accidental needle sticks post-administration (for more detail regarding the 2000 Needlestick Safety Act, see [http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=106\\_cong\\_public\\_laws&docid=f:publ430.106](http://frwebgate.access.gpo.gov/cgi-bin/getdoc.cgi?dbname=106_cong_public_laws&docid=f:publ430.106)). Such protectors can either be part of the assembly or be assembled during the finishing process. Needlestick prevention can be manual (shield activated manually by the user, although there is still the risk of accidental sticking), active (automated needle shielding activated by user), or passive (automated needle shielding without action by the user).

## PYROGENS (ENDOTOXINS)

Water and packaging materials are the greatest sources of pyrogens (pyrogenic contamination). Pyrogens are products of metabolism of microorganisms. The most potent pyrogenic substances (endotoxins) are constituents (lipopolysaccharides, LPS) of the cell wall of gram-negative bacteria (e.g., *Pseudomonas sp*, *Salmonella sp*, *Escherichia coli*). Gram-positive bacteria and fungi also produce pyrogens but of lower potency and of different chemical nature. Gram positive bacteria produce peptidoglycans, whereas fungi produce  $\beta$ -glucans, both of which can cause non-endotoxin pyrogenic responses. Endotoxins are lipopolysaccharides that exist in high molecular weight aggregate forms. However, the monomer unit of LPS is less than 10,000 daltons, enabling endotoxin to easily pass through sterilizing 0.2 micron filters. The lipid portion of the molecule is responsible for the biological activity. Since endotoxins are the most potent pyrogens and gram-negative bacteria are ubiquitous in the environment, especially water, this discussion focuses on endotoxins and the risk of their presence as contaminants in sterile products.

Pyrogens, when present in parenteral drug products and injected into patients, can cause fever, chills, pain in the back and legs, and malaise. Although pyrogenic reactions are rarely fatal, they can cause serious discomfort and, in the seriously ill patient, shock-like symptoms that can be fatal. The intensity of the pyrogenic response and its degree of hazard are affected by the medical condition of the patient, the potency of the pyrogen, the amount of the pyrogen, and the route of administration (intrathecal is most hazardous followed by intravenous, intramuscular, and subcutaneous). When bacterial (exogenous) pyrogens are introduced into the body, LPS targets circulating mononuclear cells (monocytes and macrophages) that, in turn, produce pro-inflammatory cytokines, such as interleukin 2, interleukin 6, and tissue necrosis factor. Besides LPS, gram-negative bacteria also release many peptides (e.g., exotoxin A, peptidoglycan, and muramyl peptides) that can mimic the activity of LPS and induce cytokine release. The Limulus Amebocyte Lysate (LAL) test can only detect the presence of LPS. It has been suggested that the Monocyte Activation Test, replace LAL as the official pyrogen test, due to its greater sensitivity to all agents that induce the release of cytokines that cause fever and a potential cascade of other adverse physiological effects.<sup>23</sup>

## CONTROL OF PYROGENS

It is impractical, if not impossible, to remove pyrogens, once present, without adversely affecting the drug product. Therefore, the emphasis should be on preventing the introduction or development of pyrogens in all aspects of the compounding and processing of the product.

Pyrogens may enter a preparation through any means that will introduce living or dead microorganisms. However, current technology permits the control of such contamination, and the presence of pyrogens in a finished product indicates processing under inadequately controlled conditions. It also should be noted that time for microbial growth to occur increases the risk for elevated levels of pyrogens. Therefore, compounding and manufacturing processes should be carried out as expeditiously as possible, preferably planning completion of the process, including sterilization, within the maximum allowed time, according to process validation studies. Aseptic processing guidelines require establishment of time limitations throughout processing for the primary purpose of preventing the increase of endotoxin (and microbial) contamination that, subsequently, cannot be destroyed or removed.

Pyrogens can be destroyed by heating at high temperatures. A typical procedure for depyrogenation of glassware and equipment is maintaining a dry heat temperature of 250°C for 45 min. Exposure of 650°C for 1 min or 180°C for 4 hours, likewise, will destroy pyrogens. The usual autoclaving cycle will not

do so. Heating with strong alkali or oxidizing solutions destroys pyrogens. It has been claimed that thorough washing with detergent will render glassware pyrogen-free, if subsequently rinsed thoroughly with pyrogen-free water. Rubber stoppers cannot withstand pyrogen-destructive temperatures, so reliance must be on an effective sequence of washing, thorough rinsing with WFI, prompt sterilization, and protective storage to ensure adequate pyrogen control. Similarly, plastic containers and devices must be protected from pyrogenic contamination during manufacture and storage, since known ways of destroying pyrogens affect the plastic adversely. It has been reported that anion-exchange resins and positively-charged membrane filters remove pyrogens from water. Also, although reverse osmosis membranes will eliminate them, the most reliable method for their elimination from water is distillation.

A method that has been used for the removal of pyrogens from solutions is adsorption on adsorptive agents. However, since the adsorption phenomenon may also cause selective removal of chemical substances from the solution, this method has limited application. Other in-process methods for their destruction or elimination include selective extraction procedures and careful heating with dilute alkali, dilute acid, or mild oxidizing agents. In each instance, the method must be studied thoroughly to be sure it will not have an adverse effect on the constituents of the product. Although ultrafiltration now makes pyrogen separation on a molecular-weight basis possible and the process of tangential flow is making large-scale processing more practical, use of this technology is limited, except in biotechnological processing.

## SOURCES OF PYROGENS

Through understanding the means by which pyrogens may contaminate parenteral products, their control becomes more achievable. Therefore, it is important to know that water is probably the greatest potential source of pyrogenic contamination, since water is essential for the growth of microorganisms and frequently contaminated with gram-negative organisms. When microorganisms metabolize, pyrogens will be produced. Therefore, raw water can be expected to be pyrogenic and only when it is appropriately treated to render it free from pyrogens, such as WFI, should it be used for compounding the product or rinsing product contact surfaces, such as tubing, mixing vessels, and rubber closures. Even when such rinsed equipment and supplies are left wet and improperly exposed to the environment, there is a high risk they will become pyrogenic. Although proper distillation will provide pyrogen-free water, storage conditions must be such that microorganisms are not introduced and subsequent growth is prevented.

Other potential sources of contamination are containers and equipment. Pyrogenic materials adhere strongly to glass and other surfaces, especially rubber closures. Residues of solutions in used equipment often become bacterial cultures, with subsequent pyrogenic contamination. Since drying does not destroy pyrogens, they may remain in equipment for long periods. Adequate washing reduces contamination, and subsequent dry-heat treatment can render contaminated equipment suitable for use. However, all such processes must be validated to ensure effectiveness. Aseptic processing guidelines require validation of the depyrogenation process by demonstrating at least 3-log reduction in an applied endotoxin challenge.

Solutes may be a source of pyrogens. For example, the manufacturing of bulk chemicals may involve the use of pyrogenic water for process steps, such as crystallization, precipitation, or washing. Bulk drug substances derived from cell culture fermentation will almost certainly be heavily pyrogenic. Therefore, all lots of solutes used to prepare parenteral products should be tested to ensure they will not contribute unacceptable quantities of endotoxin to the finished product. It is standard practice, today, to establish valid endotoxin limits on active pharmaceutical ingredients and most solute additives.

The manufacturing process must be carried out with great care and as rapidly as possible, to minimize the risk of microbial contamination. Preferably, no more product should be prepared than can be processed completely within one working day, including sterilization.

## PRODUCTION FACILITIES

The production facility and its associated equipment must be designed, constructed, and operated properly for the manufacture of a sterile product to be achieved at the quality level required for safety and effectiveness. Materials of construction for sterile product production facilities must be 'smooth, cleanable, and impervious to moisture and other damage'. Further, the processes used must meet cGMP standards. Since the majority of SVIs are aseptically processed (finished product not terminally sterilized), strict adherence to cGMP standards with respect to sterility assurance (particularly, the FDA and EU aseptic processing guidance documents, which can be found at <http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm070342.pdf> and Eudra. ex Vol 4, Annex I. Manufacture of Sterile Medicinal Products, [http://ec.europa.eu/health/files/eudralex/vol-4/2008\\_11\\_25\\_gmp-an1\\_en.pdf](http://ec.europa.eu/health/files/eudralex/vol-4/2008_11_25_gmp-an1_en.pdf)) is essential.

## FUNCTIONAL AREAS

To achieve the goal of a manufactured sterile product of exceptionally high quality, many functional production areas are involved: warehousing or procurement; compounding (formulation); materials (containers, closures, equipment) preparation; filtration and sterile receiving; aseptic filling; stoppering; lyophilization (if warranted); and packaging, labeling, and quarantine. The extra requirements for the aseptic area are designed to provide an environment where a sterile fluid may be exposed to the environment for a brief period during subdivision from a bulk container to individual-dose containers, without becoming contaminated. Contaminants, such as dust, lint, and other particles and micro-organisms, are found floating in the air, lying on counters and other surfaces, attached to clothing and body surfaces of personnel, concentrated in the exhaled breath of personnel, and deposited on the floor. The design and control of an aseptic area is directed toward reducing the presence of these contaminants, so they are no longer a hazard to aseptic filling.

Although the aseptic area must be adjacent to support areas, so an efficient flow of components may be achieved, barriers must be provided to minimize ingress of contaminants to the critical aseptic area. Such barriers may consist of a variety of forms, including sealed walls, manual or automatic doors, airlock pass-throughs, ports of various types, or plastic curtains. Figure 26-6 shows an example of a floor plan for a clinical supply production facility (selected as an example of a small-scale, noncomplex facility) in which the two fill rooms and the staging area constitute the walled critical aseptic area, access to which is only by means of pass-through airlocks. Adjacent support areas (rooms) consist of glass preparation, equipment wash, capping, manufacturing (compounding), and various storage areas. Figure 26-7 shows an example of a Class 100/Grade A small scale filling room with operators properly gowned and practicing good aseptic techniques.

## FLOW PLAN

In general, the components for a parenteral product flow from the warehouse, after release, to either the compounding area, as for ingredients of the formula, or the materials support area, as for containers and equipment. After proper processing in these areas, the components flow into the security of the aseptic area for filling of the product in appropriate containers. From there the product passes into the quarantine and packaging area, where it is held until all necessary tests have been performed. If the product is to be sterilized in its final container, its passage

**Figure 26-6.** Floor plan of aseptic filling rooms and staging room with adjacent support areas.

**Figure 26-7.** Properly gowned and trained aseptic processing operators in a Class 100/Grade A Clean Room. (Courtesy of Dr. Laura Thoma, The University of Tennessee College of Pharmacy.)

is interrupted after leaving the aseptic area for subsection to the sterilization process. After the results from all tests are known, the batch records have been reviewed, and the product has been found to comply with its release specifications, it passes to the finishing area for final release for shipment. There, sometimes, are variations from this flow plan to meet the specific needs of an individual product or to conform to existing facilities. Automated operations have much larger capacity and convey the components from one area to another with little or no handling by operators.

## Clean Room Classified Areas

Due to the extremely high standards of cleanliness and purity that must be met by parenteral products, it has become standard practice to prescribe specifications for the environments (clean rooms) in which these products are manufactured (Table 26-4). Table 26-4A compares US and European classifications and

**Table 26-4A. Clean Room Classifications**

European	United States	International Society of	Max No. of Particles	Max No. of Particles
Grade	Classification	Pharm. Eng. Description	per m <sup>3</sup> >= 0.5 μm	per m <sup>3</sup> >= 5 μm
A	100	Critical	3,500	0
B	100	Clean	3,500	0
C	10,000	Controlled	350,000	2,000
D	100,000	Pharmaceutical	3,500,000	20,000

**Table 26-4B. ISO 14644 Classification of Cleanroom Particle Limits**

ISO Classification	Maximum Concentration Limits (Particles per Cubic Meter of Air) for Particles ≥ the Sizes per Each Column				
	0.1 μm	0.3 μm	0.5 μm	1 μm	5 μm
1	10	-	-	-	-
2	100	10	4	-	-
3	1,000	102	35	8	-
4	10,000	1,020	352	83	-
5	100,000	10,200	3,520	832	29
6	1,000,000	102,000	35,200	8320	290
7	-	-	352,000	83,200	2,930
8	-	-	3,520,000	832,000	29,300
9	-	-	-	8,320,000	293,000

clean room designations assigned by the International Society of Pharmaceutical Engineers. Table 26-4B provides the International Standards Organization (ISO) 14644 Classification of Cleanroom Particle Limits adhered to by the parenteral manufacturing industry. Table 26-4A numbers are based on the maximum allowed number of airborne particles/ft<sup>3</sup> or particles/m<sup>3</sup> of 0.5 μm or larger size and, for Europe, 5.0 μm or larger size. The classifications used in pharmaceutical practice normally range from Class 100,000 (Grade D) for materials support areas to Class 100 (Grade A) for aseptic areas. To achieve Class 100 conditions, HEPA filters are required for the incoming air, with the effluent air sweeping the downstream environment at a uniform velocity, 100 ft/min ± 20%, along parallel lines (laminar air flow). HEPA filters are defined as 99.99% or more efficient in removing, from the air, 0.3 μm particles generated by vaporization of the hydrocarbon Emory 3004.

Because so many parenteral products are manufactured at one site for global distribution, air quality standards in aseptic processing areas must meet both US and European requirements. European standards differ from US standards, as European standards:

- use Grades A, B, C, and D classifications, rather than Class X (100, 1,000, etc);
- use particle and microbial limits per cubic meter, rather than per cubic foot;
- require particle measurements at 5 microns in addition to 0.5 microns in Grade A and B areas; and
- differentiate area cleanliness dynamically and 'at rest.'

For the sake of convenience, the remainder of this chapter uses Class X (e.g., 100, 1,000, 10,000, 100,000) designations, although it is recognized that the use of Grades or ISO numbers are more contemporary.

**Air Cleaning**—Since air is one of the greatest potential sources of contaminants in clean rooms, special attention must be given to air drawn into clean rooms by the heating, ventilating, and air conditioning (HVAC) systems. This may be done by a series of treatments that vary somewhat from one installation to another.

In one such series, air from the outside, first, is passed through a prefilter, usually of glass wool, cloth, or shredded plastic, to remove large particles. Then, it may be treated by passage through an electrostatic precipitator. Such a unit induces an electrical charge on particles in the air and removes them by attraction to oppositely charged plates. The air then passes through the most efficient cleaning device, a HEPA filter.

For personnel comfort, air conditioning and humidity control should be incorporated into the system. The latter is also important for certain products, such as those that must be lyophilized, and for the processing of plastic medical devices. The clean, aseptic air is introduced into the Class 100 area and maintained under positive pressure, which prevents outside air from rushing into the aseptic area through cracks, temporarily open doors, or other openings.

**Laminar-Flow Enclosures**—The required environmental control of aseptic areas has been made possible by the use of laminar airflow, originating through a HEPA filter, occupying one entire side of the confined space. Therefore, it bathes the total space with very clean air, sweeping away contaminants. The orientation for the direction of airflow can be horizontal (Figure 26-8A) or vertical (Figure 26-8B) and may involve a limited area, such as a workbench, or an entire room. Figure 26-9 shows a syringe-filling line in a Grade A/Class 100 area using vertical laminar airflow. The machine is placed in a conventional clean room with vertical LF provided through either the ceiling or a LF hood on top of the machine. The machine guarding is a stainless steel frame that can hold the LF hood. The panes are safety glass. This could be an example of a Restricted Access Barrier System (RABS), although there are no gloves installed, thus, requiring doors to be open to access the equipment, which is contrary to the requirements of an authentic RABS. The area outside the RAB can be maintained at a slightly lower level of cleanliness than that inside, perhaps Class 10,000 down to Class 1,000.

Critical areas of processing, wherein the product or product contact surfaces may be exposed to the environment, even for a brief period of time, must meet Class 100 clean room standards.

Any contamination introduced upstream by equipment, arms of the operator, or leaks in the filter will be blown downstream.

**Figure 26-8.** Horizontal and vertical laminar air flow. (Courtesy of Cosslett AG, *The design of controlled environments*. In: Denyer SP, Baird RM, eds. *Guide to Microbiological Control in Pharmaceuticals and Medical Devices*, 2nd ed. London: CRC Press, Taylor & Francis, 2007: 69–88.)

In the instance of horizontal flow, this may be toward the critical working site, the face of the operator, or across the room. Should the contaminant be, for example, penicillin powder, a biohazard material, or viable micro-organisms, the danger to the operator is apparent.

Further, great care must be exercised to prevent cross-contamination from one operation to another, especially with horizontal laminar air flow. For most large-scale operations, as shown in Figure 26-8B and Figure 26-9, a vertical system is much more desirable, with the air flowing through perforations in the countertop or through return louvers at floor level, where it can be directed for decontamination. Laminar-flow environments provide well-controlled work areas, only if proper precautions are observed. Any reverse air currents or movements exceeding the velocity of the HEPA-filtered airflow may introduce contamination, as may coughing, reaching, or other manipulations of the operator. Therefore, laminar-flow work areas should be protected by being located within controlled environments. Personnel should be attired for aseptic processing, as subsequently described. All movements and processes should be planned carefully, to avoid the introduction of contamination upstream of the critical work area. Checks of the air stream should be performed initially and at regular intervals (usually every six months), to be sure no leaks have developed through or around the HEPA filters.

Clean room design, traditionally, has Class 100 rooms adjacent to Class 100,000 rooms. Regulatory authorities have raised great concerns about this significant change in air quality from critical to controlled areas. It is now preferable to have an area classified from Class 1,000 to Class 10,000 in a buffer area between a Class 100 and Class 100,000 area.

**Materials Support Area**—This area is constructed to withstand moisture, steam, and detergents and is, usually, a Class 100,000 clean room. The ceiling, walls, and floor should be constructed of impervious materials, so moisture runs off and is not held. One of the finishes with a vinyl or epoxy-sealing coat

**Figure 26-9.** High speed syringe filling machine for pre-sterilized syringes. (Courtesy of Robert Bosch GmbH.)

provides a continuous surface free from all holes or crevices. All such surfaces can be washed at regular intervals to keep them thoroughly clean. These areas should be exhausted adequately, so the heat and humidity are removed for the comfort of personnel. Precautions must be taken to prevent the accumulation of dirt and the growth of micro-organisms due to the high humidity and heat. In this area, preparation for the filling operation, such as cleaning and assembling equipment, is undertaken. Adequate sink and counter space must be provided. This area must be cleanable, and the microbial load must be monitored and controlled. Precautions must also be taken to prevent deposition of particles or other contaminants on clean containers and equipment, until they have been properly boxed or wrapped preparatory to sterilization and depyrogenation.

**Compounding Area**—The formula is compounded in this area. Although it is not essential that this area be aseptic, control of micro-organisms and particulates should be more stringent than in the materials support area. For example, means may need provided to control dust generated from weighing and compounding operations. Cabinets and counters should, preferably, be constructed of stainless steel. They should fit snugly to walls and other furniture, so there are no catch areas dirt can accumulate. The ceiling, walls, and floor should be similar to those for the materials support area.

**Aseptic Area**—The aseptic area requires construction features designed for maximum microbial and particulate control. The ceiling, walls, and floor must be sealed, so they may be washed and sanitized with a disinfectant, as needed. All counters should be constructed of stainless steel and hung from the wall, so there are no legs to accumulate dirt, where they rest on the floor. All light fixtures, utility service lines, and ventilation fixtures should be recessed in the walls or ceiling to eliminate ledges, joints, and other locations for the accumulation of dust and dirt. As much as possible, tanks containing the compounded product should remain outside the aseptic filling area, with the product fed into the area through hose lines. Proper sanitization is required, if the tanks must be moved in. Large mechanical equipment located in the aseptic area should be housed as completely as possible within a stainless steel cabinet, to seal the operating parts and their dirt-producing tendencies from the aseptic environment. Further, all such equipment parts should be located below the filling line. Mechanical parts that will contact the parenteral product should be demountable, so they can be cleaned and sterilized.

Personnel entering the aseptic area should enter only through an airlock. They should be attired in sterile coveralls with sterile hats, masks, goggles, foot covers, and double gloves. Movement within the room should be minimal, and in-and-out movement rigidly restricted during a filling procedure. The requirements for room preparation and the personnel may be relaxed, if the product is to be sterilized terminally in a sealed container. Some are convinced, however, it is better to have one standard procedure meeting the most rigid requirements.

**Isolation (Barrier) Technology**—Isolator (or barrier) technology has long been used in the pharmaceutical industry and ranges from simple screens to restricted access barriers (RABS) to full isolation systems, all designed to isolate aseptic operations from personnel and the surrounding environment. Sterility tests are now almost exclusively conducted within isolators. A false-positive sterility test is practically unheard of these days, such that, if a positive test does occur, it likely is a true contamination, not as a result of contamination introduced during the test. Isolation technology in various formats has been adapted to automated, large-scale, aseptic filling operations.<sup>24</sup> An example of a sterility test isolator is shown in Figure 26-10, and an example of a filling operation within an isolator is shown in Figure 26-11. The sealed enclosures are presterilized, usually with peracetic acid, hydrogen peroxide vapor, or steam. Sterile supplies are introduced from sterilizable movable modules through uniquely engineered transfer ports or directly from attached sterilizers, including autoclaves and hot-air sterilizing tunnels.

**Figure 26-10.** Example of sterility test isolator with vapor phase hydrogen peroxide generator. (Courtesy of Baxter Healthcare Corporation.)

**Figure 26-11.** Example of a large-scale filling line within an isolator. (Courtesy of Robert Bosch GmbH.)

Results have been very promising, giving expectation of significantly enhanced control of the aseptic processing environment.

Isolators are enclosed, usually positively pressurized units with high efficiency particulate air (HEPA) filters, supplying ISO 5 airflow in a unidirectional manner to the interior. Air recirculates by returning it to the air handlers through sealed ductwork. Cleaning can be manual or automated (clean-in-place). Access to an isolator is through glove ports and sterile transfer systems. Isolators can be located in an ISO 8 or better environment.

The operations are performed within windowed, sealed walls, with operators working through glove ports. The sealed enclosures are presterilized, usually with peracetic acid, hydrogen peroxide vapor, or steam. Sterile supplies are introduced from sterilizable, movable modules, through uniquely engineered transfer ports or directly from attached sterilizers, including autoclaves and hot-air sterilizing tunnels.

Recent isolator development has been significant, and such systems are now better specified than ever. In advanced aseptic processing facilities, it has been proven that isolators can provide zero colony forming unit (0 cfu) contamination in process operations, whereas the background environment is only at ISO 8 - EC grade D level. However, cost-savings in cleanroom construction and operation may be offset by the construction and validation costs of the isolator system.

For existing production lines, where conversion from conventional filling to filling within an isolator is time and cost

prohibitive, modifications of isolation systems, RABS, have been applied. RABS offer a combined physical (e.g., plexiglas partitions) and aerodynamic barrier, ideally controlled by positive pressure with clean-air filtration, providing air exchanges and particulate clean-up for an ISO 5 critical process zone. RABS come in two types—‘passive,’ where there is no in-process open door access; and ‘active,’ where, under certain validated system configurations and control conditions, access may be included.

Several factors have contributed to the increased importance and utilization of barrier isolator technology:

1. The high level of concern from manufacturers and regulatory agencies over the level of sterility assurance in aseptic processing.
2. Continued, relatively high level of product recalls, due to concerns—proven or suspected—over contamination potential.
3. The surge of potential heat-labile products from biotechnology and the inability to terminally sterilize these molecules. There are needs to control the environment not only from contamination, but also with respect to stability considerations—temperature, humidity, and, if necessary, anaerobics.
4. Many new drug compounds are cytotoxic or otherwise highly potent, where safety considerations demand separation of these drugs from human operators.
5. Because so many biopharmaceutical drugs are so expensive, there is a trend toward smaller batch production. Smaller batch production makes construction of large manufacturing facilities unnecessary, yet there is still the need to manufacture in Class 100/Grade A/ISO 5 clean rooms. Isolators are ideal for smaller facilities, plus are much more economical from the standpoint of capital, labor and maintenance, and operator (e.g., number of employees, gowning) costs.

The main features of barrier/isolator technology are the ability to sterilize (more than sanitize) the environment to which sterile solution is exposed during filling and stoppering and the removal of direct human contact with the exposed sterile product. Isolators not only protect the product from potential human contamination, but also protect the human from potential toxic effects of direct exposure to the drug product, especially important for cytotoxic drugs.

## MAINTENANCE OF CLEAN ROOMS

Maintaining the clean and sanitized conditions of clean rooms, particularly the aseptic areas, requires diligence and dedication of expertly trained custodians. Assuming the design of the facilities is cleanable and sanitizable, a carefully planned cleaning schedule should be developed, ranging from daily to monthly, depending on the location and its relation to the most critical Class 100 areas. Tools used should be non-linting, designed for clean room use, held captive to the area, and, preferably, sterilizable.

Liquid disinfectants (sanitizing agents) should be selected carefully, due to data showing their reliable activity against inherent environmental micro-organisms. They should be recognized as supplements to good housekeeping, never as substitutes. They should be rotated with sufficient frequency to avoid the development of resistant strains of micro-organisms. Figure 26-12 features an example of the ‘three bucket’ system used to sanitize facilities. One bucket is to remove as much of the remnant of the ‘dirty’ mop or sponge, the second bucket contains a rinse solution to help clean the mop/sponge, and the third bucket contains the sanitizing solution. The sanitizing solution should be rendered sterile prior to use, although, once in use, it will no longer be sterile.

It should be noted that ultraviolet (UV) light rays of 237.5 nm wavelength, as radiated by germicidal lamps, are an effective

Figure 26-12. Three bucket sanitizing system. (Courtesy of Contec, Inc. and Steve Fincher Photography.)

surface disinfectant. However, it must also be noted that they are only effective, if they contact the target micro-organisms at a sufficient intensity for a sufficient time. The limitations of their use must be recognized, including no effect in shadow areas, reduction of intensity by the square of the distance from the source, reduction by particulates in the ray path, and the toxic effect on epithelium of human eyes. It is stated that an irradiation intensity of  $20 \mu\text{w}/\text{cm}^2$  is required for effective antibacterial activity.

## PERSONNEL

Personnel selected to work on the preparation of a parenteral product must be neat, orderly, and reliable. They should be in good health and free from dermatological conditions that might increase the microbial load. If personnel show symptoms of a head cold, allergies, or similar illness, they should not be permitted in the aseptic area, until recovery is complete. However, a healthy person with the best personal hygiene will still shed large numbers of viable and nonviable particles from body surfaces.<sup>25</sup> This natural phenomenon creates continuing problems, when personnel are present in clean rooms; effective training and proper gowning can reduce, but not eliminate, the problem of particle shedding from personnel.

Aseptic-area operators should be given thorough, formal training in the principles of aseptic processing and the techniques to be employed.<sup>26</sup> Subsequently, the acquired knowledge and skills should be evaluated, to assure that training has been effective, before personnel are allowed to participate in the preparation of sterile products. Retraining should be performed on a regular schedule to enhance the maintenance of the required level of expertise. An effort should be made to imbue operators with an awareness of the vital role they play in determining the reliability and safety of the final product. This is especially true of supervisors, since they should be individuals who not only understand the unique requirements of aseptic procedures, but are able to obtain the full participation of other employees in fulfilling these exacting requirements.

The uniform worn is designed to confine the contaminants discharged from the body of the operator, thereby preventing their entry into the production environment. For use in the

**Figure 26-13.** Fully gowned personnel in Class 100/Grade A/B Cleanrooms. (Courtesy of Baxter Healthcare Corporation.)

aseptic area, uniforms should be sterile. Fresh, sterile uniforms should be used after every break period or whenever the individual returns to the aseptic area. In some plants, this is not required, if the product is to be sterilized in its final container. Uniforms, usually, consist of coveralls for both men and women, hoods to cover the hair completely, face masks, and Dacron or plastic boots (Fig. 26-7 and Fig. 26-13). Sterile rubber or latex-free gloves are also required for aseptic operations, preceded by thorough scrubbing of the hands with a disinfectant soap. Two pairs of gloves are put on, one pair at the beginning of the gowning procedure, the other pair after all other apparel has been donned. In addition, goggles are required to complete the coverage of all skin areas.

Dacron or Tyvek uniforms are usually worn, are effective barriers to discharged body particles (viable and nonviable), are essentially lint-free, and are reasonably comfortable. Air showers are sometimes directed on personnel entering the processing area to blow loose lint from the uniforms.

Gowning rooms should be designed to enhance pregowning and gowning procedures by trained operators, so it is possible to ensure the continued sterility of the exterior surfaces of the sterile gowning components. Degowning should be performed in a separate exit room.

## ENVIRONMENTAL CONTROL EVALUATION

Manufacturers of sterile products use extensive means to control the environment, so these critical injectable products can be prepared free from contamination. Nevertheless, tests should be performed to determine the level of control actually achieved. Normally, the tests consist of counting viable and non-viable particles suspended in the air or settled on surfaces in the workspace. A baseline count, determined by averaging multiple counts, when the facility is operating under controlled conditions, is used to establish the optimal test results expected. During the subsequent monitoring program, the test results are followed carefully for high individual counts, a rising trend, or other abnormalities. If the results exceed selected alert or action levels, a plan of action must be put into operation to determine if or what corrective and follow-up measures are required.

The tests used measure either the particles in a volume of sampled air or the particles settling or present on surfaces. To measure the total particle content in an air sample, electronic particle counters are available, operating on the principle of the measurement of light scattered from particles as they pass through the cell of the optical system. These instruments not only count particles, but also provide a size distribution, based on the magnitude of the light scattered from the particle.

Although a volume of air measured by an electronic particle counter will detect all particles instantly, these instruments cannot differentiate between viable (e.g., bacterial and fungal) and non-viable particles. Due to the need to control the level of micro-organisms in the environment in which sterile products are processed, it is also necessary to detect viable particles. These are usually fewer in number than non-viable particles and are only detectable as colony-forming units (CFUs) after a suitable incubation period at, for example, 30°C to 35°C for up to 48 hours. Thus, test results will not be known until 48 hours after the samples are taken, unless more rapid microbial test procedures become dependable and acceptable.

Locations for sampling should be planned to reveal potential contamination levels that may be critical in the control of the environment. For example, the most critical process step is usually the filling of dispensing containers, a site obviously requiring monitoring. In fact, the FDA aseptic processing guidelines require air particle counts be measured during actual filling and closing operations and not more than one foot from the actual work site.<sup>27</sup> Other examples include the gowning room, high-traffic sites in and out of the filling area, the penetration of conveyor lines through walls, and sites near the inlet and exit of the air system.

The sample should be large enough to obtain a meaningful particle count. At sites where the count is expected to be low, the size of the sample may need increased; for example, in Class 100 areas, Whyte and Niven<sup>28</sup> suggest that the sample be at least 30 ft<sup>3</sup> and, probably, much more. Many firms employ continuous particle monitoring in Class 100 areas to study trends and/or to identify equipment malfunction.

The slit-to-agar (STA) sampler draws, by vacuum, a measured volume of air through an engineered slit, causing the air to impact the surface of a slowly rotating nutrient agar plate (Fig. 26-14). Micro-organisms adhere to the surface of the agar and grow into visible colonies counted as CFUs, since it is not known whether the colonies arise from a single micro-organism or a cluster.

A widely used method for microbiological sampling consists of the exposure of nutrient agar culture plates to the settling of micro-organisms from the air. This method is very simple and inexpensive to perform, but will detect only those organisms that have settled on the plate; therefore, it does not measure the number of micro-organisms in a measured volume of air (a non-quantitative test). Nevertheless, if the conditions of exposure are repeated consistently, a comparison of CFUs at one sampling site, from one time to another, can be meaningful.

Whyte and Niven suggested that settling plates should be exposed in Class 100 areas for an entire fill (up to 7 to 8 hours), rather than the more common 1 hour. However, excessive dehydration of the medium must be avoided, particularly in the path of laminar-flow air. The European Union GMP guidelines for sterile manufacture of medicinal products suggest an exposure period of not more than four hours that has been adopted by the FDA aseptic processing guidelines.

The number of micro-organisms on surfaces can be determined with nutrient agar plates having a convex surface (Rodac Plates; Fig. 26-15). With these, it is possible to roll the raised agar surface over flat or irregular surfaces to be tested. Organisms are picked up on the agar and grow during subsequent incubation. This method can also be used to assess the number of micro-organisms present on the surface of the uniforms of operators, either as an evaluation of gowning technique, immediately after gowning, or as a measure of the accumulation of micro-organisms during processing. Whenever used, care must be taken to remove any agar residue left on the surface tested.

(Further discussion of proposed, viable particle test methods and the counts accepted can be found in Section <1116> 'Microbial Evaluation and Classification of Clean Rooms and Other Controlled Environments' in the USP.)

Results from these tests, although not available until 2 days after sampling, are valuable to keep cleaning, production, and

**Figure 26-14.** Examples of a Slit-To-Agar (STA) Quantitative Air Sampler.

**Figure 26-15.** Example of a Rodac plate. (Courtesy of Baxter Healthcare Corporation.)

quality-control personnel apprised of the level of contamination in a given area and, by comparison with baseline counts, will indicate when more-extensive cleaning and sanitizing is needed. The results may also serve to detect environmental control defects, such as failure in air-cleaning equipment or the presence of personnel who may be disseminating large numbers of bacteria without apparent physical ill effects.

Issues regarding environmental monitoring remain among the most controversial aspects of cGMP regulatory inspections of parenteral manufacturing and testing environments. Regulatory trends include requiring an increase in the number and frequency of locations monitored in the clean room and on clean room personnel, enforcing numerical alert and action limits, and linking environmental monitoring data to the decision to release or reject the batch. It has been pointed out that fully gowned personnel still release a finite number of micro-organisms (typically 10 to 100 cfu per hour), so it is unreasonable to impose the requirement of zero microbial contamination limits at any location in the clean room.<sup>29</sup>

### MEDIA FILL (PROCESS SIMULATION TESTING)

FDA inspections have increasingly focused on media fill studies that truly simulate the production process. The media fill or process simulation test involves preparation and sterilization (often by filtration) of sterile trypticase soy broth and filling sterile containers with this broth, under conditions simulating, as closely as possible, those characteristics of a filling process for a product. The key is designing these studies to simulate all factors that occur during the normal production of a lot (Table 26-5).<sup>27</sup>

The media fill provides a 'one-time' representation of the capabilities of an aseptic processing operation. Media fills are conducted, when a new filling line or new product container is introduced. For initial qualification of a line or product, three consecutive, separate, and successful media fill runs must take place. The FDA stresses that three is a minimum number of runs. Today, the term 'successful' means there is no growth in any of the units filled with sterile broth. All activities and interventions representative of each shift on each line must be simulated during the media fill. All personnel involved in the aseptic filling of a product (i.e., operators, maintenance personnel, microbiology support personnel) must participate in at least one media fill run per year. Typically, for each filling line

**Table 26-5. Factors to Consider in the Design of Media Fill Studies**

- Duration of longest run
- Worst-case environmental conditions
- Number and type of interventions, stoppages, adjustments, transfers
- Aseptic assembly of equipment
- Number and activities of personnel
- Number of aseptic additions
- Shift breaks, changes, multiple gownings
- Number/type of aseptic equipment disconnections and connections
- Aseptic samples
- Line speed/configuration
- Manual weight checks
- Operator fatigue
- Container/closure types run on the line
- Temperature/relative humidity extremes
- Conditions permitted before line clearance
- Container/closure surfaces which contact formulation during aseptic process

and process, the filling operation is validated for the smallest and largest container size that will be used.

After initial qualification, media fills are then conducted on a periodic basis, usually twice a year on the same filling line, to ensure that conditions that existed during the initial qualification have been maintained. For periodic qualification, only one successful media fill run is required. If any media fill run fails or significant changes occur with the line, facility, or personnel, then the initial qualification media fill (three consecutive successful runs) must be conducted. Any changes in the process must be evaluated for its level of significance (change control quality system) that would necessitate a media fill validation run. Any media fill failure must be thoroughly investigated and followed by multiple repeat media fill runs. It is considered inappropriate to 'invalidate' a media fill run.

The number of containers filled with media, ideally, should be the same as the actual number filled, according to the batch record for the product being validated. Of course, this is unrealistic for large batch sizes. Therefore, the number of units filled must be sufficient to reflect the effects of all worst case filling rates. For example, operator fatigue and the maximum number of interventions and stoppages must be incorporated into the media fill protocol. When media filling first started, the acceptable rate of positives (number of containers that showed contamination after incubating the culture media) was 1 out of 1000 (0.1%). Later that number became 1 out of 3000 to account for 95% confidence of a contamination rate of 0.1%. Today, 1 positive out of 3000 is no longer acceptable. Table 26-6 presents that ISO standard used to determine the minimum number of containers filled with media and the acceptable number of positives. The most common number of containers filled with media in the industry is 4750 with three consecutive runs of 4750 used for initial performance qualification of a new product and/or filling/closing line. This same number of units filled—4750—is also used for the routine semi-annual requalification media fills. The expected number of positive media fills (growth seen upon incubation) is zero. One or more failures likely means there is a significant breach in the aseptic manufacturing process, and the ensuing investigation must do everything possible to find the assignable cause.

After filling with culture media, but prior to incubation, all units should be inverted or swirled to enable the media to make contact with all internal surfaces of the container/closure system.

The culture media used for each media fill exercise must be tested to ensure it will support the growth of microorganisms, if they are present. Challenge organisms used in the media challenge pretesting should include those isolated from

environmental/personnel monitoring, those isolated from positive sterility test results and USP growth promotion microorganisms. The positive control units inoculated with approximately 100 CFUs of these challenge organisms are incubated at temperatures and times validated to show microbial growth if present. After the 14 day incubation period of the media fill containers, negative control units should then be inoculated with challenge organisms, to prove the media will still support growth, if present.

Inspection of media filled units, before and after incubation, is conducted by individuals trained as qualified inspectors and certified by the quality control unit. It is permissible that any unit, after filling, that is found to lack integrity be rejected from being part of the media fill incubation, just as a product vial would be rejected if a critical defect were found. However, if a media fill unit is found damaged after incubation is underway, it must remain incubated and counted in the data for the media fill batch. Procedures must be very clear and specific regarding samples taken during the media fill that simulate the actual sampling process and why these units are not part of those incubated.

Other requirements of a valid media fill experiment include:

- Must have the appropriate criteria for batch yield and accountability, just like a product batch.
- Must identify any contaminant to the species level and perform complete investigations of failed media fills.
- FDA advocates videotape media fills to identify personnel practices that could negatively impact the aseptic process.
- Media fill duration, according to FDA, EU, ISO, CEN (European Committee of Standardization), and PIC, must be sufficiently long to include all required manipulations and cover the same length of time normally consumed by the commercial process. Most media fills are a minimum of 3 hours; some may be as long as 24 hours.

## PRODUCTION PROCEDURES

The processes required for preparing sterile products constitute a series of events initiated with the procurement of approved raw materials (drugs, excipients, vehicles, etc.) and primary packaging components (containers, closures, etc.) and ending with the sterile product sealed in its dispensing package. Each step in the process must be controlled very carefully, so the product has its required quality. To ensure the latter, each process should be validated to ensure it is accomplishing what it is intended to do. For example, an autoclave sterilization process must be validated by producing data showing it effectively kills resistant forms of microorganisms; or, a cleaning process for rubber closures should provide evidence that it is cleaning closures to the required level of cleanliness; or, a filling process should provide evidence that it repeatedly delivers the correct fill volume per container. The validation of processes requires extensive and intensive effort to be successful and is an integral part of cGMP requirements.

## CLEANING CONTAINERS AND EQUIPMENT

Containers and equipment coming in contact with parenteral preparations must be cleaned meticulously. It should be obvious that even new, unused containers and equipment are contaminated with such debris as dust, fibers, chemical films, and other materials arising from such sources as the atmosphere, cartons, the manufacturing process, and human hands. Residues from previous use must be removed from used equipment, before it is suitable for reuse. Equipment should be reserved exclusively for use only with parenteral preparations and, where conditions dictate, only for one product to reduce the risk of contamination. For many operations, particularly with biologic and biotechnology products, equipment is dedicated for only one product.

**Table 26-6. ISO 13408-1 Standards for Minimum Number of Containers Filled with Media and the Acceptable Number of Positives**

Number of Media Fill Units	Allowable Number of Failed Units (95% C.L.) by ISO	Allowable Number of Failed Units by Simple Math
3,000	1	3
4,750	2	4
6,300	3	6
7,760	4	7
9,160	5	9
10,520	6	10
11,850	7	11
13,150	8	13
14,440	9	13
15,710	10	15
16,970	11	17

A variety of machines are available for cleaning new containers for parenteral products. These vary in complexity from a small, hand loaded, rotary rinsers to large, automatic washers capable of processing several thousand containers per hour. The selection of the particular type is determined largely by the physical type of containers, the type of contamination, and the number to be processed in a given period of time.

Validation of cleaning procedures for equipment is another 'hot topic,' with respect to cGMP regulatory inspections. Inadequate cleaning processes have been a frequent citing by FDA and other regulatory inspectors, when inspecting both active ingredient and final product manufacturing facilities. It is incumbent upon parenteral manufacturers to establish scientifically justified acceptance criteria for cleaning validation. If specific analytical limits for target residues are arbitrarily set, this will cause concern for quality auditors. Validation of cleaning procedures can be relatively complicated, due to issues with sample methods (e.g., swab, final rinse, and testing of subsequent batch), sample locations, sensitivity of analytical methods, and calculations used to establish cleaning limits. Cleaning validation involves challenging the 'hardest to clean' surfaces with a well-defined sample, typically an active pharmaceutical ingredient (API) or a known 'hard to remove' substance like a sparingly soluble pharmaceutical or 'sticky' protein. The cleaning procedure is applied, using either swab samples or rinse samples obtained from the 'hardest to clean' surface locations. These samples are analyzed for residual API, using either a specific analytical technique, such as high performance liquid chromatography, or non-specific method, such as total organic carbon. Acceptance limits must be justified that the cleaning procedure accomplishes repeatedly before the cleaning method can be considered valid. (Additional discussion of this topic is found in Chapter 25 – Sterilization Processes and Sterility Assurance.)

### CHARACTERISTICS OF MACHINERY

Regardless of the type of cleaning machine selected, certain fundamental characteristics are usually required:

1. The liquid or air treatment must be introduced in such a manner that it will strike the bottom of the inside of the inverted container, spread in all directions, and smoothly flow down the walls and out the opening with a sweeping action. The pressure of the jet stream should be such that there is minimal splashing and turbulence inside. Splashing may prevent cleaning all areas, and turbulence may redeposit loosened debris. Therefore, direct introduction of the jet stream within the container with control of its flow is required.
2. The container must receive a concurrent outside rinse.
3. The cycle of treatment should provide a planned sequence, alternating very hot and cool treatments. The final treatment should be an effective rinse with WFI.
4. All metal parts coming in contact with the containers and with the treatments should be constructed of stainless steel or some other non-corroding and non-contaminating material.

### TREATMENT CYCLE

The cycle of treatments to be employed varies with the condition of the containers to be cleaned. In general, loose debris can be removed by vigorous rinsing with water. Detergents are rarely used for new containers, due to the risk of leaving detergent residues. However, a thermal-shock sequence in the cycle is usually employed to aid, by expansion and contraction, loosening of debris that may be adhering to the container wall. Sometimes, only an air rinse is used for new containers, if only loose debris is present. In all instances, the final rinse, whether air or WFI, must be ultraclean, so no particulate residues are left by the rinsing agent.

**Figure 26-16.** Loading end of large conveyer vial washer for vials from a rotary rinser through a sterilizing tunnel with vertical laminar-airflow protection of clean vials. (Courtesy of Baxter Healthcare Corporation.)

Only new containers are used for parenterals. Improvements have been made in maintaining their cleanliness, during shipment from the manufacturer through tight, low-shedding packaging, including plastic blister packs.

### MACHINERY FOR CONTAINERS

The machinery available for cleaning containers embodies the previously mentioned principles, but varies in the mechanics by which it is accomplished. In one manual loading type, the jet tubes are arranged on arms like the spokes of a wheel, which rotate around a center post through which the treatments are introduced. An operator places the unclean containers on the jet tubes, as they pass the loading point, and removes the clean containers as they complete one rotation. A continuous automated line operation, capable of cleaning hundreds of containers per hour, is shown in Figure 26-16. The vials are fed into the rotary rinser in the foreground, transferred automatically to the covered sterilizing tunnel in the center, conveyed through the wall in the background, and discharged into the filling clean room.

### HANDLING AFTER CLEANING

The wet, clean containers must be handled in such a way that contamination is not reintroduced. A wet surface will collect contaminants much more readily than a dry surface will. For this reason, wet, rinsed containers must be protected (e.g., by a laminar flow of clean air until covered, within a stainless steel box, or within a sterilizing tunnel). In addition, microorganisms are more likely to grow in the presence of moisture. Therefore, wet, clean containers should be dry-heat sterilized, as soon as possible after washing. Doubling the heating period is also adequate to destroy pyrogens; for example, increasing the dwell time at 250° from 1 to 2 hours, however, the actual time-temperature conditions required must be validated.

Increases in process rates have necessitated the development of continuous, automated line processing, with a minimum of individual handling, still maintaining adequate control of the cleaning and handling of the containers.<sup>17</sup> The clean, wet containers are protected by filtered, laminar-flow air from the rinser, through the tunnel, and until they are delivered to the filling line (Fig. 26-16).

### CLOSURES

The rough, elastic, and convoluted surface of rubber closures renders them difficult to clean. In addition, any residue of lubricant from molding or surface 'bloom' of inorganic constituents must be removed. The normal procedure calls for gentle agitation in a hot solution of a mild water softener or

detergent. The closures are removed from the solution and rinsed several times, or continuously for a prolonged period, with filtered WFI. The rinsing is done in a manner that flushes away loosened debris. The wet closures are carefully protected from environmental contamination, sterilized, usually by steam sterilization (autoclaving), and stored in closed containers, until ready for use. This cleaning and sterilizing process must also be validated with respect to rendering the closures free from pyrogens. Actually, it is the cleaning and final, thorough rinsing with WFI that must remove pyrogens, since autoclaving does not destroy pyrogens. If the closures were immersed during autoclaving, the solution is drained off, before storage, to reduce hydration of the rubber compound. If the closures must be dry for use, they may be subjected to vacuum drying at a temperature in the vicinity of 100°C. Some freeze-dried products require extremely dry closures to avoid desorption of moisture from the closure into the moisture-sensitive powder during storage. This may require drying times of hours, following steam sterilization.

The equipment used for washing large numbers of closures is usually an agitator or horizontal basket-type automatic washing machine. Due to the risk of particulate generation from the abrading action of these machines, some procedures simply call for heating the closures in kettles in detergent solution, followed by prolonged flush rinsing. The final rinse should always be with low-particulate WFI. Figure 26-17 shows an example of a modern closure processor that washes, siliconizes, sterilizes, and transports closures directly to the filling line.

It is also possible to purchase rubber closures already cleaned and lubricated in sterilizable bags supplied by the rubber closure manufacturer.

#### EQUIPMENT

All equipment should be disassembled as much as possible to provide access to internal structures. Surfaces should be scrubbed thoroughly with a stiff brush, using an effective detergent and paying particular attention to joints, crevices, screw threads, and other structures where debris is apt to collect. Exposure to a stream of clean steam aids in dislodging residues from the walls of stationary tanks, spigots, pipes, and similar

structures. Thorough rinsing with distilled water should follow the cleaning steps.

Due to the inherent variation in manual cleaning, the difficult accessibility of large stationary tanks, and the need to validate the process, computer-controlled systems, usually automated, known as clean-in-place (CIP) systems, have been developed. Such an approach involves designing the system, normally of stainless steel, with smooth, rounded internal surfaces and without crevices. That is, for example, with welded, rather than threaded, connections. Cleaning is accomplished with the scrubbing action of high-pressure spray balls or nozzles delivering hot detergent solution from tanks captive to the system, followed by thorough rinsing with WFI. The system is often extended to allow sterilizing-in-place (SIP), to accomplish sanitizing or sterilizing as well.

Rubber tubing, rubber gaskets, and other rubber parts may be washed in a manner as described for rubber closures. Thorough rinsing of tubing must be done by passing WFI through the tubing lumen. However, due to the relatively porous nature of rubber compounds and the difficulty in removing all traces of chemicals from previous use, it is considered by some inadvisable to reuse rubber or polymeric tubing. Rubber tubing must be left wet when preparing for sterilization by autoclaving.

#### PRODUCT PREPARATION

The basic principles employed in the compounding of the product are essentially the same as those used, historically, by pharmacists. However, large-scale production requires appropriate adjustments in the processes and their control.

A master formula should be developed and be on file. Each batch formula sheet should be prepared from the master and confirmed for accuracy. All measurements of quantities should be made as accurately as possible and checked by a second qualified person. Frequently, formula documents are generated by computer, and the measurements of quantities of ingredients are computer controlled. Although most liquid preparations are dispensed by volume, they are prepared by weight, since weighing can be performed more accurately than volume measurements, and no consideration needs to be given to the temperature.

**Figure 26-17.** Examples of Rubber Stopper Preparation Systems that clean, siliconize, and depyrogenate stoppers. (Courtesy of Getinge.)

Care must be taken that equipment is not wet enough to dilute the product significantly or, in the case of anhydrous products, to cause a physical incompatibility. The order of mixing of ingredients may affect the product significantly, particularly those of large volume, where attaining homogeneity requires considerable mixing time. For example, the adjustment of pH by the addition of an acid, even though diluted, may cause excessive local reduction in the pH of the product, so adverse effects are produced before the acid can be dispersed throughout the entire volume of product.

Parenteral dispersions, including colloids, emulsions, and suspensions, provide particular problems. In addition to the problems of achieving and maintaining proper reduction in particle size under aseptic conditions, the dispersion must be kept in a uniform state of suspension throughout the preparative, transfer, and subdividing operations.

Biopharmaceuticals are usually extremely sensitive to many environmental and processing conditions exposed to during production, such as temperature, mixing time and speed, order of addition of formulation components, pH adjustment and control, and contact time with various surfaces, such as filters and tubing. Development studies must include evaluation of manufacturing conditions to minimize adverse effects of the process on the activity of the protein.

Among many causes for protein aggregation are protein particles, resulting from heterogeneous nucleation on foreign micro- or nanoparticles, originating from the manufacturing process (i.e., mixing tanks, process tubing, filter systems, filling machines<sup>30</sup> or any other stainless steel, rubber, glass, or plastic surface<sup>31</sup>) and from the container/closure system.<sup>30</sup> It is well known that silicone oil, used as a lubricant for rubber closures, on vials, on rubber plungers, in prefilled syringes, and to coat the inner surface of glass syringes and cartridges can also induce protein aggregation.<sup>32,33</sup> Although switching from silicone-coated containers to plastic containers and using coated rubber closures, rather than siliconized rubber closures, may minimize or eliminate the problems of protein aggregation, other challenges surface, such as unknown leachate potential, sterilization of components, vendor reliability, and cost.

The formulation of a stable product is of paramount importance. Certain aspects of this are mentioned in the discussion of components of the product. (Exhaustive coverage of the topic is not possible within the limits of this text, but further coverage is provided in Chapters 24 [Solutions, Emulsions, Suspensions and Extracts] and 4 [Stability of Pharmaceutical Products]). It should be mentioned here, however, that the thermal sterilization of parenteral products increases the possibility of chemical reactions. Such reactions may progress to completion, during the period of elevated temperature in the autoclave, or be initiated at this time but continue during subsequent storage. The assurance of attaining product stability requires a high order of pharmaceutical knowledge and responsibility.

## FILTRATION

After a product has been compounded, it must be filtered, if it is a solution. The primary objective of filtration is to clarify a solution. A further step, removing particulate matter down to 0.2  $\mu\text{m}$  in size, would eliminate micro-organisms and would accomplish cold sterilization. A solution with a high degree of clarity conveys the impression of high quality and purity, desirable characteristics for a parenteral solution.

Filters are thought to function by one or, usually, a combination of: 1) sieving or screening, 2) entrapment or impaction, and 3) electrostatic attraction (Fig. 26-18). When a filter retains particles by sieving, they are retained on the surface of the filter. Entrapment occurs when a particle smaller than the dimensions of the passageway (pore) becomes lodged in a turn or impacted on the surface of the passageway. Electrostatic attraction causes particles opposite in charge to that of the surface of the filter pore to be held or adsorbed to the surface. It should be noted that

Figure 26-18. Membrane filter characteristics. (Courtesy of EMD Millipore Corporation.)

increasing, prolonging, or varying the force behind the solution may tend to sweep particles initially held by entrapment or electrostatic charge through the pores and into the filtrate.

Membrane filters are used exclusively for parenteral solutions, due to their particle-retention effectiveness, non-shedding property, non-reactivity, and disposable characteristics. However, it should be noted that non-reactivity does not apply in all cases. For example, polypeptide products may show considerable adsorption through some membrane filters, but those composed of polysulfone and polyvinylidene difluoride (PVDF) have been developed to be essentially non-adsorptive for these products. The most common membranes are composed of Cellulose esters, Nylon, Polysulfone, Polycarbonate, PVDF, or Polytetrafluoroethylene (Teflon).

Filters are available as flat membranes or pleated into cylinders (Fig. 26-19) to increase surface area and, thus, flow rate. Each filter in its holder should be tested for integrity before and after use, particularly, if it is being used to eliminate micro-organisms. This integrity test is performed either as the 'bubble-point test' or as the 'diffusion or forward flow' test. The bubble point test is commonly used on smaller filters. As the surface area of filters becomes large, diffusion of air through the water-filled pores tends to obscure the bubble point. Therefore, the diffusion test has been developed as an integrity test for filters with large surface areas. A 'pressure hold test' can also be applied to large surface area filters. The filter manufacturer will recommend the best integrity test for the filter system in question.

These are tests to detect the largest pore or other opening through the membrane. The basic test is performed by gradually raising air pressure on the upstream side of a water-wet filter. The bubble point is the pressure obtained when air bubbles first appear downstream of the filter. The diffusion or forward flow test raises pressure to some point below the known bubble point pressure, then diffusion flow (usually in mL/min) is measured. These pressures are characteristic for each pore size of a filter and are provided by the filter manufacturer. For example, a 0.2- $\mu\text{m}$  cellulose ester filter will bubble at about 50 psig or a diffusive flow rating of no greater than 13 mL/min at a pressure of 40 psig. If the filter is wetted with other liquids, such as a product, the bubble point will differ and must be determined experimentally. If the bubble point is lower than the rated

Figure 26-19. Cartridge and disc filters. Courtesy of EMD Millipore Corporation.

pressure, the filter is defective, probably due to a puncture or tear, and should not be used.

Although membrane filters are disposable and, thus, discarded after use, the holders must be cleaned thoroughly between uses. Today, clean, sterile, pretested, disposable assemblies for small, as well as large, volumes of solutions are available commercially. (Other characteristics of these filters, important for a full understanding of their use, are given in Chapter 14 – Separation Methods.)

There have been some reports that that 0.2  $\mu\text{m}$  filters do not remove all possible microbial contamination, necessitating the need to use certain types of 0.1  $\mu\text{m}$  membrane filters. However, most of the parenteral pharmaceutical industry continues to use 0.2  $\mu\text{m}$  filters, although now employing redundant (two 0.2  $\mu\text{m}$  filters side-by-side) filtration systems.

## FILLING

During the filling of containers with a product, the most stringent requirements must be exercised to prevent contamination, particularly if the product has been sterilized by filtration and will not be sterilized in the final container. Under the latter conditions, the process is called an ‘aseptic fill’ and is validated with media fills. During the filling operation, the product must be transferred from a bulk container or tank and subdivided into dose containers. This operation exposes the sterile product to the environment, equipment, and manipulative technique of the operators, until it can be sealed in the dose container. Therefore, this operation is carried out with a minimum exposure time, even though maximum protection is provided by filling under a blanket of HEPA-filtered laminar-flow air within the aseptic area.

Most frequently, the compounded product is in the form of a liquid. However, products are also compounded as dispersed systems (e.g., suspensions and emulsions) and as powders. A liquid is more readily subdivided uniformly and introduced into a container having a narrow mouth than is a solid. Mobile liquids are considerably easier to transfer and subdivide than viscous, sticky liquids, which require heavy-duty machinery for rapid production filling.

Although many devices are available for filling containers with liquids, certain characteristics are fundamental to them all. A means is provided for repetitively forcing a measured volume of the liquid through the orifice of a delivery tube introduced into the container. The size of the delivery tube will vary from that of about a 20-gauge hypodermic needle to a tube 1/2 in or more in diameter. The size required is determined by the physical characteristics of the liquid, the desired delivery speed, and the inside diameter of the neck of the container. The tube must enter the neck and deliver the liquid well into the neck to eliminate spillage, allowing sufficient clearance to allow air to leave the container as the liquid enters. The delivery tube should be as large in diameter as possible to reduce resistance and decrease velocity of flow of the liquid. For smaller volumes of liquids, delivery usually is obtained from the stroke of the plunger of a syringe, forcing the liquid through a two-way valve, providing for alternate filling of the syringe and delivery of mobile liquids. For heavy, viscous liquids, a sliding piston valve, the turn of an auger in the neck of a funnel, or the oscillation of a rubber diaphragm may be used. Also, stainless steel syringes are required with viscous liquids, because glass syringes are not strong enough to withstand the high pressures developed during delivery. For large volumes, the quantity delivered is measured in the container by the level of fill in the container, the force required to transfer the liquid being provided by gravity, a pressure pump, or a vacuum pump.

The narrow neck of an ampoule limits the clearance possible between the delivery tube and the inside of the neck. Since a drop of liquid normally hangs at the tip of the delivery tube after a delivery, the neck of an ampoule will be wet as the delivery tube is withdrawn, unless the drop is retracted. Therefore, filling machines should have a mechanism by which this drop can be

**Figure 26-20.** Syringe filling machine. (Courtesy Baxter Healthcare Corporation.)

drawn back into the lumen of the tube. Since the liquid will be in intimate contact with the parts of the machine through which it flows, these must be constructed of non-reactive materials, such as borosilicate glass or stainless steel. In addition, they should easily be demountable for cleaning and sterilization.

## LIQUIDS

There are three main methods for filling liquids into containers with high accuracy: volumetric filling, time/pressure dosing, and net weight filling. Volumetric filling machines, employing pistons or peristaltic pumps, are most commonly used.

When high-speed filling rates are desired but accuracy and precision must be maintained, multiple filling units are often joined in an electronically coordinated machine (Fig. 26-20 and Fig. 26-21). When the product is sensitive to metals, a peristaltic-pump filler may be used, because the product comes in contact only with silicone rubber tubing. However, this sacrifices filling accuracy.

Time-pressure (or time-gravity) filling machines are gaining popularity in filling sterile liquids. A product tank is connected to the filling system equipped with a pressure sensor. The sensor continuously measures pressure and transmits values to the PLC system controlling the flow of product from tank to filling manifold. Product flow occurs when tubing is mechanically unpinched and stops when tubing is mechanically pinched. The main advantage of time/pressure filling operations is that these filling apparatuses do not contain mechanical moving parts in the product stream. The product is driven by pressure (usually nitrogen) with no pumping mechanism involved. Thus, especially for proteins that are quite sensitive to shear forces, time/pressure filling is preferable.

Most high-speed fillers for large-volume solutions use the bottle as the measuring device, transferring the liquid either by vacuum or by positive pressure from the bulk reservoir to the individual unit containers. Therefore, a high accuracy of fill is not achievable.

The USP requires that each container be filled with a sufficient volume in excess of the labeled volume to ensure withdrawal of the labeled volume and provides a table of suggested fill volumes.

The filling of a small number of containers may be accomplished with a hypodermic syringe and needle, the liquid drawn into the syringe and forced through the needle into the container. An example of such a device that provides greater speed of filling is the Cornwall Pipet (Becton Dickinson). The device has a two-way valve between the syringe and the needle and a means for setting the stroke of the syringe, so the same volume is delivered each time. Clean, sterile, disposable assemblies operating on the same principle have particular usefulness in hospital pharmacy or experimental operations.

**Figure 26-21.** Vial filling machine, distant and close-up views. (Courtesy, Baxter Healthcare Corporation.)

## SOLIDS

Sterile solids, such as antibiotics, are more difficult to subdivide evenly into containers than are liquids. The rate of flow of solid material is slow and often irregular. Even though a container with a larger-diameter opening is used to facilitate filling, it is difficult to introduce the solid particles, and the risk of spillage is ever-present. The accuracy of the quantity delivered cannot be controlled, as well as with liquids. Due to these factors, the tolerances permitted for the content of such containers must be relatively large.

Some sterile solids are subdivided into containers by individual weighing. A scoop is usually provided to aid in approximating the quantity required, but the quantity filled into the container is finally weighed on a balance. This is a slow process. When the solid is obtainable in a granular form, so it will flow more freely, other methods of filling may be employed. In general, these involve the measurement and delivery of a volume of the granular material that has been calibrated in terms of the weight desired. In the machine shown in Figure 26-22, an adjustable cavity in the rim of a wheel is filled by vacuum and

**Figure 26-22.** Perry Accofil Sterile Powder Filling Machine. A. Principle of operation. B. Filler inside a barrier system. C. Close-up view of filler. (Courtesy of M&O Perry Industries, Inc.)

the contents held by vacuum, until the cavity is inverted over the container. The solid material is then discharged into the container by a puff of sterile air.

## SEALING

### AMPOULES

Filled containers should be sealed as soon as possible, to prevent the contents from being contaminated by the environment. Ampoules are sealed by melting a portion of the glass neck. Two types of seals are employed normally: tip-seals (bead-seals) or pull-seals.

Tip-seals are made by melting enough glass at the tip of the neck of an ampoule to form a bead and close the opening. These can be made rapidly in a high-temperature gas-oxygen flame. To produce a uniform bead, the ampoule neck must be heated evenly on all sides, such as by burners on opposite sides of stationary ampoules or by rotating the ampoule in a single flame. Care must be taken to properly adjust the flame temperature and the interval of heating to completely close the opening with a bead of glass. Excessive heating results in the expansion of the gases within the ampoule against the soft bead seal, which causes a bubble to form. If the bubble bursts, the ampoule is no longer sealed; if it does not, the wall of the bubble will be thin and fragile. Insufficient heating will leave an open capillary through the center of the bead. An incompletely sealed ampoule is called a 'leaker'.

Pull-seals are made by heating the neck of the ampoule below the tip, leaving enough of the tip for grasping with forceps or other mechanical devices. The ampoule is rotated in the flame from a single burner. When the glass has softened, the tip is grasped firmly and pulled quickly away from the body of the ampoule, which continues to rotate. The small capillary tube, thus, formed is twisted closed. Pull-sealing is slower, but the seals are more secure than tip-sealing. Figure 26-23 shows a machine combining the steps of filling and pull-sealing ampoules.

Ampoules having a wide opening must be sealed by pull-sealing. Fracture of the neck of ampoules during sealing may occur, if wetting of the necks occurs at the time of filling. Also, wet necks increase the frequency of bubble formation and unsightly carbon deposits, if the product is organic.

To prevent decomposition of a product, it is sometimes necessary to displace the air in the space above the product in the ampoule with an inert gas, by introducing a stream of the gas, such as nitrogen or carbon dioxide, during or after filling with the product. Immediately thereafter, the ampoule is sealed, before the gas can diffuse to the outside. This process should be validated to ensure adequate displacement of air by the gas in each container.

**Figure 26-23.** FPS2CA Automatic Monoblock Closed Ampule Filling and Sealing Machine. (Courtesy of and with permission from Cozzoli Machine Company.)

### VIALS AND BOTTLES

Glass or plastic vials and bottles are sealed by closing the opening with a rubber closure (stopper). This must be accomplished as rapidly as possible after filling and with reasoned care, to prevent contamination of the contents. The large opening makes the introduction of contamination much easier than with ampoules. Therefore, during the critical exposure, the open containers should be protected from the ingress of contamination, preferably with a blanket of HEPA-filtered laminar airflow.

The closure must fit the mouth of the container snugly enough, so its elasticity seals rigid to slight irregularities in the lip and neck of the container. However, it must not fit so snugly that it is difficult to introduce into the neck of the container. Preferably, closures are inserted mechanically, using an automated process, especially with high-speed processing. To reduce friction, so the closure may slide more easily through a chute and into the container opening, the closure surfaces are halogenated or treated with silicone. When the closure is positioned at the insertion site, it is pushed mechanically into the container opening (Fig. 26-24). When small lots are encountered, manual stoppering with forceps may be used, but such a process poses greater risk of introducing contamination than automated processes. This is a good test for evaluation of operator aseptic techniques, but not recommended for any product filling and stoppering.

Container-closure integrity testing has become a major focus for the industry, due to emphasis by regulatory agencies. Container-closure integrity measures the ability of the seal between the glass or plastic container opening and the rubber closure to remain tight and fit and to resist any ingress of microbial contamination during product shelf life. Container-closure integrity test requirements are covered in USP <1207>, and the various test methods are described by Guazzo.<sup>34</sup>

Rubber closures are held in place by means of aluminum caps. The caps cover the closure, crimped under the lip of the vial or bottle to hold them in place. The closure cannot be removed without destroying the aluminum cap; it is tamperproof. Therefore, an intact aluminum cap is proof that the closure has not been removed intentionally or unintentionally. Such confirmation is necessary to ensure the integrity of the contents, as to sterility and other aspects of quality.

The aluminum caps are designed so the outer layer of double-layered caps, or the center of single-layered caps, can be removed to expose the center of the rubber closure, without disturbing the band that holds the closure in the container. Rubber closures for use with intravenous administration sets often have a permanent hole through the closure. In such cases, a thin rubber disk, overlaid with a solid aluminum disk, is

**Figure 26-24.** Mechanical device for inserting rubber closures in vials. (Courtesy of Baxter Healthcare Corporations.)

**Figure 26-25.** Examples of aluminum-plastic seals. A. Flip-Off Seals: Aluminum shell with a removable plastic button in order to access stopper surface. B. Flip-Tear Seals: Aluminum shell is completely removed from container by flipping off the plastic button—allows stopper removal. (Courtesy of West Pharmaceutical Services.) **Figure 26-26.** CM200 Continuous Motion Crimping Machine. (Courtesy of and with permission from Cozzoli Machine Company.)

placed between an inner and outer aluminum cap, thereby providing a seal of the hole through the closure.

Single-layered aluminum caps may be applied using a hand crimper. Double- or triple-layered caps (Fig. 26-25) require greater force for crimping; therefore, heavy-duty mechanical crimpers (Fig. 26-26) are required.

## STERILIZATION

Whenever possible, the parenteral product should be sterilized, after being sealed in its final container (terminal sterilization) and within as short a time as possible after filling and sealing are completed. Since this usually involves a thermal process, although there is a trend in applying radiation sterilization to finished products, due consideration must be given to the effect of the elevated temperature, upon the stability of the product. Many products, both pharmaceutical and biological, are affected adversely by elevated temperatures required for thermal sterilization. Heat-labile products must, therefore, be sterilized by a non-thermal method, usually by filtration through bacteria-retaining filters. Subsequently, all operations must be carried out in an aseptic manner, so contamination is not introduced into the filtrate. Colloids, oleaginous solutions, suspensions, and emulsions that are thermolabile may require a process in which each component is sterilized separately and the product is formulated and processed under aseptic conditions.

The performance of an aseptic process is challenging, but technical advances in aseptic processing, including improved automation, use of isolator systems, formulations to include antimicrobial effects, and combinations of limited sterilization with aseptic processing, have decreased the risk of contamination. Therefore, the successes realized should encourage continued efforts to improve the assurance of sterility achievable with aseptic processing. The importance of this is that, for many drug solutions and essentially all biopharmaceutical products, aseptic processing is the only method that can be considered for preparing a sterile product.

Interaction among environmental conditions, the constituents in the closure, and the product may result in undesirable closure changes, such as increased brittleness or stickiness, which may cause loss of container-closure seal integrity. Thus, shelf life integrity is an important consideration in closure selection and evaluation.

The assessment of aseptic-processing performance is based on the contamination rate resulting from periodic process simulations using media-filling, instead of product-filling of containers. A contamination rate no greater than 0.1% at 95% confidence has been considered indicative of satisfactory performance in the industry. However, with current advances in aseptic processing capabilities, lower contamination rates may be achievable.

Radiation sterilization, as mentioned, is gaining momentum as an alternative terminal sterilization method. There has been limited understanding of the molecular transformations that may occur in drug molecules and excipients under exposure to the high-energy gamma radiation levels of the process. However, lower energy beta particle (electron beam) radiation has seen some success. Significant research must still be accomplished, before radiation sterilization is used as a terminal sterilization process. The use of radiation for the sterilization of materials, such as plastic medical devices, is well established.

Dry-heat sterilization may be employed for a few dry solids not affected adversely by the high temperatures and for the relatively long heating period required. This method is applied most effectively to the sterilization of glassware and metalware. After sterilization, the equipment will be sterile, dry, and, if the sterilization period is long enough, pyrogen-free.

Saturated steam under pressure (autoclaving) is the most commonly used and the most effective method for the sterilization of aqueous liquids or substances that can be reached or penetrated by steam. A survival probability of at least  $10^{-6}$  is readily achievable with terminal autoclaving of a thermally stable product.

**Figure 26-27.** An example of a modern autoclave for sterilization. (Courtesy of Getinge.)

However, it needs noted that, for terminal sterilization, the assurance of sterility is based on an evaluation of the lethality of the process (i.e., of the probable number of viable microorganisms remaining in product units). However, for aseptic processing, where the components used have been sterilized separately by validated processes and aseptically put together, the level of sterility assurance is based on an evaluation of the probable number of product units contaminated during the process.

Figure 26-27 shows an example of a modern autoclave for sterilization. Since the temperature employed in an autoclave is lower than that for dry-heat sterilization, equipment made of materials, such as rubber and polypropylene, may be sterilized, if the time and temperature are carefully controlled. As mentioned previously, some injections are affected adversely by the elevated temperature required for autoclaving. For some products, such as Dextrose Injection, a shortened cycle, using an autoclave designed to permit a rapid temperature rise and rapid cooling with water spray or other cooling methods, makes it possible to use this method. It is ineffective in anhydrous conditions, such as within a sealed ampoule containing a dry solid or an anhydrous oil. Other products that will not withstand autoclaving temperatures may withstand marginal thermal methods, such as tyndalization or pasteurization (e.g., 10 to 12 hours at 60°C). These methods may be rendered more effective for some injections, by the inclusion of a bacteriostatic agent in the product.

Articles to be sterilized must be properly wrapped or placed in suitable containers to permit penetration of sterilants and provide protection from contamination after sterilization. Sheets or bags made of special steam-penetrating paper or polymeric materials are available for this purpose. Further, containers or bags impervious to steam can be equipped with a microbe-excluding vent filter to permit adequate steam penetration and air exit. Multiple wrapping permits sequential removal of outer layers, as articles are transferred from zones of lower to higher environmental quality. The openings of equipment subjected to dry-heat sterilization are often covered with metal or glass covers. Laboratories often used silver-aluminum foil for covering glassware used for endotoxin testing. Wrapping materials commonly used for steam sterilization may be combustible or otherwise become degraded under dry-heat sterilization conditions.

The effectiveness of any sterilization technique must be proved (validated), before it is employed in practice. Since the goal of sterilization is to kill micro-organisms, the ideal indicator to prove the effectiveness of the process is a resistant form of an appropriate micro-organism, normally resistant spores (a biological indicator, or BI). Therefore, during validation of a sterilization process, BIs of known resistance and numbers are used in association with

physical-parameter indicators, such as recording thermocouples. Once the lethality of the process is established in association with the physical measurements, the physical measurements can be used for subsequent monitoring of in-use processes without the BIs. Eliminating the use of BIs in direct association with human-use products is appropriate, due to the ever-present risk of an undetected, inadvertent contamination of a product or the environment. The number of spores and their resistance in BIs used for validation studies must be accurately known or determined. Additionally, the manner in which BIs are used in validation is critical and must be controlled carefully.

In addition to the data printout from thermocouples, sometimes other physical indicators are used, such as color-change and melting indicators, to give visual indication that a package or truckload has been subjected to a sterilization process. Such evidence can become a part of the batch record to confirm that sterilization was accomplished.

Further details concerning methods of sterilization and their application can be found in Chapter 25 (Sterilization Processes and Sterility Assurance). In addition, the USP provides suggestions concerning the sterilization of injections and related materials.

## FREEZE-DRYING (LYOPHILIZATION)

Many parenteral drugs, particularly biopharmaceuticals, are too unstable in solution to be available as ready-to-use liquid dosage forms. Such drugs can still be filled as solutions, placed in a chamber, where the combined effects of freezing and drying under low pressure will remove the solvent and residual moisture from the solute components, resulting in a dry powder that has sufficient long term stability. The process of freeze-drying has taken on greater prominence in the parenteral industry, due to the advent of recombinant DNA technology. Proteins and peptides must be freeze-dried for clinical and commercial use. There are other technologies available to produce sterile dry powder drug products besides freeze-drying, such as sterile crystallization or spray-drying and powder filling. However, freeze-drying is the most common unit process for manufacturing drug products too unstable to be marketed as solutions.

The term 'lyophilization' describes a process to produce a product that 'loves the dry state.' However, this term does not include the freezing process. Therefore, although lyophilization and freeze-drying are used interchangeably, freeze-drying is a more descriptive term. Equipment used to freeze-dry products are called freeze-dryers or lyophilizers.

Table 26-7 lists the advantages, features, and disadvantages of freeze-drying.

Freeze-drying, essentially, consists of:

- Freezing stage— Freezing the product solution at a temperature below its eutectic (crystalline) or glass transition temperature.
- Primary drying stage— Removing the solvent (ice) from the product, by evacuating the chamber, usually below 0.1 torr (100  $\mu\text{m Hg}$ ), and subliming the ice onto a cold, condensing surface at a temperature below that of the product, the condensing surface being within the chamber or in a connecting chamber. During primary drying, the temperature of the product must remain slightly below its critical temperature, called 'collapse temperature.' Collapse temperature is best measured by visual observation using a freeze-dry microscope that simulates the freeze-drying process. Collapse temperature is similar to the eutectic or glass transition temperature of the product.
- Secondary drying stage— Removing bound water from solute(s) to a level that assures long term stability of the product. This is accomplished by introducing heat to the product under controlled conditions, thereby providing additional energy to the product to remove adsorbed water. The temperature for secondary drying should be as high as possible, without causing any chemical degradation of the active ingredient. For small molecules,

**Table 26-7. Advantages and Disadvantages of Freeze-Drying and Desirable Characteristics of the Finished Freeze-Dried Dosage Form**

Advantages of Freeze-Dried Products	
1. Product is stored in dry state-few stability problems	
2. Product is dried without elevated temperatures	
3. Good for oxygen and/or air-sensitive drugs	
4. Rapid reconstitution time	
5. Constituents of the dried material remain homogeneously dispersed	
6. Product is process in the liquid form	
7. Sterility of product can be achieved and maintained	
Disadvantages of Freeze-Dried Products	
1. Volatile compounds may be removed by high vacuum	
2. Single most expensive unit operation	
3. Stability problems associated with individual drugs	
4. Some issues associated with sterilization and sterility assurance of the dryer chamber and aseptic loading of vials into the chamber	
Desired Characteristics of Freeze-Dried Products	
• Intact cake	
• Sufficient strength	
• Uniform color	
• Sufficiently dry	
• Sufficiently porous	
• Sterile	
• Free of pyrogens	
• Free of particulates	
• Chemically stable	

the highest secondary drying temperature used is 40°C, whereas for proteins it is no more than 30°C.

A small-scale lyophilization system and its functional components is shown in Figure 26-28. The product may be frozen on the shelf in the chamber by circulating refrigerant (usually silicone) from the compressor through pipes within the shelf. After freezing is complete, which may require several hours, the chamber and condenser are evacuated by the vacuum pump, the condenser surface having been chilled previously by circulating refrigerant from the large compressor.

Heat then is introduced from the shelf to the product under graded control by electric resistance coils or by circulating

**Figure 26-28.** Example of a laboratory freeze-dryer. (Courtesy of Baxter Healthcare Corporation.)

silicone or glycol. Heat transfer proceeds from the shelf into the product vial and mass transfer (ice) proceeds from the product vial by sublimation through the chamber and onto the condenser. The process continues, until the product is dry (usually 1% or less moisture, except for some proteins that require a minimum amount of water for conformational stability), leaving a sponge-like matrix of the solids originally present in the product, the input of heat being controlled so as not to degrade the product.

For most pharmaceuticals and biologicals, the liquid product is sterilized by filtration before being filled into the dosage container aseptically. The containers must remain open during the drying process to allow water vapor to escape; therefore, they must be protected from contamination during transfer from the filling area to the freeze-drying chamber, while in the freeze-drying chamber and at the end of the drying process until sealed. Automated loading and unloading of product to and from the freeze-dryer shelves is now state-of-the-art, where partially open vials are always under the auspices of Class 100 air and human intervention is eliminated.

Freeze-dryers are equipped with hydraulic or pneumatic internal-stoppering devices designed to push slotted rubber closures into the vials to be sealed while the chamber is still evacuated, the closures having been partially inserted immediately after filling, so the slots were open to the outside. If internal stoppering is not available or containers, such as ampoules, are used, filtered dry air or nitrogen should be introduced into the chamber at the end of the process to establish atmospheric pressure.

Table 26-8 provides some guidance on a typical formulation approach and initial cycle chosen to freeze-dry a typical product.

**Table 26-8. Practical Aspects of Freeze-Drying**

- Have appropriate analytical tools and methods in place for formulation characterization and stability studies
- Depend on literature, previous experience (if none, use consultants), and what is known about the active ingredient, design and develop initial formulations and conduct preliminary stability and compatibility studies
- Initial formulations should use commonly-known excipients used in freeze-drying
  - that produce acceptable cakes with rapid reconstitution times
  - that have known minimal collapse temperatures
  - that provide the desired finished product with respect to nature of the final solid (crystalline or amorphous)
- Solids content should be between 5% and 30% with a target of 10% to 15%
- Should have several initial formulations to evaluate and compare. Usually know the qualitative, but not quantitative composition of additives until after initial comparative stability studies have been conducted
- Determine the maximum allowable temperature permitted during freezing and primary drying
  - Know eutectic, glass transition, and/or collapse temperatures, as appropriate
- Select the appropriate size of vial and product fill volume
- Select the appropriate rubber closure
  - Low water vapor transmission
  - No absorption of oil vapor
  - Top design minimizes sticking to shelf during/after stoppering
- Determine appropriate processing parameters

(continued)

- Rate of freezing
- Set point temperatures during all three phases
- Need for annealing
- Pressure during primary drying
- Pressure during secondary drying
- Stopper seating conditions (e.g., vacuum or gas)
- Optimize formulation and process based on stability information during and after freeze-drying and after storage in dry state
- Use a sample thief attachment for laboratory dryers to remove samples during the freeze-dry cycle in order to measure moisture, potency, or other parameters. Provides information for final selection of type and amount of stabilizer(s), if needed, and the cycle parameters necessary to provide an acceptable final moisture level in product
- Typical freeze-dry formulation components
 

Buffers:	Phosphate, citrate, acetate
Stabilizers:	Sucrose, trehalose, glycine
Bulking agents:	Mannitol, lactose
Collapse temperature modifiers:	Polymers, sugars
- Typical freeze-dry cycle (without knowing where to start)
  - Freezing phase
    - After loading, cool to 5°C
    - Decrease shelf temperature to -40°C
    - Hold for 2 hours
  - Primary drying phase
    - Must know collapse temperature ( $T_c$ )
    - Set shelf temperature approximately 20°C above  $T_c$  but making sure product temperature is 5°C below  $T_c$
    - Maintain chamber pressure at 10% to 30% of vapor pressure of ice at the primary drying temperature (usually 100 to 200 microns)
    - Use temperature probes, pressure rise test, or dewpoint measurement to determine end of primary drying
  - Secondary drying
    - Use moderate to high vacuum (typically 100 microns)
    - Adjust shelf temperature to 25°C to 30°C for proteins; 35°C to 40°C for non proteins and hold for at least 4 hours
    - Adjust shelf temperature to 25°C or 5°C prior to stoppering, neutralizing and unloading

## FACTORS AFFECTING THE PROCESS RATE

From the diagram in Figure 26-29, it can be seen that the direction of heat and mass transfer causes the top of the product to dry first with drying proceeding downward to the bottom of the vial. Therefore, as drying proceeds, there exists a three-component or layer system in each vial—the upper dry product, the middle sublimation front, and the lower frozen liquid product. As the dried layer increases, it becomes a greater barrier or the source of greatest resistance to the transfer of mass out of the vials. This points out the importance of vial dimensions and volume of product per vial on the efficiency of the freeze-drying process. If large volumes of solution must be processed, the surface area relative to the depth may be increased, utilizing larger vials or by using such devices as freezing the container in a slanted position to increase the surface area.

The actual driving force for the process is the vapor pressure differential between the vapor at the surface where drying of the product is occurring (the drying boundary) and at the surface of the ice on the condenser. The latter is determined by the temperature of the condenser, as modified by the insulating effect of the accumulated ice. The former is determined by a number of factors, including:

1. The rate of heat conduction through the container and the frozen material, both relatively poor thermal conductors, to the drying boundary, while maintaining all of the product below its eutectic temperature.
2. The impeding effect of the increasing depth of dried, porous product above the drying boundary.
3. The temperature and heat capacity of the shelf itself.

The passageways between the product surface and the condenser surface must be wide open and direct for effective operation. The condensing surfaces in large freeze-dryers may be in the same chamber as the product or located in a separate chamber connected by a duct to the drying chamber. Evacuation of the system is necessary to reduce the impeding effect that collisions with air molecules would have on the passage of water molecules. However, the residual pressure in the system must be greater than the vapor pressure of the ice on the condenser, or the ice will be vaporized and pulled into the pump, an event detrimental to most pumps.

The amount of solids in the product, the ice crystal size, and their thermal conductance affect the rate of drying. The more solids present, the more impediment will be provided to the escape of the water vapor. The degree of supercooling (i.e., how much lower the product temperature goes below its equilibrium

Figure 26-29. Schematic of heat and mass transfer in the freeze dryer.

freezing point before ice crystals first form) and the rate of ice crystallization define the freezing process and efficiency of primary drying. The larger the size of ice crystals formed, usually as a result of slow freezing, the larger the pore sizes are when the ice sublimates and, consequently, the faster the rate of drying. A high degree of supercooling produces a large number of small ice crystals, a small pore size when the ice sublimates in the dried layer, and a greater resistance to water vapor transport during primary drying. The poorer the thermal conducting properties of the solids in the product, the slower the rate of heat transfer through the frozen material to the drying boundary.

The rate of drying is slow, most often requiring 24 hours or longer for completion. The actual time required, the rate of heat input, and the product temperatures used must be determined for each product and then reproduced carefully with successive processes.

### FACTORS AFFECTING FORMULATION

The active constituent of many pharmaceutical products is present in such a small quantity that, if freeze-dried alone, its presence would be hard to detect visually. In fact, the solids content of the original product, ideally, should be between 5% and 30%. Therefore, excipients are often added to increase the amount of solids. Such excipients are called 'bulking agents,' the most commonly used bulking agent in freeze-dried formulations is mannitol. However, most freeze-dried formulations must contain other excipients, due to the need to buffer the product and/or to protect the active ingredient from the adverse effects of freezing and/or drying. Thus, buffering agents, such as sodium or potassium phosphate, sodium acetate, and sodium citrate, are commonly used in freeze-dried formulations. Sucrose, trehalose, dextran, and amino acids, such as glycine, are commonly used lyoprotectants.

Each of these substances contributes to the appearance characteristics of the plug, such as whether dull and spongy or sparkling and crystalline, firm or friable, expanded or shrunken, and uniform or striated. Therefore, the formulation of a product to be freeze-dried must include consideration not only of the nature and stability characteristics required during the liquid state, both freshly prepared and when reconstituted before use, but also the characteristics desired in the dried plug.

### MODIFICATIONS IN THE PROCESS AND EQUIPMENT

In some instances, a product may be frozen in a bulk container or in trays, rather than in the final container, and then handled as a bulk solid. Such a state requires a continuation of aseptic processing conditions as long as the product is exposed to the environment.

When large quantities of material are processed, it may be desirable to use ejection pumps in the equipment system. These draw the vapor into the pump and eject it to the outside, thereby eliminating the need for a condensing surface. Such pumps are expensive and usually practical only in large installations.

Available freeze-dryers range in size from small laboratory units (Fig. 26-28), with shelf surface areas of approximately 5 square feet to large industrial models with shelf surface areas of several hundred square feet. Their selection requires consideration of such factors as:

- Tray area required,
- Volume of water to be removed,
- How the chamber will be sterilized,
- Whether internal stoppering is required,
- Whether separate freezers will be used for initial freezing and condensation of the product, and
- Degree of automatic operation desired.

Other factors involved in the selection and use of equipment are considered in the literature.<sup>35</sup>

Freeze-drying is now used for research in the preservation of human tissue and is finding increasing application in the food industry. Most biopharmaceuticals require lyophilization

to stabilize their protein content effectively. Therefore, many newer developments in the lyophilization process focus on the requirements of this new class of drug products.

### QUALITY ASSURANCE AND CONTROL

The importance of undertaking every possible means to ensure the quality of the finished product cannot be overemphasized. Every component and step of the manufacturing process must be subjected to intense scrutiny to be confident quality is attained in the finished product. The responsibility for achieving this quality is divided appropriately in concept and practice into Quality Assurance (QA) and Quality Control (QC). QA relates to the studies made and the plans developed for ensuring quality of a product prospectively, with a final confirmation of achievement. QC embodies the carrying out of these plans during production and includes all of the tests and evaluations performed to ensure quality exists in a specific lot of product.

The principles for achieving quality are basically the same for the manufacture of any pharmaceutical. These are discussed in Chapter 3 (Quality Assurance and Control) During the discussion of preparation of injections in this chapter, mention was made of numerous quality requirements for components and manufacturing processes. Here, only selected tests characteristically required before a finished parenteral product is released are discussed briefly, including sterility, pyrogen, and particulate tests.

### STERILITY TEST

All lots of injectables in their final containers must be tested for sterility, except products that are allowed to apply parametric release (i.e., terminally sterilized by a well-defined, fully validated sterilization process, has a sterility assurance level sufficient to omit the sterility test for release). The USP prescribes the requirements for this test for official injections. The FDA uses these requirements as a guide for testing official sterile products. The primary official test is performed by means of filtration, but direct transfer is used if membrane filtration is unsuitable. To give greater assurance that viable micro-organisms will grow, if present, the USP requires that all lots of culture media be tested for their growth-promotion capabilities. However, it must be recognized that the reliability of both test methods has the inherent limitations typical of microbial recovery tests. Therefore, it should be noted that this test is not intended as a thoroughly evaluative test for a product subjected to a sterilization method of unknown effectiveness. It is intended as a check test on the probability that a previously validated sterilization procedure has been repeated or to give assurance of its continued effectiveness. A discussion of sterility testing is given in Chapter 25 (Sterilization Processes and Sterility Assurance).

In the event of a sterility-test failure, the immediate issue concerns whether the growth observed came from viable micro-organisms in the product (true contamination) or from adventitious contamination during the testing (a false positive). The USP does not permit a retest, unless specific evidence is discovered to suggest contamination occurred during the test. Therefore, a thorough investigation must be launched to support the justification for performing the retest and assessing the validity of the retest results relative to release of the lot of product.

It should be noted that a 'lot,' with respect to sterility testing, is that group of product containers that has been subjected to the same sterilization procedure. For containers of a product that have been sterilized by autoclaving, for example, a lot would constitute those processed in a particular sterilizer cycle. For an aseptic filling operation, a lot would constitute all of those product containers filled during a period in which there was no change in the filling assembly or equipment and which is no longer than one working day or shift.

As stated previously, isolator technology has been applied to significantly reduce the incidence of false positives in the conductance of the sterility test. Figure 26-10 shows an example of a sterility testing isolator. Validation of isolator systems for sterility testing is described in USP <1208>.

## PYROGEN TEST

The USP evaluates the presence of pyrogens in parenteral preparations by a qualitative fever response test in rabbits, the Pyrogen Test (Section <151>), and by the Bacterial Endotoxins Test (Section <85>). These two USP tests are described in Chapter 25 (Sterilization Processes and Sterility Assurance). Rabbits are used as test animals in Section <151>, because they show a physiological response to pyrogenic substances similar to that of man. Although a minimum pyrogenic dose (MPD), the amount just sufficient to cause a positive USP Pyrogen Test response, may produce uncertain test results, a content equal to a few times the MPD will leave no uncertainty. Therefore, the test is valid and has continued in use, since introduced by Seibert in 1923. It should be understood that not all injections may be subjected to the rabbit test, since the medicinal agent may have a physiological effect on the test animal such that any fever response would be masked.

The Bacterial Endotoxins Test (BET) is an *in vitro* test based on the formation of a gel or the development of color in the presence of bacterial endotoxins and the lysate of the amoebocytes of the horseshoe crab (*Limulus polyphemus*). The *Limulus* Amoebocyte Lysate (LAL) test, as it also is called, is a biochemical test performed in a test tube and is simpler, more rapid, and of greater sensitivity than the rabbit test. Figure 26-30 shows an example of a positive endotoxin test result in a test tube. Although it detects only the endotoxic pyrogens of gram-negative bacteria, these are the most prominent environmental microbial contaminants likely to invade sterile products. The test has been automated and can determine the quantitative amount of endotoxin in a sample. This test has enabled endotoxin limits to be established on finished products and bulk drug substances and excipients.

To provide standardization for the test, the USP has established a reference standard endotoxin (RSE) against which lots of the lysate is standardized. Thus, the sensitivity of the lysate is given in terms of endotoxin units (EU). Most USP injections have now been given limits in terms of EUs (e.g., Bacteriostatic Sodium Chloride Injection, 1.0 EU/mL), thus, indicating an increasing priority for the BET in testing for the presence of endotoxin in parenteral products and in medical devices.

Figure 26-30. Example of positive (left tube) endotoxin test.

## PARTICULATE MATTER EVALUATION

Particulate matter in parenteral solutions has been recognized as unacceptable, since the user could be expected to conclude that the presence of visible dirt would suggest that the product is of inferior quality. Today, it is recognized that the presence of particles in solution, particularly if injected intravenously, can be harmful. Although data defining the extent of risk and the effects produced are still limited, it has been shown that particles of lint, rubber, insoluble chemicals, and other foreign matter can produce emboli in the vital organs of animals and man. Further, it has been shown that the development of infusion phlebitis may be related to the presence of particulate matter in intravenous fluids.

The particle size of particular concern has not been clearly delineated, but it has been suggested that, since erythrocytes have a diameter of approximately 4.5  $\mu\text{m}$ , particles of more than 5  $\mu\text{m}$  should be the basis for evaluation. This is a considerably smaller particle than can be seen with the unaided eye; approximately 50  $\mu\text{m}$  is the lower limit, unless the Tyndall effect is used, whereby particles as small as 10  $\mu\text{m}$  can be seen by the light scattered from them.

The USP specifies that good manufacturing practice requires each final container of an injection be subjected individually to a visual inspection and containers in which visible particles can be seen should be discarded. This 100% inspection of a lot of product is designed to prevent the distribution and use of parenterals that contain particulate matter. Therefore, all of the product units from a production line are currently being inspected individually, by human inspectors, under a good light, baffled against reflection into the eye, and against a black-and-white background. This inspection is subject to the limitation of the size of particles that can be seen, the variation of visual acuity from inspector to inspector, their emotional state, eye strain, fatigue, and other personal factors that will affect what is seen. However, it does provide a means for eliminating the few units that normally contain visible particles. Automated inspection machines are increasingly being used today.

The assessment of the level of particulate matter below the visible size of about 50  $\mu\text{m}$  has become an increasingly used QC indicator of process cleanliness in the manufacture of injections. The tests used, however, are destructive of container units. Therefore, they are performed on appropriately selected samples of products. Further, all of these methods require very stringent, ultraclean preparation techniques to ensure accuracy in the counting and sizing of particles only in the product, rather than those that may have been introduced inadvertently during the sample preparation or the testing procedure.

The USP has identified two test methods in <788>, *Particulate Matter in Injections*. All LVIs for single-dose infusion and those SVIs for which the monograph specifies a limit (primarily those commonly added to infusion solutions) are subject to the specified limits given in Table 26-9. The first test used is the light obscuration test, which uses an electronic instrument designed to count and measure the size of particles by means of a shadow cast by the particle as it passes through a high-intensity light beam. If the injection formulation is not a clear, colorless solution (e.g., an emulsion) or it exceeds the limits specified for the light obscuration test, it is to be subjected to the microscopic count test. The latter method consists of filtering a measured sample of solution through a membrane filter under ultraclean conditions and then counting the particles on the surface of the filter, using a microscope and oblique light at 100 $\times$  magnification. The time requirements for performing the latter test are very long. These standards are readily met in the United States today by the manufacturers of LVIs and the specified SVIs.

Whether or not these standards are realistic, toxicologically has not been established; rather, the objective of the compendium is to establish specification limits that encourage the preparation of clean parenteral solutions, particularly those to be given intravenously.

**Table 26-9. Subvisible Particulate Matter Limits in Injectable Products**

Compendia	LVI/SVI	Method	≥10µm	≥25µm
USP	LVI	Light Blockage Microscope	25 part/mL 12 part/mL	3 part/mL 2 part/mL
USP	SVI	Light Blockage Microscope	6000 part/contain. 3000 part/contain.	600 part/contain. 300 part/contain.
EP	LVI SVI Soln SVI Powder	light Blockage light Blockage light Blockage	25 part/mL 6000 part/contain. 10000 part/contain.	3 part/mL 600 part/contain. 1000 part/contain.
BP	LVP	Coutler Counter Light Blockage	1000 part/mL≥2µm 500 part/mL≥2µm	100 part/mL≥5µm 80 part/mL≥5µm
JP	LVP	Microscope	20 part/mL	2 part/mL

It also should be realized that administration sets and the techniques used for preparing and administering intravenous infusion fluids may introduce substantial amounts of particulate matter into an otherwise clean solution. Therefore, the pharmaceutical manufacturer, the administration set manufacturer, the pharmacist, the nurse, and the physician must share responsibility for making sure the patient receives a clean intravenous injection.

### CONTAINER/CLOSURE INTEGRITY TEST

Ampoules that have been sealed by fusion must be subjected to a test to determine whether or not a passageway remains to the outside; if so, all or a part of the contents may leak to the outside and spoil the package, or micro-organisms or other contaminants may enter. Changes in temperature during storage cause expansion and contraction of the ampoule and contents, and will accentuate interchange, if a passageway exists, even if microscopic in size.

This test is usually performed by producing a negative pressure within an incompletely sealed ampoule, while the ampoule is submerged entirely in a deeply colored dye solution. Most often, approximately 1% methylene blue solution is employed. After carefully rinsing the dye solution from the outside, color from the dye will be visible within a leaker. Leakers, of course, are discarded.

Vials and bottles are not subjected to such a leaker test, because the sealing material (rubber stopper) is not rigid. Therefore, results from such a test would be meaningless. However, assurance of container-closure sealing integrity should be an integral part of product development, by developing specifications for the fit of the closure in the neck of the container, the physical characteristics of the closure, the need for lubrication of the closure, and the capping pressure.

### SAFETY TEST

The National Institutes of Health requires, of most biological products, routine safety testing in animals. Under the Kefauver-Harris Amendments to the Federal Food, Drug, and Cosmetic Act, most pharmaceutical preparations are now required to be tested for safety. Because it is entirely possible for a parenteral product to pass the routine sterility test, pyrogen test, and chemical analyses, and still cause unfavorable reactions when injected, a safety test in animals is essential, particularly for biological products, to provide additional assurance that the product does not have unexpected toxic properties.

### PACKAGING AND LABELING

A full discussion of the packaging of parenteral preparations is beyond the scope of this text. It is essential, of course, that the packaging provide ample protection for the product against physical damage from shipping, handling, and storage, as well as protecting light-sensitive materials from ultraviolet radiation.

### PACKAGING

The USP includes certain requirements for the packaging and storage of injections:

1. The volume of injection in single-dose containers is defined as that which is specified for parenteral administration at one time and is limited to a volume of 1 L.
2. Parenterals intended for intraspinal, intracisternal, or peridural administration are packaged only in single-dose containers.
3. Unless an individual monograph specifies otherwise, no multiple-dose container shall contain a volume of injection more than sufficient to permit the withdrawal and administration of 30 mL.
4. Injections packaged for use as irrigation solutions or for hemofiltration or dialysis or for parenteral nutrition are exempt from the foregoing requirements relating to packaging. Containers for injections packaged for use as hemofiltration or irrigation solutions may be designed to empty rapidly and may contain a volume in excess of 1 L.
5. Injections intended for veterinary use are exempt from the packaging and storage requirements concerning the limitation to single-dose containers and to volume of multiple-dose containers.

### LABELING

The labeling of an injection must provide the physician or other user with all information needed to ensure the safe and proper use of the product. Since all of this information cannot be placed on the immediate container and be legible, it may be provided on accompanying printed matter.

A restatement of the labeling definitions and requirements of the USP for injections is as follows:

The term 'labeling' designates all labels and other written, printed, or graphic matter upon an immediate container or upon, or in, any package or wrapper in which it is enclosed, with the exception of the outer shipping container. The term 'label' designates that part of the labeling upon the immediate container.

The label states the name of the preparation, the percentage content of drug of a liquid preparation, the amount of active ingredient of a dry preparation, the volume of liquid to be added to prepare an injection or suspension from a dry preparation, the route of administration, a statement of storage conditions, and an expiration date. The label must state the name of the vehicle and the proportions of each constituent, if it is a mixture, and the names and proportions of all substances added to increase stability or usefulness.

Also, the label must indicate the name of the manufacturer or distributor and carry an identifying lot number. The lot number is capable of providing access to the complete manufacturing history of the specific package, including each

single manufacturing step. The container label is so arranged that a sufficient area of the container remains uncovered for its full length or circumference to permit inspection of the contents.

Preparations labeled for use as dialysis, hemofiltration, or irrigation solutions must meet the requirements for injections, other than those relating to volume, and must also bear on the label statements that they are not intended for intravenous injection. Injections intended for veterinary use are so labeled.

## INTRODUCTION

Medications that are compounded and injected into humans or other animals must be sterile and free from contaminants and pyrogen. Mortality and morbidity from contaminants being injected into the blood stream require that personnel involved in intravenous compounding follow more stringent guidelines when compounding sterile preparations. In 2004, the *United States Pharmacopeia – National Formulary (USP – NF)* published standards of practice for compounding sterile preparations. The chapter, referred to as USP <797>, was developed in part as a result of patient injuries and deaths that had occurred secondary to problems with medication delivery and sterile compounding.<sup>1</sup> Publication of USP <797> is meant to increase practitioners understanding of how sterile preparations must be prepared in order to achieve safe, accurate, quality sterile compounds for patient use.<sup>2</sup> The chapter was updated in 2008 to clarify risk levels, primary engineering controls (PECs), personnel training and evaluation, verification of compounding accuracy, finished preparation checks and tests, storage and beyond use dating, maintenance of sterility and purity of dispensed and distributed sterile preparations, and suggested standard operating procedures.<sup>2</sup> The 2008 USP <797> also introduced new topics and made some significant changes in the areas of immediate use sterile preparations, single use and multiple dose vials, hazardous compounding including radiopharmaceuticals and allergen extracts, environmental quality control, personnel training and competency evaluation.<sup>2</sup> Since its publication in 2008, the *International Journal of Pharmaceutical Compounding* and the American Society of Health Systems Pharmacy (ASHP) have published numerous articles to help practitioners implement chapter USP <797> into all aspects of sterile compounding.<sup>1-2,3</sup> The objective of the USP <797> chapter is to “describe conditions and practices to prevent harm, including death, to patients that could result from (1) microbial contamination (nonsterility), (2) excessive bacterial endotoxins, (3) variability in the intended strength of correct ingredients that exceeds either monograph limits for official articles (sic) or 10% for nonofficial articles, (4) unintended chemical and physical contaminants, and (5) ingredients of inappropriate quality in compounded sterile preparations (CSPs).”<sup>2</sup> While many pharmacies have become compliant, others cite costs and lack of scientific justification to support these changes.<sup>3,4</sup> Most hospitals and facilities have gradually implemented the standards from the original recommendations in 2004, and are now taking steps towards becoming compliant with the 2008 revisions.<sup>3,4</sup>

In order to facilitate implementation of the standards, Baxter Healthcare Corporation and ASHP developed a discussion guide<sup>1</sup> that suggests among other things, that a gap analysis be completed. A gap analysis in this context is used to identify areas in need of improvement in sterile compounding facilities.<sup>1</sup> USP <797> requirements should be compared to the current practices of compounding personnel and environmental standards of

the compounding facility to determine where “gaps” exist. Successful completion of a gap analysis and subsequent revisions to address the identified gaps may result in a direct positive impact on the delivery of quality patient care and may be used to demonstrate compliance with the standards to regulatory authorities.<sup>5</sup>

## COMPOUNDING PERSONNEL: RESPONSIBILITIES IN IMPLEMENTING USP <797>

Compounding personnel have the responsibility to ensure that sterile preparations do not harm patients.<sup>1,2,5-7</sup> Prevention of morbidity and mortality from contaminated CSPs is of utmost importance and can help be assured by strictly adhering to aseptic technique standards. Pharmacists, technicians and others who compound sterile preparations must have appropriate education to ensure that USP <797> is understood and must have training to develop skills required for proper aseptic technique.<sup>2</sup> *ASHP’s Compounding Sterile Preparations Video Guide to Chapter <797>* sets forth best practices for compounding personnel, centering on personnel education and skill development.<sup>5</sup> All components of drug use from sourcing and delivering of the medication to the institution, compounding, and then delivery of the medication for therapeutic patient use are addressed. The importance of sterility of the preparation in preventing harm and fatalities cannot be understated. The following sections discuss the various components needed to ensure sterile compounding including equipment, personnel training, facilities, and appropriate product/device use.

## LAMINAR AIR FLOW HOODS AND ASEPSIS

Clean air that is free of particulates is necessary when compounding in order to achieve sterile preparations. In order to achieve cleaner air, methodical use of a laminar air flow hood (LAFH) is a requirement. Air is double filtered prior to coming into contact with products placed on the counter of the LAFH. The first filter, or pre-filter, is usually located below the counter-top of a horizontal LAFH (Figure 27-1). It removes large or gross contaminants from the air. The air is then pressurized to insure constant flow through the second filter prior to washing over the products. The second filter is a high efficiency particulate arrester (HEPA) that removes particulates from air as small as a 0.3 micron size. The HEPA filter also removes most microorganisms from the air. However, bacteria and viruses <0.3 microns can still persist in the air. Thus, personnel training to decrease transmission of these organisms to the product and ultimately to the patient becomes of paramount importance.<sup>5,7</sup>

There are several types of LAFHs including horizontal (Figure 27-1), vertical (Figure 27-2), and compounding aseptic isolators (CAI) or compounding aseptic containment isolators (CACI). CAI and CACI are often referred to as glove box airflow hoods, as compounding personnel must put their hands into gloves that then can be manipulated inside the airflow hood (or inside the box). Generally, horizontal LAFHs are the easiest for

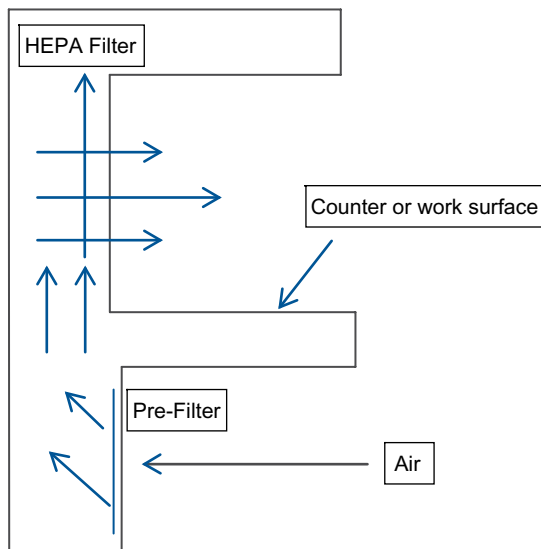

Figure 27-1. Horizontal Laminar Airflow Hood.

Figure 27-2. Vertical Laminar Airflow Hood.

personnel to use, followed by vertical, and then CAI or CACI.<sup>2</sup> LAFHs, CAIs, and CACIs should be serviced every 6 months and whenever they are moved.<sup>2</sup> The filters should be checked for particulates or tears during these services and changed as needed. If damage is done at any time to the filters, they must be immediately changed to ensure air quality. As recommendations may vary, refer to the LAFHs manufacturer instructions for more details. Appropriate placement and use of the LAFHs is discussed in the basics of aseptic compounding and facilities sections.

### BASICS OF ASEPTIC COMPOUNDING

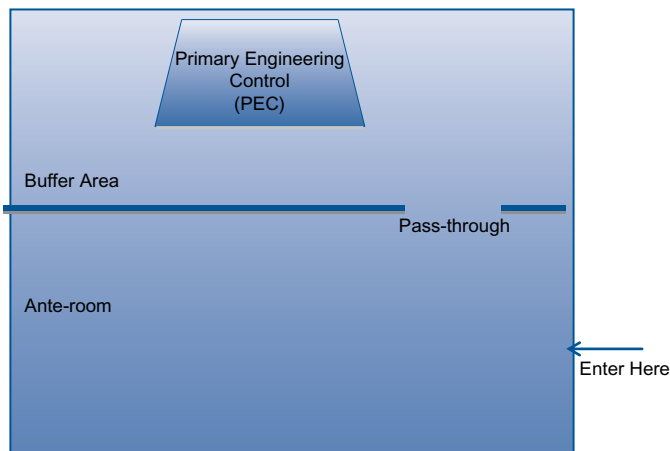

Personnel who compound sterile preparations must have training from experts to develop the skills necessary for proper aseptic technique.<sup>2</sup> Touch contamination poses the greatest microbial risk to patient safety when compounding sterile preparations. Pharmacy and technician schools should have both didactic and hands-on experiences including aseptic skill development, prior to students rotating through settings where sterile compounding is conducted. Skill development should include proper aseptic technique, an understanding of how LAFHs op-

erate in conjunction with other environmental controls to promote an aseptic environment, filling and checking medication orders for appropriateness of dose and therapy, accuracy of fill, any potential contaminants or leaks, and proper labeling.<sup>2,3,5</sup> In all facilities, it is recommended that a second check of the medication order and preparation should be completed by another individual, preferably one who did not process the order, prior to delivery of the CSP for patient use. The competence of individuals should be tested prior to making CSPs for patient use.<sup>2,5</sup> A discussion on competency testing can be found in the quality assurance portion of this chapter.

### PERSONNEL HYGIENE AND GARBING

As touch contamination poses a great risk for microbial contamination of sterile preparations, standard operating procedures should be developed to include proper washing and garbing with personal protective equipment (PPE).<sup>2,5,8</sup> Prior to entering the compounding area, personnel must cleanse and garb. Hand hygiene should consist of the use of warm water and anti-septic (examples include antimicrobial washes and povidone-iodine) gently rubbed from hands to elbows for 30 seconds. Nails should be gently scrubbed and then a nail pick used to remove debris from under the nails. This should be followed by rinsing, and then drying with a lint-free disposable towel. As humans shed up to  $10^6$  squamous cells per hour,<sup>2</sup> care must be taken to ensure that skin is not damaged during this process. Damaged skin can result in increased shedding and thus heightens the risk of contamination of CSPs. Additionally, skin damage could promote the development of infections which could also increase the risk of CSP contamination. Individuals with rash, sunburn, weeping sores, conjunctivitis, and active respiratory infections must not compound sterile products.<sup>2</sup> Additionally, jewelry including any visible piercings must be removed. Artificial nails may harbor microbes and skin cells that cleaning cannot remove so artificial nails are excluded from use by compounding personnel. Natural nails should be kept clean and trimmed. As cosmetics can shed particles, no make-up is allowed in compounding areas. Finally, outer clothes (jackets, shawls, etc.) should be removed prior to garbing. Institutions may require personnel to change into scrubs prior to washing and garbing. Scrubs should be cleaned professionally and separately to reduce lint and particles that could contaminate the compounding area.<sup>2,5,8</sup>

In USP <797>, it is recommended that garbing be completed following a head-to-toe pattern with a couple of exceptions. This allows any particles or contaminants to fall to the ground or be covered up by PPE. The first element of this process is covering the hair with a head cover. If facial hair exists a special beard cover must be worn. Second, facial covers or surgical masks are donned such that the nose and mouth are completely covered. Eye shields can then be added, especially if irritants are to be compounded. Third, shoe covers must be placed over shoes carefully to prevent dirt from touching the outside of the shoe cover or from tracking dirt into the sterile environment. Fourth, hands and arms must be washed from hands to elbow. Fifth, a non-shedding gown with snug fitting wrist and neck closures is donned. This is followed by use of an anti-septic hand cleaner, prior to the placement of sterile gloves. The sterile gloves should be placed such that the outside of the gloves is never touched and the end of the gloves covers the wrist of the gown. The anti-septic hand cleaner is used again over the sterile gloves to decrease potential for touch contamination. Additional garb is recommended for hazardous compounding by the Department of Health and Human Services National Institute for Occupational Safety and Health (NIOSH). As sterile chemotherapy gloves are not currently manufactured, double gloving is recommended. After donning the chemotherapy protective glove (nonsterile), hand anti-septic should be used, followed by sterile glove placement over the chemotherapy glove. A final anti-septic hand cleanser should be used over the

**Figure 27-3.** Example of Sterile Compounding Facilities.

sterile glove prior to entering the buffer area (Figure 27-3) for compounding.<sup>2,5,8,9</sup>

## FACILITIES

### RISK LEVELS

The air quality in a sterile compounding area is classified according to the number of particles per meter cubed of air, as shown in Table 27-1. Figure 27-3 shows the recommended set-up of the sterile compounding facilities. The first area personnel enter prior to washing and garbing is the ante-room. The ante-room must be ISO class 8 or better. After washing and garbing are completed and medications and supplies are gathered, personnel then enter the buffer area. The buffer area must be ISO class 7 or better and the PEC must be ISO class 5 or better.<sup>2,5</sup>

Risk level is determined by the potential risk for contamination of a CSP. USP <797> defines low-risk CSPs as ones that (1) are compounded within a LAFH of ISO class 5 or better using only sterile ingredients, (2) involve only transfer, measuring or mixing of not more than 3 commercially manufactured sterile products (e.g., bags or vials), and (3) involve manipulations limited to aseptically opened ampules, or penetration of sterile products and disinfected stoppers with sterile needles and syringes.<sup>2</sup> In the absence of passing a sterility test, the storage period of a low-risk CSP cannot exceed 48 hours if kept at controlled room temperature, 14 days if refrigerated, or 45 days if frozen.<sup>2,10</sup> Medium-risk CSPs are compounded with sterile ingredients as well. However, the difference lies in the complexity of the process including time needed to compound the CSP and number of manipulations needed to complete the order.<sup>10</sup> USP <797> defines medium-risk CSPs as (1) multiple individual or small doses of sterile products that are combined or pooled to prepare a CSP that will be administered either to multiple patients or to one patient on multiple occasions, (2) compounding processes that include complex aseptic manipulations, and (3) compounding processes that require an unusually long duration to complete.<sup>2</sup> In the absence of passing a sterility test, the storage period of medium-risk CSPs cannot exceed 30 hours if kept at controlled room temperature, 9 days if refrigerated, or 45 days if frozen.<sup>2,10</sup> Examples of medium-risk CSPs include batches of sterile preparations that are compounded for multiple patients or a parenteral nutrition that is compounded with multiple ingredients.<sup>10</sup>

**Table 27-1. ISO Classification Levels**

ISO 8	3,520,000/m <sup>3</sup>
ISO 7	352,000/m <sup>3</sup>
ISO 6	35,200/m <sup>3</sup>
ISO 5	3,520/m <sup>3</sup>

High-risk level conditions occur when CSPs are compounded from non-sterile bulk ingredients that then must be sterilized for use, CSPs that are exposed to less than an ISO class 5 level air quality for more than 1 hour, CSPs where measuring and mixing of ingredients occurs in non-sterile devices before sterilization is completed, and CSPs where an assumption has been made that packages of bulk ingredients contain at least 95% by weight of their active chemical moiety and have not been contaminated or adulterated between uses.<sup>2,10</sup> High-risk may also be characterized by personnel who do not meet appropriate garbing and gloving requirements or where non-sterile water-containing preparations are stored for greater than 6 hours before sterilization occurs.<sup>2,5</sup> A majority of institutions that compound sterile preparations are classified as a low- to medium-risk level.

### SET-UP OF FACILITIES AND ENVIRONMENTAL CONTROLS

Ideally, the sterile compounding facility layout should appear as in Figure 27-3, where the ante-room contains a hand washing station, PPE/garbing, and high use materials such as sterile syringes, needles, admixture solutions, and medications.<sup>5</sup> In Figure 27-3, the buffer area is shown separating the ante-room from the PEC. The PEC can be a LAFH, CAI or CACI. The buffer areas should be kept at an ISO class 7 level or better.<sup>2,5,11-12</sup> USP <797> does allow for some exceptions to this rule, although it is discouraged.<sup>2</sup> The PECs are designed to reduce the exposure of CSPs to the buffer area (ISO class 7 level). The PEC should be kept at an ISO class 5 level or better.<sup>2</sup> Placement of the PEC is paramount to maintaining the air quality; it should not be in an area where a draft could push air from the surrounding environment into the hood.<sup>2,11-12</sup> When compounding in a PEC, the “critical sites” are all surfaces or openings on a CSP (e.g., vial septa, injection port, beaker, opened ampules, needle hubs, etc.) exposed and at risk of direct contact with air (whether from the PEC or buffer area), moisture, or touch contamination. The critical sites are the primary areas to safeguard for CSPs as they represent potential ports of entry for contaminants such as micro-bacterial, viral, or foreign matter.<sup>2,5,10-12</sup>

### CLEANING AND DISINFECTING

In addition to air quality, the buffer area and PEC must be kept in immaculate condition.<sup>5</sup> In order to accomplish this, USP <797> recommends that the floors, walls, ceilings and PECs be cleaned regularly.<sup>2</sup> As some substances or ingredients do not dissolve in the disinfectants typically used, cleaning the PEC can be accomplished with sterile water and lint free disposable towels. For disinfecting the PEC, 70% isopropyl alcohol or 3% hydrogen peroxide can be used to maintain the air quality in the PEC and to kill any microbes that may be present. The PEC should be cleaned and disinfected between shifts, after each batch or every 30 minutes whichever comes first, when spills occur, and when contamination is suspected.<sup>2,5,11-12</sup> Floors must be mopped daily, walls and ceilings cleaned weekly, and shelves cleaned monthly at a minimum. Mops must be dedicated to the clean room only. Mops that have disposable pads are recommended to decrease the transfer of dirt or other contaminants. Trash should be emptied daily and as needed. Care should be taken not to disturb the air while bags are removed and replaced from the trash cans. Personnel should also be trained to decarbon and wipe down all products with an appropriate disinfectant prior to bringing them in to the ante-room. Additionally, all products should be wiped again prior to transferring them into the buffer area and PEC for use in compounding.<sup>11-12</sup>

## COMPOUNDING STERILE PREPARATIONS

### BEYOND USE DATING

Compounding sterile preparations requires many environmental controls as previously described. Personnel working with CSPs must have the knowledge, skills, and motivation to fol-

**Table 27-2. Beyond Use Dates**

USP Temperature Ranges	Low-risk CSP	Medium-risk CSP	High-risk CSP
Controlled Room Temperature	48 hours	30 hours	24 hours
Refrigerated	14 days	9 days	3 days
Frozen	45 days	45 days	45 days

low these processes in order to make them effective.<sup>5,12</sup> Understanding the risk levels in relation to the preparations viability (ability to remain sterile) after leaving the PEC is important for patient safety. Equally as important is the potency and purity of the compounded preparation. Beyond use dating (BUD) is a measure of the time interval from when the CSP is compounded until the compound starts to lose its purity and potency.<sup>2,13-14</sup> BUDs are often confused with manufacturer's expiration dates. However, once a manufacturer's product leaves its original packaging and is mixed with other components, the expiration date ceases to exist and a BUD must be established.<sup>5,13-14</sup> A BUD can be established via several routes. First, an extra CSP can be made during routine compounding and then tested to determine how long it retains its potency and purity. Many pharmacies contract out these services. Second, the BUD can be obtained from a reliable source (e.g., *Trissel's Handbook of Injectable Drugs*<sup>15</sup> or other reference) that shows stability testing. Third, some manufacturers have done stability testing and reported this in their package inserts. In the absence of testing or evidence of the product's stability, USP <797> sets BUDs as shown in Table 27-2.<sup>2,5,13-14</sup>

### EXCEPTIONS TO USP <797> STANDARDS

In instances of life and death, CSPs may be compounded and injected in to a patient (e.g., during a patient emergency or code) without the use of LAFHs.<sup>2</sup> This exception to USP <797> standards applies only to such immediate use CSPs.<sup>2,16,24</sup> Sterile solutions, needles, and syringes must still be utilized and sterile technique must be strictly maintained.

In rural areas, where facilities are not up to recommended standards, USP <797> allows for another exception. This exception is not to excuse institutions from the standards. However, when there is no clean room area available (i.e., no buffer area or ante-room) for the PEC, USP <797> states that the medications must be used within 12 hours of compounding.<sup>2,16</sup> It should be noted that USP <797> has 4 requirements that must be met in order for this to be acceptable. First, the PEC must be of an ISO class 5 or better and must be in a segregated and restricted compounding area. Second, the segregated area must not have unsealed windows, doors to high traffic areas or be adjacent to construction sites, warehouses, food preparation areas, or similar sites. Third, policy and procedures must be written and followed. Sinks for washing cannot be located next to the PEC (as they may introduce contaminants including bacteria into the PEC). Finally, procedures for cleaning, disinfecting, personnel training, garbing, aseptic technique, and environmental air sampling must be written and followed.<sup>2</sup>

### SINGLE-USE CONTAINERS AND MULTI-DOSE VIALS

In the 2008 revision of USP <797>, focus was placed on how single use containers and multi-dose vials (MDVs) should be used.<sup>2,5</sup> Single use containers cannot be stored and re-used. These products contain no preservatives, and thus when punctured or opened, are subject to potential contamination. In contrast, MDVs contain preservatives and have been tested by the manufacturer for the length of time they retain their purity and potency once punctured. Unless otherwise specified, MDV have a BUD of 28 days.<sup>2,13</sup>

## COMPOUNDING DEVICES

Many pharmacies that compound parenteral nutrition (PN) use automated compounding devices (ACDs). PN requires a complex process of mixing multiple ingredients into a large volume bag meant to provide nutrition to patients via an intravenous route. ACDs are designed to help decrease the complexity of the compounding and reduce the time required to prepare PN preparations. However, care must be taken to ensure that these devices are kept in working order. ACDs should be checked regularly to ensure that the correct amounts of ingredients are delivered as programmed. For example, if the ACD is programmed to deliver 10 mL of water, personnel should weigh the water to check that it is 10 grams.<sup>2</sup> A daily record should be kept by compounding personnel of this check. It is recommended by USP <797> that these records should be reviewed at least weekly by the pharmacist-in-charge to avoid any potentially clinically significant cumulative errors.<sup>2,5,17</sup>

### Hazardous drugs

Another area where extra care must be taken when compounding sterile preparations is with hazardous drugs. A hazardous drug is defined as one that has been shown to potentially cause carcinogenicity, developmental or reproductive toxicity, or harm to organs in animal or human studies. The Department of Health and Human Services National Institute for Occupational Safety and Health (NIOSH) maintains a list of hazardous drugs in healthcare settings.<sup>18,25</sup> Compounding personnel should review this list and develop and follow standard operating procedures regarding the handling and compounding with these agents. Routes, time, and extent of potential exposure must be considered when working with hazardous drugs. Although most pharmacists and technicians are careful while compounding of these agents, other routes of exposure must be considered. For example, when an anti-neoplastic agent is removed from its original carton, personnel should be wearing PPE to prevent potential inadvertent exposure from the bottles or packaging materials.<sup>25</sup> For specific information on this topic, USP <797> and the *International Journal of Pharmaceutical Compounding on Hazardous Drugs* should be read.<sup>25</sup>

### Sterilization methods

For pharmacies that compound high-risk preparations, non-sterile components and medications must be sterilized prior to human use.<sup>2</sup> Methods for sterilizing compounded preparations and components include: filtration, autoclaving, and dry heating.<sup>19</sup> The appropriate method must be employed to ensure that compounds do not lose their stability, strength, or purity during sterilization.<sup>2,13,20</sup> Quality assurance testing of these methods must be undertaken to ensure that sterilization and depyrogenation occur.

General considerations for filters include the size of the filter and the type of fluid to be filtered. In order to filter out bacteria a pore size must be 0.22 micrometers or less. The fluid to be filtered should be a solution that is chemically and physically compatible with membrane filtration. It is preferred for medications that are thermo-labile. The fluid should be filtered rapidly and completely without filter replacement. When deciding if filtration is the best method for sterilization, a few items must be taken into consideration including: microbes and viruses that are <0.22 microns cannot be filtered out; medications in the form of suspensions are not appropriate for filtration as medication will be filtered out; solutions that are not fully dissolved will get filtered out; and filtration does not remove pyrogens, and thus heat must be used to render pyrogens inactive. A simple test to determine the integrity of a filter is the bubble point test.<sup>2,19</sup> It is a nondestructive (will not affect the sterility, purity, or strength of the fluid) test that can be performed before or after filtration. The bubble point is the pressure required to force air or gas through the pores of the filter. When the bubble point

is reached, bubbles will appear. The pressure is documented and compared to the manufacturer's standard for that filter.

More effective methods of sterilization include autoclaving and dry heating.<sup>19</sup> Autoclaving uses steam heat (water vapor under elevated pressure) to kill spores, bacteria, and viruses. Sealed vials and ampules of an aqueous solution will generate their own steam that will sterilize the inner contents. It is the preferred method. However, some CSPs may not be stable when exposed to steam heat. Thus dry heat may be used in these circumstances. Dry heat sterilization will also kill spores, bacteria and viruses via dehydration. This requires higher temperatures for longer periods of time, so medication stability must be considered. For components used in compounding, depyrogeneration by dry heat is the preferred method. Dry heat works well for oil-based suspensions and solutions as well as bulk powders.

## LABELING REQUIREMENTS

The compounded CSP must be labeled with the following information: the drug and ingredient(s) names, quantities, strength, concentration, and volumes; the time that the CSP was compounded with a BUD; the personnel who compounded and checked the CSP; how the CSP should be stored; any auxiliary labels; and any other instructions necessary for proper use of the preparation.<sup>2</sup> In addition, if the compounded preparation is for a specific patient, the patient's name and an identifier along with the instructions for use must be included on the label.<sup>5</sup>

## VERIFICATION

All CSPs should undergo a final visual inspection of the labeling as well as product. This final check should be done by a pharmacist. It is prudent for all CSPs to be double checked by someone other than the personnel who compounded the CSP. The order should be placed alongside the CSP with quantities or amounts written and any calculations shown. Additionally, the CSP should be examined for any contaminants and color changes against a light and dark background, and for any leaks. If any doubt exists, the CSP should be discarded and a new CSP made. In cases where high-risk level compounding is involved, one CSP out of the batch must be sent out for sterility (required) and endotoxin (recommended) testing prior to the CSP being dispensed.<sup>12</sup>

## STORAGE AND DELIVERY

Nurses, patients, physicians, or any other person to whom CSPs are dispensed should be educated on how to properly store CSPs. When CSPs are delivered to medication rooms (e.g., in institutional settings), pharmacy personnel should educate those who administer the CSPs to monitor room and refrigerator temperatures to ensure product integrity. Areas where CSPs are kept should be inspected monthly by pharmacy personnel and standard operating procedures (SOPs) should be in place to ensure that CSPs maintain their quality in the patient care setting until administration. When CSPs are returned to the pharmacy, any outdated CSPs (those past their BUD) should be properly disposed of. If CSPs are to be re-used, strict SOPs should be in place delineating the circumstances when this is appropriate.<sup>5</sup>

One area that is often overlooked is the delivery of CSPs via personnel who are not under direct administrative control by the pharmacy (e.g., truck delivery service). Basic training of these personnel should occur so that the quality of the CSP is maintained.<sup>5</sup>

## QUALITY ASSURANCE

USP <797> requires that a quality assurance (QA) plan and formal QA programs are developed to ensure the continuous quality of compounded preparations.<sup>2</sup> Quality assurance programs should be formalized in writing and encompass all aspects of CSPs.<sup>5,21-22</sup> Detailed procedures on monitoring and evaluation activities should be described. QA programs should

specify how results are reported and evaluated, and identify mechanisms for follow-up when results are out of range. In addition, descriptions of responsibilities for personnel maintaining the QA program(s) should be clearly identified. Documentation is key to providing evidence to accrediting agencies that a QA plan and programs are in place and being routinely followed. Quality assurance programs should be detailed in your SOPs.

## STANDARD OPERATING PROCEDURES

Standard operating procedures are important for maintaining continuous quality care to patients, especially when there is high turnover or when resources are scarce. Developing and implementing SOPs can be daunting to personnel. USP <797> details the competencies, conditions, practices, and quality assurances that are required and recommended in an appendix. These should be used to develop SOPs for sterile compounding facilities. Appendix 1 summarizes these by main topic. For greater details, USP <797> and an article by Okeke and Allen can be reviewed.<sup>2,23</sup>

## PERSONNEL TRAINING AND QUALIFICATIONS

Personnel who compound sterile products must be adequately trained. USP <797> states that theoretical principles and practical skills of aseptic technique in achieving and maintaining ISO Class 5 level conditions should come from expert personnel through hands-on, audio-video instruction, and professional publications.<sup>2</sup> It further states that personnel shall perform didactic reviews, pass written tests as well as media-fill challenge tests of aseptic technique initially and annually thereafter. Media-fill challenge testing uses a microbiological growth medium (broth) to simulate admixture compounding. This testing shows objective evidence that personnel and processes are in place to produce sterile products. Personnel should also pass finger/touch testing using agar plates that contain compounds to de-activate antimicrobial substances on the glove. Personnel who fail either of these tests or written exams will need to be re-instructed and re-evaluated prior to compounding sterile preparations. For high-risk level compounding, these processes should occur semi-annually.<sup>2,5,7,8</sup>

## PATIENT AND CAREGIVER TRAINING

When intravenous therapy is required after discharge from an institutional setting, patient and caregiver training becomes essential for the safe use of CSPs. Elements of training programs for patients and caregivers should include written and visual materials as well as hands on practice (skill development) with the CSPs and devices.<sup>2,22</sup> Training should include how to check the CSP to ensure its integrity, how to handle and store the CSP, how to administer the CSP using proper techniques, how to care for catheters, dressings and maintain patency of injection site, how to use any devices associated with the delivery of CSPs, how to monitor for complications or adverse effects, how to dispose of waste, and how to seek emergency services if needed. SOPs must be in place so that all personnel, patients and caregivers understand the process surrounding safe and effective use of CSPs, and patient and caregiver understanding of these processes should be assessed prior to dispensing the CSP and any devices.<sup>2,22,23</sup>

## ADVERSE EVENT REPORTING AND PATIENT MONITORING

Pharmacists must participate actively in adverse event reporting and patient monitoring. In many cases, the pharmacist is the primary point of contact for the patient and caregiver with the healthcare team. When CSPs and devices are dispensed to patients, pharmacists should inquire about adverse events and how the treatment is working for the patient. Additionally, pharmacists should be available to answer patients' questions on CSPs, devices and to report problems to physicians and others.<sup>5,22</sup>

**Table 27-3. Temperature Ranges for Compounded Sterile Products**

Environment	Temperature Range
Controlled Room Temperature	20°C to 25°C (68°F to 77°F)
Controlled Cold Temperature	2°C to 8°C (36°F to 46°F)
Freezing Temperature	-25°C to -10°C (-13°F to 14°F)

## ENVIRONMENTAL MONITORING

Testing of the air quality should be performed every 6 months to ensure that the PEC, buffer area, and ante-room area remain at an ISO class 5, 7, and 8 or less, respectively.<sup>2,11-12,21</sup> Volumetric air sampling by impaction should be utilized to test for viable and nonviable particles. Commercial products and services are available for this purpose. LAFH, CAI and CACI should also be tested using agar plates to determine sterility in the ISO Class 5 environment. Each facility should have a sampling plan that should describe the sample location(s), method of collection, frequency of sampling, volume of air sampled (in the case of air sampling), and the time of the day that the activity will be performed. If compounding is occurring at the time of sampling, this should be noted in the records. Records must be maintained and reviewed by supervising personnel to ensure that the environmental controls comply with USP <797> standards. These records may also be reviewed by accrediting agencies. In addition to air quality control, pressure differential or airflow monitoring and recording must be completed at a minimum of once daily. For low- to medium-risk compounding, pressure differential or airflow displacement can be measured. Facility design determines which measurement is utilized. In the case of airflow displacement, the PEC, buffer area and ante-room are located together without any separation. Airflow displacement should measure at least 40 feet per minute for this facility design.<sup>2</sup> Pressure differential monitoring is utilized for facilities where the PEC and buffer area are separated from the ante-room. A positive pressure differential of at least 0.02-inch water column is required.<sup>2</sup> In compounding facilities with positive pressure environments, the air flows from the buffer room to the ante-room to the general pharmacy. The ante-room typically has an intake panel that facilitates this pressure differential by pulling air from the buffer into the ante-room. Digital electronic devices to measure the pressure differential can be purchased. These devices must be placed appropriately to ensure that the desired pressure differentials are measured. Temperature in buffer rooms should be maintained to prevent microorganisms from growing and for personnel comfort. Additionally, personnel often wear multiple layers of clothing, head covers, and facemasks when they compound CSPs that could cause sweating or general discomfort.<sup>5</sup> Temperature in the ante-room and buffer area should be maintained cooler than the general pharmacy areas for these reasons. Although not required by USP <797>, other environmental parameters may be monitored such as light, humidity, and sound. Humidity should be maintained between 35% to 65%. Light and sound levels should meet state and federal requirements and be comfortable for personnel working in the environment.<sup>5</sup>

## MEDICATION AND CSP STORAGE

Medications should be stored according to manufacturer specifications. Table 27-3 shows the temperature range according to USP-NF requirements. These must be monitored daily at a minimum.<sup>2</sup>

## CONCLUSION

In an effort to control the purity and sterility of intravenous medications, the USP-NF developed rules and recommendations termed USP Chapter <797>. These rules and recommendations

apply to all injected medications whether made by pharmacy, nursing, medicine, dental, or any other health care provider. The costs associated with implementation have created some controversy. However, a majority of institutions have come into compliance with the 2004 standards, and are now in the process of implementing the 2008 standards. The risks associated with injectable medications are high when standards are not followed. Quality patient care must be the number one priority. Developing QA programs and following standard operating procedures are necessary to maintain continuous quality care to patients.

## INTRODUCTION<sup>1</sup>

Ophthalmic preparations are specialized dosage forms designed to be instilled onto the external surface of the eye (topical), administered inside the eye (intraocular) or adjacent to it (periocular, e.g., juxtasclear or subtenon), or used in conjunction with an ophthalmic device. The latter include preparations used in conjunction with surgical implantation (such as an intraocular lens) and dry eye formulations compatible with a punctal appliance (e.g., a punctal plug), and extends to a variety of solutions used in the maintenance of contact lenses. The preparations may have any of several purposes (e.g., therapeutic, prophylactic, or palliative for topically administered agents) but include mechanical, chemical, and biochemical actions of agents used in the care of ocular appliances and tissue prophylaxis during or following surgery. Because of the dangers associated with the administration or repetitive administration of intraocular and periocular preparations, their suitability is restricted to therapeutic applications or surgical adjuncts.

The versatility of dosage forms of ophthalmic preparations allows the clinician to choose the form most suitable for the function desired. Therapeutically active formulations can be designed to provide extended action for convenience or for reduction in risk of repetitive administration, improved bioavailability of the agent, or improved delivery to a targeted tissue. The residence of an ocular preparation can range from the few seconds needed for tears to clear an irritating substance; to hours for a gel, a gel-forming solution, or an ointment; to months or years for an intraocular or periocular dosage form. A preparation may be strictly therapeutic or may serve in prophylaxis. The latter includes surgical adjuncts to maintain the health of fragile cells, and postsurgical or post-trauma preparations designed to prevent or reduce the likelihood of infection. Another form of prophylaxis, one for a device, is the antisoiling function provided by some contact lens solutions.

Ophthalmic preparations are similar to parenteral dosage forms in their requirement for sterility as well as considerations for osmotic pressure (tonicity), preservation, tissue compatibility, the avoidance of pyrogens in intraocular dosage forms, particulate matter, and suitable packaging.

Topical therapeutic dosage forms have customarily been restricted to solutions, suspensions, and ointments. But with advances in materials science, the range of ophthalmic dosage forms has expanded significantly to include gels, either preformed or spontaneous gels responsive to the ocular environment, and ocular inserts, both forms reducing dosage frequency. These are most often multidose products, containing suitable preservative(s) to meet compendial preservative effectiveness test [e.g., *US Pharmacopeia* (USP),<sup>2</sup> *European Pharmacopoeia*,<sup>3</sup> or *Japanese Pharmacopoeia*<sup>4</sup>] requirements. Now, however, single-dose units (also referred to as unit-dose products) that are preservative-free preparations have become available, generally packaged in form-fill-seal plastic containers with 0.25 mL to up to 0.8 mL, have become available. These unit-dose containers are designed to be discarded after a single use or after a single day's use if the container has a reclosable feature and the product is so labeled.

Injections and implants have been developed for intraocular drug delivery. Irrigating solutions and viscoelastic gels are available specifically for adjunctive use in ophthalmic surgery. Specialized formulations are now available for use in the care of contact lenses. The designs of these preparations, meeting all of the requirements for safety, efficacy, component compatibility, tissue acceptability, storage, shipping, and shelf-life, are beyond the scope of this review. Nonetheless, a description of the requirements and the designs for some of these formulations should be illustrative and didactic.

From a historical perspective, preparations intended for treatment of eye disorders can be traced to the writings of the Egyptians, Greeks, and Romans. In the Middle Ages, *collyria* were referred to as materials that were dissolved in water, milk, or egg white and used as eyedrops. One such collyrium contained the mydriatic substance belladonna to dilate the pupils of milady's eyes for cosmetic purpose.

From the time of belladonna collyria, ophthalmic technology progressed at a pharmaceutical snail's pace until after World War II. Before World War II and into the 1950s, ophthalmic preparations were mostly compounded by the pharmacist for immediate use. Not until 1953 was there a legal requirement by the US Food and Drug Administration (FDA) that all manufactured ophthalmic solutions be sterile. The range of medicinal

agents to treat eye disorders was limited, as was the state of eye surgery and vision correction, which was limited to eye-glasses. In the past 50 years, a modern pharmaceutical industry specializing in ophthalmic preparations has developed to support the advances in diagnosis and treatment of eye diseases, in eye surgery, and in contact lens design and use. Because of the variety of ophthalmic products readily available commercially, the pharmacist now is rarely required to compound a patient's ophthalmic prescription. More important, however, is that the pharmacist appreciate even subtle differences in formulations that may impact efficacy, comfort, compatibility, or suitability of a preparation for particular patients.

Currently and in the future, in addition to the advances in dosage-form technology, drug molecules will be designed and optimized specifically for ophthalmic application. New therapies may become available for preventing blindness caused by degenerative disease – including age-related macular degeneration (AMD), macular edema, and diabetic retinopathy. Biotechnological products may also become available to treat causes of multifactorial eye disorders like glaucoma. Such specialized therapeutic agents also will require carefully designed and compatible dosage forms.

Because dosage forms are fashioned to complement the requirements of the therapeutic agent, and the latter are selected for their action upon particular tissues so as to modify their function, we will now turn to a description of ocular tissues and their physiology.

## ANATOMY AND PHYSIOLOGY OF THE EYE

In many ways the human eye is an ideal organ for studying drug administration and disposition, organ physiology, and function. Unlike many bodily organs, most of its structure can be inspected without surgical intervention. Its macroscopic responses can be investigated by direct observation. Its miraculous function, so intricate and complex, converting a physical electromagnetic stimulus into a chemical signal that is coupled to distant neurons for signal processing by an electrochemical wave, is detectable by sensitive instruments attached to external tissues. The basis for the function and protection of this important organ that links humans to

their external environment is the tissues composing it. The structures to be described are illustrated in Figures 28-1 to 28-3. Figure 28-1 provides a horizontal section of the eyeball identifying the major structures and their interrelationships.<sup>5</sup> Figure 28-2 shows in greater detail the anterior portion of the eye and eyelids, in vertical section, emphasizing some of the structures associated with tear apparatus.<sup>6</sup> Figure 28-3 emphasizes the flow of tears into the nasal structures.<sup>6</sup> This brief introduction will focus on the anatomical structures composing the eye and their function.

### EYELIDS

Eyelids serve two purposes: mechanical protection of the globe and creation of an optimum milieu for the cornea. The inner surfaces of the eyelids and the outermost surfaces of the eye are lubricated by the tears, a composite of secretions from both lacrimal glands and specialized cells residing in both the bulbar (covering the sclera) and palpebral (covering the inner surface of the lids) conjunctiva. The antechamber has the shape of a narrow cleft directly over the front of the eyeball, with pocket-like extensions upward and downward. The pockets are called the superior and inferior fornices (vaults), and the entire space, the conjunctival cul-de-sac. The elliptical opening between the eyelids is called the palpebral fissure, and the corner of the eyes where the eyelids meet are the canthi.

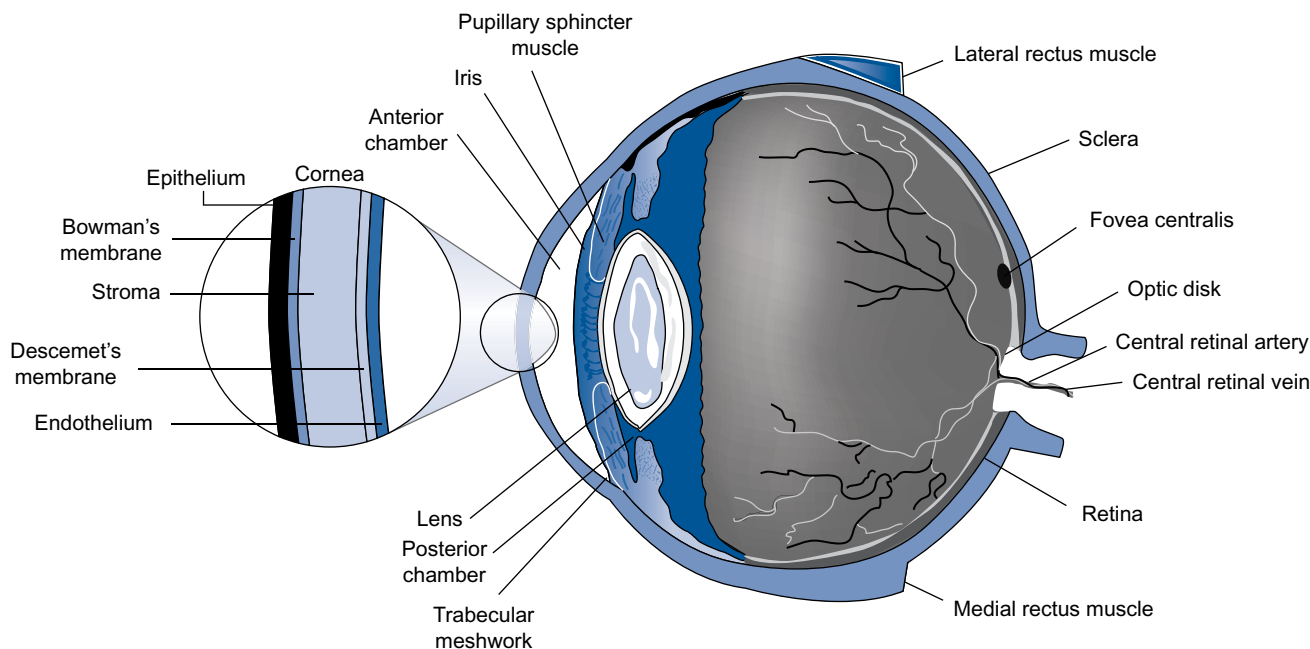

### OVERVIEW OF STRUCTURE AND FUNCTION OF THE EYEBALL

#### Structure

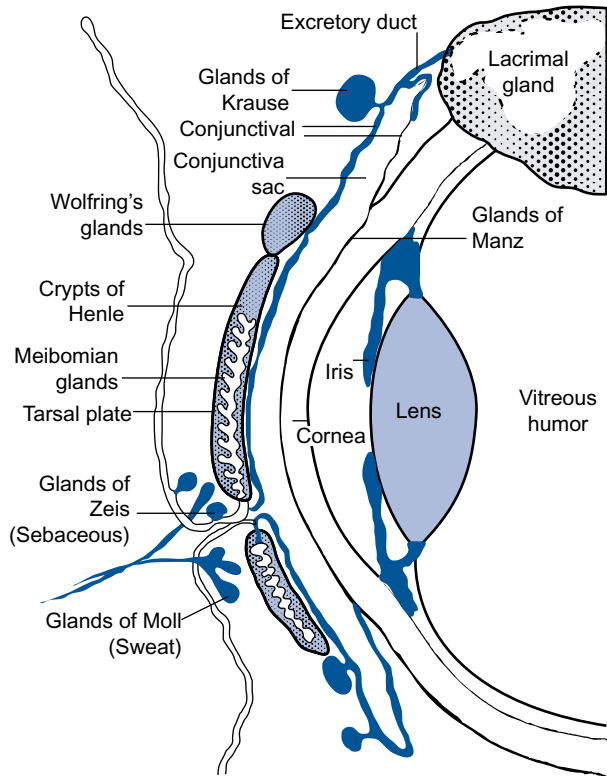

The eyeball is housed in the bones of the skull, joined to form an approximately pyramid-shaped housing for the eyeball, called the orbit. The wall of the human eyeball (bulbus, globe) is composed of three concentric layers that envelop the fluid and lenticular core.<sup>7-9</sup>

#### OUTER FIBROUS LAYER

The outer scleral layer is tough and pliable but only slightly elastic. The anterior third is covered by the conjunctiva, a clear, transparent, mucous surface. The most anterior portion of the outer layer forms the cornea, a structure so regular and the

**Figure 28-1.** A cutaway horizontal section of the eyeball, illustrating the important anatomic structures and their interrelationships diagrammatically. The different layers of the cornea are illustrated in the magnified view. Relative sizes are suggestive and not proportional. The diameter of a mature eyeball is generally slightly greater than one inch. (Courtesy, Alcon Laboratories, Inc., Fort Worth, TX).

**Figure 28-2.** The front half of the eye, in vertical section, identifying the important structures associated with cornea and the front of the eye, including the eyelids and the glands associated with tears.

**Figure 28-3.** The structures associated with the tears and lacrimal flow and access to the nasolacrimal system.

water content so carefully adjusted that it acts as a transparent window. It is devoid of blood vessels. Over the remaining two thirds of the globe, the fibrous collagen-rich coat is opaque (the *white* of the eye) and is called the sclera. It contains the microcirculation, which nourishes the tissues of this anterior

segment, and is usually white except when irritated vessels become dilated.

The cornea, slightly thicker than the sclera and ranging in thickness from 500 micrometers to 1 mm, consists of five identifiable layers. Proceeding from the most anterior layer, these are the hydrophobic stratified squamous epithelium, which is underlaid by the Bowman membrane, then the stroma and the Descemet membrane, and then the innermost layer, the endothelium. The stroma is a hydrophilic elastic network of highly organized connective tissue and is the thickest layer of the cornea. The fibrous collagen-rich Descemet membrane separates the stroma from the single squamous-cell layer of endothelium, the location of the pump that keeps the cornea in its relatively dehydrated, transparent state. The cornea functions as a bilayer barrier, with the hydrophobic epithelium as the primary barrier to hydrophilic molecules and the hydrophilic stroma as the primary barrier to hydrophobic molecules. A schematic drawing of the cornea is provided in Figure 28-1 and its relation to other anterior tissues in Figure 28-2.

### MIDDLE VASCULAR LAYER

The middle vascular layer, or uvea, provides nourishment to the eye and consists (from the back of the eye to the front) of the choroid, the ciliary body, and the iris. The choroid consists of a pigmented vascular layer, colored by melanocytes and traversed by medium-sized arteries and veins, with the choriocapillaris containing a network of small vessels that nourish the neural retina. The ciliary body contains muscles that control the extension of the lens, allowing visual accommodation, as well as the ciliary processes that secrete aqueous humor into the posterior chamber to maintain the intraocular pressure (IOP) that, in turn, keeps the eyeball fully expanded. The pigmented iris is a ring of muscular tissue around the pupil, a round centric hole that acts as a variable aperture to control pupil diameter and, thereby, the level of light entering the eye. The canal of Schlemm, one of the important paths for outflow of the aqueous humor, resides in the angle of the iris. Bruch's membrane separates the choroid from the retina.

### NEURAL RETINA

This innermost layer of the eyeball is a complex tissue that supports the harvesting of light through the collective action of photoreceptors and nerve cells specialized for distinguishing white from black (rods) or for discerning color (cones). In addition, the retina consists of cells that support metabolism (like the heavily pigmented retinal pigmented epithelium, which purges photoreceptors of spent molecules and metabolites, and regenerates the *cis*-retinal), provide structure (astrocytes and Müller cells), or contribute to the primary function of photo-detection/signal processing (the ganglion cells that begin to process the electrochemical information transmitted from the photoreceptors).

### OCULAR CORE

Within the globe, the crystalline lens spans the interior fluid-filled center close to the iris and is anchored by zonule fibers to the ciliary body. The lens is composed of a single layer of replicating epithelial cells that, with age, flatten into layers of long, thin crystalline-filled lamellar fibers. The lens is the only tissue in the body that retains all cells ever produced, a fact that contributes to age-related alterations in size, clarity, and extensibility. A tough, thin transparent membrane called the capsule covers the outermost layer of the lens.

The aqueous and vitreous humors are interposed between the solid structures of the eye. The clear, fluid aqueous humor fills the globe anterior to the lens and is primarily responsible for maintaining correct IOP. The gel-like vitreous humor accounts for most of the weight of the eye and resides posterior to the lens, in direct contact with the retina.

## FUNCTION

The eyeball houses the optical apparatus that causes the formation on the neural retina of inverted, reduced images of the outside world.

### Dimensional Stability

#### *DIMENSIONAL STABILITY*

The optical function of the eye calls for stability of its dimensions, which is provided partly by the fibrous outer coat but more effectively by the intra ocular pressure (IOP), which exceeds the pressure prevailing in the surrounding tissues. This IOP is the result of a steady production of specific fluid, the aqueous humor, which originates from the ciliary processes anterior to the lens and exits the eye by an intricate system of outflow channels. The resistance encountered during this passage and the rate of aqueous production are the principal factors determining the level of the IOP. In addition to this hydromechanical function, the aqueous humor acts as a carrier of nutrients, substrates, and metabolites for the avascular tissues of the eye.<sup>10</sup>

#### *OPTICAL PATHWAY*

The optical pathway consists, in sequence, of the precorneal tear film, the cornea, the aqueous humor, the pupil, the crystalline lens, the vitreous humor, and the retina. The chief refraction of light for the eye occurs at the outer surface of the cornea, where the index of refraction changes from that of air (1.00) to that of precorneal substance (1.38). After traversing the cornea, light passes through the clear aqueous humor to the pupil, where the amount of light entering the eye is regulated by the pupillary diameter, and to the second refractive element of the eye, the lens, whose variable focal length allows objects both near and far to be brought into focus (accommodation). The shape of the lens, controlled by the muscles of the ciliary body, refracts and focuses the reduced inverted image on the retina. That image is sharp and clear, in part because of the high transparency of the vitreous humor, which, because of its gel-like state, keeps debris and cells from entering the pathway for the light. The image formed by the electromagnetic light signal on the neural retina is converted to a chemical signal, changing *cis*-retinal to *trans*-retinal, which in turn is processed by neural cells into an electrochemical signal transported through axons to central nerve cell bodies. Continuous maintenance of the photoreceptors and neural tissues in a state capable of supporting the conversion of the excitation associated with a retinal image to processable information is integral to the functioning of the retina and is the reason retinal tissue is among the most rapidly metabolizing tissues in the body. The dependence of the neural retina on the metabolic support provided by the underlying cell layer, the retinal pigmented epithelium, explains why damage to the tissue—such as detachment of the retina or diminished blood supply—can result in nearly immediate and permanent loss of vision.<sup>11</sup>

#### *TISSUES RESPONSIBLE FOR REFRACTION*

Any alteration in the shape or transparency of the *cornea* interferes with the formation of a clear image; therefore, any pathological process, however slight, may interfere seriously with the resolving power or visual acuity of the eye. Transparency of the cornea is largely attributable to its organized laminar arrangement of cells and fibers, and the absence of blood vessels. The normal cornea possesses no blood vessels except at the sclero-corneal junction, the limbus. The cornea must therefore derive its nutrition by diffusion and must have certain permeability characteristics; it also receives nourishment from the fluid circulating through the chambers of the eye and from the air. That the normal cornea is devoid of blood vessels is an important feature in surgical grafting.

Cloudiness of the cornea may occur as a result of disease (e.g., excess pressure in the eyeball, a symptom associated with

glaucoma); the presence of scar tissue due to injury or infection; or deficiency of oxygen or excess hydration, such as may occur during the wearing of improperly fitted contact lenses. A wound of the cornea may heal as an opaque patch that can be a permanent impairment of vision unless it is located in the periphery of the cornea.

The corneal nerves do not supply all forms of sensation to the cornea, but pain and cold are well supplied. The pain fibers have a very low threshold, which makes the cornea one of the most sensitive areas on the surface of the body. It now is agreed that the cornea possesses a true sense of touch; nerve endings supplying the sensation of heat appear to be lacking.

The corneal epithelium provides an efficient barrier against bacterial invasion. Unless its continuity has been broken by an abrasion (a traumatic opening or defect in the epithelium), pathogenic bacteria, as a rule, cannot gain a foothold. Trauma, therefore, plays an important part in most of the infectious diseases of the cornea that occur exogenously. A means of detecting abrasions on the corneal surface is afforded by staining the cornea with sodium fluorescein. Any corneal abrasion is subject to infection.

As with the cornea, any change in the transparency of the *lens* as a result of age or disease can significantly affect visual clarity. Loss of flexibility of the lens can reduce visual accommodation and cause difficulty in focusing on near objects. Also, upon aging or as a result of trauma, the lens may generate opacities caused by the oxidation and crosslinking of lens proteins. When cataract surgery is required to restore clarity to cloudy vision, the natural lens is removed and replaced by an artificial one. The capsule, though, is preserved so that it can provide scaffolding for the implanted synthetic intraocular lens.

### Lacrimal System

The conjunctival and corneal surfaces are covered and lubricated by a precorneal tear film, a fluid secreted by the conjunctival and lacrimal glands.<sup>11</sup> The clear, watery secretion of the lacrimal gland, delivered through a number of fine ducts into the conjunctival fornix, contains numerous salts, glucose, other organic compounds, and approximately 0.7 percent protein, including the enzyme lysozyme. Small accessory lacrimal glands are situated in the conjunctival fornices. The tear film, compatible with both aqueous and lipid ophthalmic preparations, is composed of a thin outer lipid layer, a thicker middle aqueous layer, and a thin inner mucoid layer. It is renewed during blinking and, when blinking is suppressed, may dry in patches. It seems to be unaffected by the addition of concentrations of up to 2 percent sodium chloride to conjunctival fluid. A pH below 4.0 or above 9.0 causes derangement of the film. The film affects the movement of contact lenses and forms more easily on hydrophilic than on hydrophobic prostheses.

The innermost mucin protein layer of the film is especially important in maintaining the stability of the film and is postulated to be held in place by the microvilli of the corneal epithelial cells. Sebaceous meibomian glands of the eyelids secrete an oily fluid that forms the outer layer of the tears, helps to prevent overflow at the lid margin, and reduces evaporation from the exposed surfaces of the eye.

Spontaneous blinking replenishes the fluid film by pushing a thin layer of fluid ahead of the lid margins as they come together. The excess fluid is directed into the lacrimal lake—a small, triangular area lying in the angle bound by the innermost portions of the lids. The skin of the eyelids is the thinnest in the body and folds easily, thus permitting rapid opening and closing of the palpebral fissures, at velocities of tens of centimeters per second. The movement of the eyelids includes a narrowing of the palpebral fissures in a zipper-like action from lateral to medial canthus. This aids transport or movement of fluid toward the lacrimal lake and elimination of unwanted contaminants.

Tears are drained from the lacrimal lake through two small openings, the superior and inferior puncta, which drain into connecting small tubes, the lacrimal canaliculi, which

themselves join at the common canaliculus that leads into the upper part of the nasolacrimal duct, the beginning of which is the lacrimal sac, as shown in Figure 28-3. The drainage of tears into the nose does not depend merely on gravity. Fluid enters and passes along the lacrimal canaliculi by capillary action, aided by aspiration resulting from contraction of muscles embedded in the eyelids, and by peristalsis in the muscles near the canaliculi. When the lids close, as in blinking, contraction of the muscle causes dilatation of the upper part of the lacrimal sac and compression of its lower portion. Tears aspirated into the sac are forced down the nasolacrimal duct toward its opening into the nose. As the lids open, the muscle relaxes. The upper part of the sac then collapses and forces fluid into the lower part, which at the same time is released from compression. Thus, the act of blinking exerts a suction force-pump action in removing tears from the lacrimal lake and emptying them into the nasal cavity. Lacrimation is induced reflexively by stimulation of nerve endings of the cornea or conjunctiva. This reflex is abolished by anesthetization of the surface of the eye and by disorders affecting its nerve function.

The normal cul-de-sac is maintained free of pathogenic organisms in part by the chemical action of enzymes, such as lysozyme, which normally destroy saprophytic organisms with limited action against pathogens, and in part by the continuous physical flow of normally sterile secretions, which constantly wash the bacteria, dust, etc., away from the eye down into the nose. In certain diseases or upon aging, the lacrimal gland, like other glandular structures in the body, may undergo involution, with the result that the lacrimal fluid becomes scanty. Changes in the conjunctival glands may lead to alteration in the character of the secretion, so that quality as well as quantity of tears may be abnormal. This can lead to symptoms of dryness, burning, and general discomfort, and ultimately may interfere with visual acuity.

## Summary

This brief overview of the structure and function of the eye should provide a basis for understanding the highly integrated tissues comprising this miraculous organ and suggest the importance of providing medications that in no way impair the balance of functions required for maintaining normal functioning of the eye.

## BIOAVAILABILITY

### THERAPEUTIC TARGETS

Bioavailability of pharmacological agents is dictated by the ocular structure and physiology just discussed. But bioavailability also is controlled by physical constraints and tissue biochemistry (to be discussed in the next subsections), by physical and chemical characteristics of the therapeutic agents, and by the preparations by which they are presented. The bioavailability and potential efficacy of an agent also are determined by the therapeutic targets, which are governed by disease etiology.

For example, treatment of a superficial infection of the cornea, while possibly requiring sustained delivery to enable less frequent administration of antimicrobial therapy, does not involve special considerations of corneal permeation or access to the target tissue. In this circumstance, product design might be directed toward the reduction of any corneal or scleral transport, in that these would be regarded as drug lost from the target site. On the other hand, a recalcitrant case of uveitis may require both topical and systemic administration of anti-inflammatory agents so as to eliminate the condition. In this case, however, transport to the uvea, an internal tissue, is desirable.

Chronic diseases associated with aging, like glaucoma, may be amenable to routine administration of a topical medication. The target, however, may be determined by the particular mechanism for treating the disease. For instance, a drug influencing the generation of aqueous humor may target the iris

ciliary body, whereas a drug influencing the outflow of aqueous humor might target the trabecular meshwork that opens into the canal of Schlemm. The inherent characteristics of the drug also will determine, in part, any need for sustained delivery. In general, a lipophilic agent will be absorbed readily into the lipophilic corneal epithelium, whereas an ionic or hydrophilic agent will be absorbed more slowly. But corneal permeation may still be a significant barrier to delivery at the target tissue even for a lipophilic drug, because transport through the largely aqueous stroma is still required. The capacity of the epithelium for the drug, in part controlled by its partitioning characteristics, may govern any need for sustained administration as well as the dosing regimen. The solubility of the drug, especially for often relatively insoluble hydrophobic lipophilic agents, can limit the size of the reservoir of drug administered, or the exposure to the drug, where the latter is defined as the area under the curve in a concentration-vs.-time plot of drug residence.

Recently, treatments for ocular diseases of the deep tissues have invoked techniques more commonly utilized in targeted systemic delivery. For example, the treatment of retinal cytomegalovirus infection, accompanying end-stage HIV infections, has engendered treatments delivering drug directly to the vitreous humor, with either intracameral injection or an implant. Photodynamic therapy utilizes a radiation (generally light) to activate a drug delivered systemically. Angiostatic agents for the treatment of wet AMD are delivered from an implant. As Higuchi, years ago, and others more recently have described, the rate of delivery from such devices can be controlled by the design of the device, by drug characteristics (primarily solubility), or by a balance of both.<sup>12</sup>

Nonetheless, eyedrops remain the most common modality for administration of therapeutic agents, and so considerations of the quantitative relationships governing the balance of effects controlling access of these agents to their target tissues are of significance and will be summarized in the next few sections. The approach will be primarily hydrodynamic,<sup>13,14</sup> though molecular theories are now available to give rationale for the macroscopic transport laws.<sup>15</sup> More intricate transport characteristics, such as those occurring when membranes actively transport the therapeutic agent, are less common than simple passive diffusion and therefore will be neglected here. The approach highlights the interrelationships of phenomena whose subtle control in commercial products improves their efficacy. While transmembrane transport is most relevant to transcorneal delivery, some of the same considerations apply to active drugs delivered from implants, because these drug reservoirs serve only as a source for the agents that must traverse tissues or tissue boundaries to reach their target sites.<sup>16</sup>

## CORNEAL ABSORPTION AND DRUG ACCESS

### Physical and Chemical Considerations

Under normal conditions the human tear volume averages about 7 microliters.<sup>17</sup> The estimated maximum volume of the cul-de-sac is about 30 microliters, with drainage capacity far exceeding lacrimation rate. The outflow capacity accommodates the sudden large volume resulting from the instillation of an eyedrop. Most commercial eyedrops range from 25 to 50 microliters in volume.

Within the rabbit cul-de-sac, the drainage rate has been shown to be proportional to the instilled drop volume. Multiple drops administered at intervals produced higher drug concentrations. Ideally, a high concentration of drug in a minimum drop volume is desirable. Patton<sup>18</sup> has shown that approximately equal tear film concentrations result from the instillation of 5 microliters of  $1.61 \times 10^{-2}$  M pilocarpine nitrate or from 25 microliters of  $1.0 \times 10^{-2}$  M solution. The 5 microliters contains only 38 percent as much pilocarpine, yet its bioavailability is greater because of decreased drainage loss. Human responses can be expected to be similar, and this is supported by studies of gamma scintigraphy.<sup>19</sup> However, human tear responses are

much more significant, and variable, than those in some *in vivo* models. When the therapeutic agents themselves are irritating, excess tearing may occur that may influence bioavailability in affected individuals. There is a practical limit to the concept of minimum dosage volume. There is a difficulty in designing and producing a dropper configuration that will deliver small volumes reproducibly.<sup>20</sup> Also, the patient often cannot detect the administration of such a small volume. This sensation, or lack of sensation, is particularly apparent at the 5.0- to 7.5-microliter dose-volume range.

The concept of dosage-volume drainage and cul-de-sac capacity directly affects the prescribing and administering of separate ophthalmic preparations. The first drug administered may be diluted significantly by the administration of the second. On this basis, combination drug products for use in ophthalmology have considerable merit.

Though this is generally not a major concern, an instilled drug can be subject to protein binding in the tear fluid and metabolic degradation by enzymes such as lysozyme. Stability, however, is always a primary consideration, both in the bottle and in the tissues. Rapid conversion of a drug to a metabolite is generally to be avoided unless by design (prodrugs).

### Corneal Absorption

Penetration of drugs administered topically occurs primarily through the cornea. Drugs administered by instillation must penetrate the eye and do so primarily through the cornea. Corneal absorption is generally more effective than scleral or conjunctival absorption, in which drug is removed by circulatory flow into the general circulation. This is also true because most therapeutic agents tend to be reasonably lipophilic. In the case of more hydrophilic materials, which as mentioned earlier are more slowly absorbed into the corneal epithelium, there is evidence to suggest that a scleral route may be more common. A practical example comes from studies of carbonic anhydrase inhibitors,<sup>21</sup> a class of drug used in the treatment of glaucoma.

Many ophthalmic drugs are weak bases and are conveniently applied to the eye as aqueous solutions of their salts. If the molecule is maintained in an ionized state, for example, by employing a weakly acidic buffered vehicle, stability of the drug often can be prolonged. If the buffer is weak, little discomfort is generally experienced at the time of instillation. Once neutralized by the tears, the fraction of free base may increase, and this may be the form of the drug most readily absorbed by the corneal epithelium. Nonetheless, during transport through the hydrophilic stroma, an important fraction of the agent may be ionized. Similarly, the form transported through the endothelium may be the free base, and that presented to the ciliary body (one of the sites of pharmacological action) in transport from the aqueous humor may be the ionized salt. This scenario is described simply to suggest the complexity that can be exploited in targeting an ophthalmic drug, as well as complementary considerations involved in providing a preparation capable of the requisite stability for a conventional two-year shelf-life.

The cornea can be penetrated by ions to a small but measurable degree. Under comparable conditions, the permeabilities are similar for all ions of low molecular weight, which suggests that the passage is through extracellular spaces. The diameter of the largest particles that can pass across the cellular layers seems to be in the range of 10 to 25 Å. Some effort has been directed toward increasing the upper molecular-weight limit for water-soluble therapeutic agents by utilizing a class of molecules referred to as penetration, or permeation, enhancers. These molecules are selected for their capacity to increase transiently permeation of larger molecules while producing minimal discomfort or toxicity.

Because highly water-soluble drugs generally penetrate the cornea less readily and the cornea is known to be a membrane including both hydrophilic and lipophilic barrier layers, most

effective penetration is obtained with drugs having both lipophilic and hydrophilic properties. As an example, highly water-soluble steroid phosphate esters penetrate the cornea poorly. Better penetration is achieved with the poorly soluble but more lipophilic steroid alcohol; still greater absorption is seen with the steroid acetate form.

Work on transport of drugs through the cornea, dating from the work of Edelhauser *et al.* in 1965,<sup>13</sup> and Lee and Robinson in 1979,<sup>22</sup> and Lee in 1990,<sup>23</sup> has indicated the interplay of physical properties that regulate access of drugs to ophthalmic tissues. The hydrodynamic principles are well known and will be outlined here. From the physical chemistry of passive diffusion across a simple membrane capable of sustaining a concentration difference (and discussed in other chapters of this volume), the main mechanism of entry into the eye,

$$J = -D dC_m/dx \quad (1)$$

according to Fick's first law of diffusion, where  $J$  is the flux of drug across the membrane (amount per area per time),  $D$  is the diffusion coefficient, and the derivative of  $C_m$  is the spatial concentration gradient in the membrane (at steady state, constant across the membrane).<sup>24</sup> Even from this simple relationship, the consequences of the physical properties of the drug can be inferred. As the solubility of the drug increases the gradient will increase, so the driving force for entry of the agent into the aqueous humor will be increased. Experiment similarly has shown specific characteristics of the diffusion coefficient; namely, the diffusion coefficient decreases with increasing molecular size (and hence molecular weight of the compound). So all else being equal, we need to balance the increased specificity and targeting of a larger active molecule against the loss in rate of membrane transport. The equation also makes clear that any means for maintaining the concentration on the donor side of the membrane, thereby sustaining the gradient term for a longer period of time, will increase the mean total flux.

To perceive the consequences of partitioning in a more complicated bilayer membrane (a good model for the cornea in that the major layers serving as barriers to drug entry are the epithelium and stroma), we need to look at the diffusion equation for a bilayer:

$$J \cong \frac{PC_w}{\frac{Pl_s}{D_s} + \frac{l_e}{D_e}} \quad (2)$$

where  $P$  is the distribution coefficient (e.g., the octanol:water partition coefficient, wherein it is a good approximation of the partitioning into the epithelium), the subscripts designate either stroma ( $s$ ) or epithelium ( $e$ ),  $l$  is the length representing the thickness of the layer, and  $C_w$  is the concentration of drug at the donor side of the membrane, i.e., in the concentration of drug in the tears.<sup>25</sup> This equation is an approximation to the differential equation. One source of approximation is that it presumes that the concentration on the donor side (in the eye, the concentration of active ingredient in the tears) is much higher than on the receiver side of the membrane (the concentration in the aqueous humor). From this equation we can observe that as the partitioning increases, the effectiveness of the epithelium as a barrier diminishes and is replaced nearly exclusively by the stroma. Similarly, as the partitioning decreases, the epithelium becomes the dominant barrier. Of course, this is just a mathematical representation of an anticipated phenomenon. Clearly there is an advantage to increasing the lipophilicity of the agent so as to improve absorption and transport. A precaution to be kept in mind, however, is that ordinarily when the lipophilicity is increased, the aqueous solubility (which  $C_w$  may approach) generally decreases. This is an example of the need to balance a number of characteristics, as mentioned earlier.

There are circumstances when sustaining the presence and concentration of the drug in the tear volume is important, especially when the drug is sufficiently hydrophilic to severely limit absorption directly into the corneal epithelium. From the equations for a stirred-tank chemical reactor, which is undergoing a

steady-state flow of fluid with a solvent entering and a solution of mixed chemicals flowing from it, we expect:

$$C_w(t) = C_i \cdot \exp\left(\frac{-\dot{V}_T \cdot t}{V_T}\right) \quad (3)$$

where the time dependence of  $C_w$  is explicitly indicated,  $C_i$  is the initial concentration,  $V_T$  is the volume of the reactor (here the tear volume), and its derivative is the rate of flow through the reactor, essentially the rate of tear generation. A number of characteristics of drug delivery are apparent from this equation. One is that if the drug causes discomfort and increases the rate of tearing ( $\dot{V}_T$  in the equation), then the concentration in the tears is depleted more rapidly. Analogously, if the preparation includes a means for retaining a drug carrier in the cul-de-sac, then only a fraction of the drug present is released free into the tears, and  $C_w(t)$  no longer changes with time and, until the reservoir is depleted, may be approximately constant. Because what is important is the total amount of drug reaching the target tissue over a time period,

$$N_{\text{eff}} = A \cdot \int dt J(t) \quad (4)$$

the effect of reducing the loss rate from tear flow may counterbalance the consequence of reducing the total level in the tears. Note, for situations in which there is a means for sustaining drug release, Equations 2 and 3 have to be modified in any event, because  $C_i$  is no longer the total initial concentration but the fraction in the tears that is transportable through the cornea. This introduction should provide some notion of the types of complexity involved in achieving improved delivery of a therapeutic agent. When more is known about the details of ocular function, characteristics of the therapeutic agents, and vehicles, it is possible to solve the differential equations numerically so as to improve the design of topically applied medications.<sup>26–28</sup>

### DELIVERY TO THE OCULAR POSTERIOR

Optimizing drug delivery to the ocular posterior requires understanding the mechanisms by which substances are cleared by diffusion, by physiological processes of hydraulic, vascular, and lymphatic flows.<sup>29,30</sup> Computational fluid dynamics can be a useful tool for predicting the influences of processes on the clearance of intravitreally injected substances<sup>30</sup> and delivery from devices implanted into the vitreous<sup>31</sup> or immediately outside the globe in the juxtasceral space.<sup>32</sup> This entails construction of an anatomically accurate model for the eye, which enables simulation of diffusion of drug in physiological flow fields with clearance mechanisms engaged. An example of such a simulation exercise modeling clearance of an intravitreal depot of triamcinolone suspension particles is illustrated in Figures 28.4 and 28.5. The significance of these activities, a subject of ongoing research, is difficult to overstate since the diseases being addressed—AMD, macular edema, and diabetic retinopathy—are sight-threatening. The current standard of treatment for AMD requires monthly injections of an antibody against vascular endothelial growth factor. Significant efforts are under way to develop alternate therapies to reduce the frequency of administration or implantation, providing durations of delivery ranging from months to years. A practical consequence is that the testing period for an implanted device is extended appreciably.

Finally, though the approach described in this section has been primarily macroscopic and phenomenological, microscopic models and calculations of transport based on them have provided additional detail about the molecular features of ocular drug transport. For example, it is generally believed that lipophilic drugs permeate the corneal epithelium by transcellular transport, whereas more hydrophilic drugs permeate the corneal epithelium by paracellular transport. A model of these different mechanisms has indicated that the transcellular transport probably is along the lipophilic bilayers of the cell outer membranes, whereas the paracellular transport is probably along

**Figure 28-4.** Ocular geometry used for computational fluid dynamic simulation of clearance of intravitreally injected substances. All tissue regions are treated as porous media except for the aqueous humor, which is treated as a simple liquid. The small gap between the ciliary body represents the Canal of Petit, a feature which becomes important for accurate simulation of the clearance of slowly diffusing materials. Aqueous fluid is produced at a rate of 3  $\mu\text{L}$  / minute on the blue boundary of the iris as shown. Most of the fluid is eliminated on the outflow boundary behind the trabecular meshwork, simulating conventional outflow. A small amount of the fluid percolates throughout the remaining ocular structure. (From Missel PJ *et al.* Simulating dissolution of intravitreal triamcinolone acetonide suspensions in an anatomically accurate rabbit eye model. *Pharm Res* 2010; 27: 1530–1546.)

the extracellular space, the “pores” of a macroscopic model.<sup>24</sup> These models provide insight into mechanisms of transport and how these may be manipulated to improve drug delivery while maintaining safety.

### TYPES OF OPHTHALMIC DOSAGE FORMS

Ophthalmic products include prescription and over-the-counter (OTC) drugs, products for the care of contact lenses, and products used in conjunction with ocular surgery. This section will focus on the pharmaceutical aspects of the various ophthalmic dosage forms encompassed by these types of products. The therapeutic uses of individual products can be found in several reference books along with the individual product’s labeling.<sup>33,34</sup>

### OPHTHALMIC SOLUTIONS

These are by far the most common dosage forms for delivering drugs to the eye. By definition, ingredients are completely soluble such that dose uniformity is not an issue, and there is little physical interference with vision. The principal disadvantage of solutions is their relatively brief contact time with the

**Figure 28-5.** Computational fluid dynamic simulation results in the model for the rabbit eye. (a) Pressure distribution within a normotensive eye (Torr). (b) Velocity, clipped to a maximum value of  $10^{-8}$  m/s to illustrate contours in the vitreous. (c) Dissolved triamcinolone acetonide concentration (grams/mL) after the dissolution process has achieved steady state for a suspension of 16 mg triamcinolone acetonide divided into 276 particles confined to a 100 microliter intravitreal depot. (From Missel PJ *et al.* Simulating dissolution of intravitreal triamcinolone acetonide suspensions in an anatomically accurate rabbit eye model. *Pharm Res* 2010; 27: 1530–1546.)

drug and the absorbing tissues of the external eye. Contact time can be increased by the inclusion of viscosity-imparting agents; however, their use is limited to relatively low viscosities so as to allow dispensing of the eyedrop from the container or eyedropper and to minimize excessive blurring of vision. A residue can be produced on the eyelashes and around the eye when any excess of a viscous solution spills out of the eye and dries. The residue usually can be removed easily by careful wiping with a moist towel to the closed eye.

### GEL-FORMING SOLUTIONS

Ophthalmic solutions (usually water-based), which contain a polymer system that is a low-viscosity liquid in the container

but gels on contact with the tear fluid, have increased contact time and can provide increased drug absorption and prolonged duration of therapeutic effect. The liquid-to-gel phase transition can be triggered by a change in temperature, pH, ionic strength, or presence of tear proteins, depending on the particular polymer system employed. Timolol maleate gel-forming solutions formulated with specific patented gellan or xanthan gums have clinically demonstrated prolonged duration of IOP lowering, such that their dosing frequency can be reduced from twice to once a day.<sup>35,36</sup> Review the labeling for commercial gel-forming solutions before dispensing for current instructions related to patient administration.

### POWDERS FOR SOLUTIONS

Drugs that have very limited stability in aqueous solution can sometimes be prepared as sterile powders for reconstitution by the pharmacist before dispensing to the patient. The sterile powder should be aseptically reconstituted with the accompanying sterile diluent that has been optimized for dissolution, preservation, and stability. The pharmacist must convey to the patient any special storage instructions, including the expiration date.

### OPHTHALMIC SUSPENSIONS

Suspensions are dispersions of finely divided, relatively insoluble drug substances in an aqueous vehicle containing suitable suspending and dispersing agents. The vehicle is, among other things, a saturated solution of the drug substance. Because of a tendency of particles to be retained in the cul-de-sac, the contact time and duration of action of a suspension could theoretically exceed that of a solution. The drug is absorbed from solution, and the solution concentration is replenished from retained particles. Each of these actions is a function of particle size, with solubility rate being favored by smaller size and retention favored by a larger size; thus, optimum activity should result from an optimum particle size.

For aqueous suspensions the parameters of intrinsic solubility and dissolution rate must be considered. The intrinsic solubility determines the amount of drug actually in solution and available for immediate absorption upon instillation of the dose. As the intrinsic solubility of the drug increases, the concentration of the drug in the saturated solution surrounding the suspended drug particle also increases. For this reason, any comparison of different drugs in suspension systems should include their relative intrinsic solubilities. The observed differences in their biological activities may be ascribed wholly or in part to the differences in this physical parameter. As the drug penetrates the cornea and the initial saturated solution becomes depleted, the particles must dissolve to provide a further supply of the drug. The requirement here is that the particles must undergo significant dissolution within the residence time of the dose in the eye if any benefit is to be gained from their presence in the dosing system.

For a drug whose dissolution rate is rapid, the dissolution requirement may present few problems, but for a slowly soluble substance the dissolution rate becomes critical. If the dissolution rate is not sufficiently rapid to supply significant additional dissolved drug, there is the possibility that the slowly soluble substance in suspension provides no more drug to the aqueous humor than does a more dilute suspension or a saturated solution of the substance in a similar vehicle. Obviously, the particle size of the suspended drug affects the surface area available for dissolution. Particle size also plays an important part in the irritation potential of the dosing system. This consideration is important, because irritation produces excessive tearing and rapid drainage of the instilled dose, as discussed earlier. It has been recommended that particles be smaller than 10 microns to minimize irritation to the eye. It should be kept in mind, however, that in any suspension system the effects of prolonged storage and changes in storage temperature might cause the smallest particles to dissolve and the largest particles to become larger.

The pharmacist should be aware of two potential difficulties inherent in suspension dosage forms. In the first instance, dosage uniformity nearly always requires brisk shaking to distribute the suspended drug. Adequate shaking is a function not only of the suitability of the suspension formulation but also—and most importantly—patient compliance. Studies have demonstrated that a significant number of patients may not shake the container at all; others may contribute a few trivial shakes. The pharmacist should use a “Shake Well” label and counsel the patient whenever an ophthalmic suspension is dispensed. An improved ophthalmic suspension has been developed for insoluble drugs such as steroids, which tend to cake upon settling.<sup>37</sup> The improved suspension controls the flocculation of the drug particles such that they remain substantially resuspended for months and provides for easy resuspension of any settled particles. Nonetheless, the pharmacist also should be aware of the possibility of crystal growth over time. This potential stability problem is especially problematic for drug substances whose solubility is significantly dependent on temperature. The majority of suspension products have a “Do Not Freeze” warning on the label, because they are likely to agglomerate on freezing and will not be resuspended by simple shaking.

A second and infrequently occurring characteristic of suspensions is the phenomenon of polymorphism, or the ability of a substance to exist in several different crystalline forms. A change in crystal structure may occur during storage, resulting in an increase (or decrease) in crystal size and alteration in the suspension characteristics, causing solubility changes reflected in increased or decreased bioavailability. Manufacturers of commercial suspensions take these possibilities into account in the development and testing of the final formulation and the labeled storage conditions.

In some cases a water-soluble drug has been converted to an insoluble form and formulated as a suspension to improve the drug's stability, compatibility, bioavailability, or patient tolerance. The insoluble forms of steroids such as prednisolone and dexamethasone have better ocular bioavailability and are considered more potent anti-inflammatories for topical ocular use. A resin-bound form of the  $\beta$ -blocker betaxolol has been formulated as a suspension and is prepared *in situ* using a carbomer polymer.<sup>38</sup> The novel suspension formulation improves both comfort and ocular bioavailability of betaxolol, the 0.25 percent suspension therapeutically equivalent to a 0.5 percent solution.

## OPHTHALMIC OINTMENTS

Ophthalmic ointments are primarily anhydrous and contain mineral oil and white petrolatum as the base ingredients, the proportions of which can be varied to adjust consistency and the melting temperature. Dosage variability probably is greater than with solutions (though probably no greater than that with suspensions). Ointments will interfere with vision, and their use is usually limited to bedtime instillation. They remain popular as a pediatric dosage form and for postoperative use. The anhydrous nature of the base enables its use as a carrier for moisture-sensitive drugs. The petrolatum base can be made more miscible with aqueous components by the addition of liquid lanolins.

Ointments do offer the advantage of longer contact time and greater total drug bioavailability, albeit with slower onset and time to peak absorption. The relationship describing the availability of finely divided solids dispersed in an ointment base was given by Higuchi,<sup>39</sup> where the amount of solid (drug) released in unit time is a function of concentration, solubility in the ointment base, and diffusivity of the drug in the base.

## OPHTHALMIC EMULSIONS

An emulsion dosage form offers the advantage of the ability to deliver a poorly water-soluble drug in a solubilized form as an eyedrop. The drug is dissolved in a nonaqueous vehicle, such as castor oil, and emulsified with water, using a nonionic surfactant and, if needed, an emulsion stabilizer. An emulsion with

water as the external phase can be less irritating and better tolerated by the patient than use of a purely nonaqueous vehicle. Such an emulsion is used to deliver cyclosporine topically for the treatment of chronic dry eye conditions.<sup>40</sup>

## OPHTHALMIC GELS

Gel-forming polymers, such as carbomer, have been used to develop aqueous, semisolid dosage forms, which are packaged and administered the same as ointments. The viscous gels have significantly increased topical residence time and can increase drug bioavailability and decrease dosage frequency, compared to solutions. Although they contain a large proportion of water, they can still cause blurring of vision. A carbomer gel of pilocarpine administered at bedtime has been shown to prolong the IOP-lowering effect in patients for up to 24 hours.<sup>41</sup>

## OCULAR INSERTS

Ocular inserts have been developed in which the drug is delivered on the basis of diffusional mechanisms. Such a solid dosage form delivers an ophthalmic drug at a near-constant known rate, minimizing side effects by avoiding excessive absorption peaks. The delivery of pilocarpine by such an insert was commercialized in 1975 (Ocuser Pilo) by *Alsa Corporation*. The Ocuser is designed to be placed in the lower cul-de-sac to provide a weekly dose of pilocarpine, at which time the system is removed and replaced by a new one. The near zero-order rate delivery is based on the selection of a non-eroding co-polymer membrane enclosing the drug reservoir.<sup>42</sup>

Ocular inserts are plagued with some of the same manipulative disadvantages as conventional eyedrops. The insert must be placed in the eye in a manner similar to the insertion of a contact lens. Additionally, the insert must be removed from the eye when exhausted of its drug content. Such manipulations can be difficult for the elderly patient. Nonetheless, such therapeutic inserts represent a notable commercialized scientific achievement in pharmaceutical sciences. The Ocuser Pilo product is no longer marketed, because the drug has largely been replaced in glaucoma therapy by topical  $\beta$ -blockers.

Ocular inserts that gradually erode in the tear fluid have been studied but not commercially developed as ocular drug delivery systems.<sup>43</sup> In theory, an erodible insert would be advantageous, because it would not require removal at the end of its therapeutic cycle, would provide precise unit dosing, and, if anhydrous, would not require a preservative. It may also increase ocular bioavailability and reduce the therapeutic dosage and possible systemic effects. The chief disadvantages may be related to patient use issues, control of erosion and drug release rates, and sterilization.

An erodible insert is available (LACRISERT) for treatment of dry eye. It is molded in the shape of a rod from a hydroxypropyl cellulose polymer, which is the active ingredient. When inserted into the lower cul-de-sac, the polymer imbibes tear fluid and forms a gel-like mass that gradually erodes while thickening the tear film over a period of several hours. The unit-dose insert is anhydrous, and no preservative is required, which is beneficial for some sensitive patients.

## DRUG ADMINISTRATION

### TOPICAL ADMINISTRATION

The instillation of eyedrops remains one of the less precise, yet more accepted means of topical drug delivery. The method of administration is cumbersome at best, particularly for the elderly, patients with poor vision who have difficulty seeing without eyeglasses, and patients with other physical handicaps. Perhaps surprisingly, most patients become quite adept at routine instillation.

The pharmacist should advise each patient to keep the following points in mind to aid in the instillation of eyedrops or ointments.

## METHODS OF USE FOR TOPICAL ADMINISTRATION

### HOW TO USE EYEDROPS

1. Wash hands.
2. With one hand, gently pull lower eyelid down.
3. If dropper is separate, squeeze rubber bulb once while dropper is in bottle to bring liquid into dropper.
4. Holding dropper above eye, drop medicine inside lower lid while looking up; do not touch dropper to eye or fingers.
5. Release lower lid. Try to keep eye open and not blink for at least 30 seconds.
6. If dropper is separate, replace on bottle and tighten cap.

### PRECAUTIONS WHEN USING EYEDROPS

- If dropper is separate, always hold it with the tip down.
- Never touch dropper to any surface.
- Never rinse dropper.
- When dropper is at top of bottle, avoid contaminating cap when removed.
- When dropper is a permanent fixture on the bottle (i.e., when supplied by a pharmaceutical manufacturer to the pharmacist), the same rules apply to avoid contamination.
- Never use eyedrops that have changed color.
- If you are using more than one kind of drop at the same time, wait several minutes before using other drops.
- After instillation of drops, do not close eyes tightly and try not to blink more often than usual, as this removes the medicine from the place on the eye where it will be effective.

### HOW TO USE OPHTHALMIC OINTMENTS/GELS

1. Wash hands.
2. Remove cap from tube.
3. With one hand, gently pull lower eyelid down.
4. While looking up, squeeze a small amount of ointment (about ¼ to ½ inch) inside lower lid. Be careful not to touch tip of tube to eye, eyelid, fingers, etc.
5. Close eye gently and roll eyeball in all directions while eye is closed. Temporary blurring may occur.
6. The closed eyelid may be rubbed very gently by a finger to distribute the drug throughout the fornix.
7. Replace cap on tube.

### PRECAUTIONS WHEN USING OPHTHALMIC OINTMENTS/GELS

- Take care to avoid contaminating cap when removed.
- When opening ointment tube for the first time, squeeze out the first 1/4 inch of ointment and discard, as it may be too dry.
- It may be helpful to practice ointment use by positioning yourself in front of a mirror.
- Never touch tip of tube to any surface.
- If you have more than one tube of the same ointment, open only one at a time.
- If you are using more than one kind of ointment at the same time, wait about 10 minutes before using another ointment.
- To improve flow of ointment, hold tube in hand several minutes to warm before use.

### NASALACRIMAL OCCLUSION

To limit absorption of topically applied drugs directly into the bloodstream from the highly vascular areas of the nasal cavity, the patient should be instructed to close the eye immediately after eyedrop instillation, place a finger between the eyeball and the nose, and apply pressure for several minutes. This will temporarily occlude both superior and inferior canaliculi, preventing nasolacrimal drainage.

## INTRAOCULAR PREPARATIONS

Ophthalmic products introduced into the anterior chamber or vitreous chamber of the internal eye structure are specialized dosage forms, requiring additional pharmaceutical considerations in their formulation, packaging, and manufacture. They are essentially parenteral-type products requiring both sterility and nonpyrogenicity as well as strict control of particulate matter, to ensure that they are compatible with sensitive internal tissues critical to visual acuity. In some cases in which the product may be introduced into the sterile field during surgery, sterility of the exterior of the primary package is required. Because preservatives commonly used in topical ophthalmic products can be toxic to sensitive intraocular tissues, such as the corneal endothelium, intraocular products are designed and packaged as preservative-free single-use products.

Present technologies are summarized in the next subsections, but many novel technologies can be expected in the next several years with the advent of new therapeutics and approaches to delivery for such devastating diseases as AMD, diabetic retinopathy, and cystoid macular edema, diseases of the back of the eye.

### IRRIGATING SOLUTIONS

During ocular surgery an irrigating solution is used to maintain hydration, ocular volume, and clarity of the cornea, providing the surgeon a clear view of the surgical field. The irrigating solution also provides a physiological medium for removing blood and cellular debris, and for replacing the natural aqueous intraocular fluid. A balanced salt solution (BSS) is the primary intraocular irrigating solution, which includes the key ionic components to maintain corneal endothelial integrity: sodium, potassium, calcium, magnesium, and chloride, as well as a neutral to slightly alkaline pH and osmolality of about 305 mOsm.<sup>44</sup> An enriched balanced salt solution (BSS Plus) is also available to provide enhanced physiological compatibility when required in an irrigating solution. The enriched solution contains oxidized glutathione, dextrose, and bicarbonate in addition to the critical ionic components.<sup>45</sup> The additional ingredients in the enriched solution require, for maximum shelf-life stability, that the product be packaged in a two-part system to be aseptically reconstituted just before use. Intraocular solutions do not contain a preservative and should be discarded after initial use. These irrigating solutions are also designed to be used without additional additives, because there is potential for intraocular toxicity. An acidic epinephrine injection containing sodium bisulfite antioxidant, when added to an intraocular irrigating solution and diluted as much as 500-fold, has been reported to produce intraocular toxicity.<sup>46</sup>

### INTRAOCULAR INJECTIONS

Products approved for direct injection into the eye include miotics and viscoelastics for ocular surgery, and two antiviral agents to treat cytomegalovirus retinitis. The miotics carbachol and acetylcholine are used at the end of cataract surgery to constrict the pupil, allowing the iris to cover the implanted intraocular lens. Both products are specially packaged such that the exterior of the primary vial is sterile. This is accomplished by use of a special outer container that is permeable to sterilant gas and prevents contamination of the exterior of the vial.

Solutions with viscoelastic properties are injected into the eye during surgery to provide a mechanical barrier between tissues and allow the eye surgeon more space for manipulation with less potential for trauma to very sensitive intraocular tissues. The primary viscoelastic substance is a highly purified fraction of sodium hyaluronate. Purification is required to remove foreign proteins to be non-antigenic and noninflammatory for intraocular use. The viscoelasticity can be varied by use of fractions and concentrations of different molecular weights. Chondroitin sulfate and purified hydroxypropyl

methylcellulose are also utilized as viscoelastic and viscoadherent surgical adjuncts. The viscoelastic products are packaged and sterilized such that the primary package can be placed in the sterile surgical field before use. Sodium hyaluronate viscoelastic products usually require refrigeration during storage to maintain their integrity.

### INTRAVITREAL INJECTIONS/IMPLANTS

Two antivirals have been approved for treatment of the ocular sequelae of AIDS with direct emplacement in the vitreous cavity so as to provide high localized ocular therapeutic concentrations. A polymer-coated sterile tablet containing ganciclovir, called a Vitrasert,<sup>47</sup> is implanted by the surgeon in the vitreous cavity, where it releases drug over a period of several months and then is removed and replaced with a new tablet. The tablet is formulated with magnesium stearate as the drug carrier and coated with polymers that provide the prolonged drug release. It is important that, during handling, this polymer coating is not damaged and the special sterile packaging not be compromised. A sterile solution of fomivirsen is also available for intravitreal injection to treat cytomegalovirus retinitis. It is supplied in single-use vials and is injected intravitreally without requiring surgery but must be repeated every 2 to 4 weeks.

### JXTASCLERAL INJECTIONS

Certain disease conditions in the back of the eye are usually untreatable through topical administration to the eye. For example, cystoid macular edema (associated with trauma, chronic inflammation, and diabetes) results in swelling of the macula and, if left untreated, loss of vision. At present there is no effective treatment available for AMD, whose incidence and severity increase with age, resulting in progression from accumulation of proteins and glycosaminoglycans (drusen) to leakage of blood vessels (hemorrhage) and eventual blindness. For such conditions, localized intravitreal or juxtasceral injections may be preferable to systemic administration of drugs (either alone or accompanied by laser-initiated events, such as photodynamic therapy).

### OTHER MODES OF ADMINISTRATION

#### Packs

These sometimes are used to give prolonged contact of a drug solution with the eye to maximize absorption. Sterile cotton pledgets, placed in the lower cul-de-sac, have been used in this manner, but more recently corneal shields and soft contact lenses, developed as bandages, have been utilized to protect the cornea during healing.<sup>48</sup> Corneal shields are made of collagen that is crosslinked to control the rate of erosion, usually 12 to 72 hours. Hydrophilic polymers used for soft contact lenses without vision correction have also been utilized as a drug reservoir. The soft lenses remain intact and therefore require removal.

### INTRACAMERAL INJECTIONS

Injections may be directly into the anterior chamber (e.g., acetylcholine chloride, alpha-chymotrypsin, carbamylcholine chloride, certain antibiotics, and steroids) or directly into the vitreous chamber (e.g., amphotericin B, gentamicin sulfate, and certain steroids).

### IONTOPHORESIS

This procedure keeps the solution in contact with the cornea by means of an eyecup bearing an electrode. An ionic drug thus is subjected to a current generated by a difference in electrical potential, which acts as an electrochemical driving force to transport the drug in the direction of the potential gradient.<sup>49</sup>

**Figure 28-6.** The locations for administration and target of therapy. Ointment: regions 1–5. Drops: regions 3–5. Parenteral injections—subconjunctival: regions 5–6, deep subtenons: regions 6–8, retrobulbar: region 8.

### SUBCONJUNCTIVAL INJECTIONS

Subconjunctival injections (Figure 28-6)<sup>50</sup> are used frequently to introduce medications that, if applied topically, either do not penetrate into the anterior segment or penetrate too slowly to attain the concentration required. The drug is injected underneath the conjunctiva and probably passes through the sclera and into the eye by simple diffusion. The most common use of subconjunctival injection is for the administration of antibiotics in infections of the anterior segment of the eye. Subconjunctival injections of mydriatics and cycloplegics also are used to achieve maximal pupillary dilation or relaxation of the ciliary muscle. If the drug is injected underneath the conjunctiva and the underlying Tenon capsule in the more posterior portion of the eye, effects on the ciliary body, choroid, and retina can be obtained.

### RETROBULBAR INJECTIONS

Drugs administered by retrobulbar injection (Figure 28-6) may enter the globe in essentially the same manner as the medications given subconjunctivally. The orbit is not well vascularized, and the possibility of significant removal via bloodstream effects from these injections is remote. In general, such injections are given for the purpose of targeting medications (e.g., antibiotics, local anesthetics, enzymes with local anesthetics, steroids, and vasodilators) to the posterior segment of the globe and affecting the nerves and other structures in that space for a sustained period of time.

### PREPARATION

#### COMMERICAL MANUFACTURE

Pharmaceutical manufacturers provide finished ophthalmic products, manufactured and tested for quality according to stringent industrial and governmental standards. The products' sterility and, where required, their nonpyrogenicity, as well as other important quality standards, are assured by end-product testing of each batch and also by the use of validated manufacturing processes developed for each individual product. The products' manufacturing and quality control are governed largely by the current Good Manufacturing Practice (GMP) regulations<sup>51</sup> promulgated and enforced by the FDA. If the product is a new or generic drug or medical device and has received FDA marketing approval, the manufacturer must also meet the requirements specified in the approved application for chemistry, microbiology, manufacturing, and quality control. Significant changes to the approved requirements must be submitted and approved by the FDA. For products not requiring prior FDA approval to market, such as monographed OTC drug products,<sup>52</sup> the manufacturer must meet the quality standards of applicable

USP or NF compendial monographs in addition to the current GMP regulations.

The manufacturer is subject to pre-approval inspections and periodic GMP postapproval inspections by the FDA. The FDA also conducts inspections of the suppliers of active ingredients, both foreign and domestic, and certain inactive ingredients and packaging operations. The manufacture is subject to recalls of batches of product that do not meet quality requirements. In some cases a recall may result, not from actual failed test results, but from a lack of assurance that the product will continue to meet quality requirements through its shelf-life.

## PHARMACY COMPOUNDING

Compounding of individual patient prescriptions by pharmacists has been and continues in some areas to be an integral part of pharmacy practice. The routine need to compound sterile ophthalmic products is no longer required with the broad range of commercially manufactured products available today. Most of the new and generic prescription ophthalmic products marketed today have been subjected to the FDA's rigorous requirements for proof of safety and efficacy or bioequivalence, as well as the manufacturing and quality requirements already described.

If the pharmacist is asked to compound a prescription for a noncommercial product, such as a preservative-free version or pediatric strength, he or she should be well versed in the preparation of sterile products, have the proper equipment and facilities, and be knowledgeable about the special requirements for ophthalmic formulations and packaging. Reference information on the standards and technology for pharmacy compounding, with special emphasis on preparation of sterile products, should be consulted.<sup>53,54</sup> The pharmacist must also consult the rules and regulations of the applicable state board of pharmacy concerning sterile pharmacy compounding as well as any federal regulatory requirements promulgated by the FDA. Congress included in the 1997 FDA Modernization Act certain legal conditions for which compounding, as defined in the Act, would be exempt from FDA regulation. The pharmacy compounding section of the Act was subsequently litigated and overturned in its entirety, because it contained unconstitutional restrictions on commercial speech. The FDA may seek new legislation to address its concerns regarding manufacturing in the guise of compounding. In the meantime, the FDA has issued a guidance document on how the agency intends to regulate pharmacy compounding of human drugs considered to be outside the bounds of traditional pharmacy practice and in violation of the US Food, Drug, and Cosmetic Act of 1938 (FDCA; [www.fda.gov/cder/pharmcomp](http://www.fda.gov/cder/pharmcomp)), and has provided a Pharmacy Compounding Compliance Policy Guide (2002).

## STERILIZATION

Common methods of sterilization include moist heat under pressure (autoclave), dry heat, filtration, gas sterilization, and ionizing radiation. Please refer to Chapter 25, where these sterilization procedures are described in detail.

## DANGERS OF NONSTERILE MEDICATIONS

The possibility of serious ocular infection resulting from the use of contaminated ophthalmic solutions has been documented amply in the literature. Such solutions have repeatedly been the cause of corneal ulcers and even loss of eyesight. Contaminated solutions have been found to be in use in physicians' offices, eye clinics, and industrial infirmaries, and have been dispensed on prescription in community and hospital pharmacies. The microbes most frequently found as contaminants are staphylococci group. *Pseudomonas aeruginosa* is a less common contaminant, and the solution most often found contaminated is sodium fluorescein.

*Ps. aeruginosa* (*Bacillus pyocyaneus*; *Pseudomonas pyocyanea*; blue pus bacillus) is a very dangerous and opportunistic organism that grows well on most culture media and produces both toxins and antibacterial products. The latter tend to kill off other contaminants and allow the *Ps. aeruginosa* to grow in pure culture. This Gram-negative bacillus also grows readily in ophthalmic solutions, which may become the source of extremely serious infections of the cornea. It can cause complete loss of sight in 24 to 48 hours. At concentrations tolerated by tissues of the eye, most of the antimicrobial agents discussed in the following sections may be ineffective against some strains of *Ps. aeruginosa*.

A sterile ophthalmic solution in a multiple-dose container can be contaminated in a number of ways unless precautions are taken. For example, if a dropper bottle is used, the tip of the dropper while out of the bottle can touch the surface of a table or shelf if laid down, or it can touch the eyelid or eyelash of the patient during administration. If the Drop-Tainer (Alcon) type of bottle is used, the dropper tip can touch an eyelash or the cap while removed to permit administration, or its edge may touch a table or finger, and that edge can touch the dropper tip as the cap is replaced.

The solution may contain an effective antimicrobial, but the next use of the contaminated solution may occur before enough time has elapsed for all of the organisms to be killed, and living organisms can find their way through an abrasion into the corneal stroma. Once in the corneal stroma, any residual traces of antimicrobial agents are neutralized by tissue components, and the organisms find an excellent culture medium for rapid growth and dissemination through the cornea and the anterior segment of the eye.

## OTHER ORGANISMS

*Bacillus subtilis* may produce a serious abscess when it infects the vitreous humor. The pathogenic fungus considered of particular importance in eye solutions is *Aspergillus fumigatus*. Other fungi or molds may cause harm by accelerating deterioration of the active drugs.

With regard to viruses, as many as 42 cases of epidemic keratoconjunctivitis were caused by one bottle of virus-contaminated tetracaine solution. Virus contamination is particularly difficult to control, because none of the preservatives now available is virucidal. Moreover, viruses are not removable by filtration. However, they are destroyed by autoclaving. The pharmacist and physician have not been made adequately aware of the dangers of transmitting viral infection via contaminated solutions. This is particularly pertinent to the adenoviruses (types III and VIII), now believed to be the causative agents of viral conjunctivitis, such as epidemic keratoconjunctivitis.

The danger of nonsterile preparations is exponentially increased for products intended for injection within the eyeball. Endophthalmitis and loss of vision can occur within a short time of onset of a bacterial infection.

## METHODS

### Steam Under Pressure

Terminal sterilization by autoclaving is an acceptable, effective method of sterilization; however, the solution or suspension components must be sufficiently heat-resistant to survive the procedure. If sterilization is carried out in the final container, the container also must be able to withstand heat and pressure. A recent addition to this technique is the so-called air-over-steam autoclave. This combination allows pressure adjustments to be made during the autoclave cycle. Pressure manipulations permit the autoclave sterilization of materials that, while heat-resistant, tend to deform (i.e., polypropylene containers). The sterilization cycle for a product should be carefully validated, and one must assure that sterilization temperature and time are monitored at the coldest spot of the autoclave load to assure sterility of the product.

## Filtration

The USP states that sterile membrane filtration under aseptic conditions is the preferred method of sterilization. Membrane filtration offers the substantial advantage of room-temperature operation with none of the deleterious effects of exposure to heat or sterilizing gas.

Sterilization by filtration does involve the transfer of the finished sterile product into previously sterilized containers, using aseptic techniques. The membrane filtration equipment itself usually is sterilized as an assembly by autoclaving.

Several types of membrane filtration equipment are available for small-scale processing, as described in Chapter 25.<sup>54</sup> Particular interest has been shown in the Swinney adapter, fitted on a syringe, and in the *Millipore* Swinnex disposable filter units. Empty sterile plastic *squeeze* containers and sterile plastic filtration units can be purchased directly from the manufacturers, including Wheaton (polyethylene containers) and *Millipore* (Swinnex filter units). They permit extemporaneous preparation of ophthalmic solutions, which have a high probability of being sterile if the work is carried out under aseptic conditions. A supplementary device can permit automatic refilling of the syringe. The filter unit must be replaced after use. To avoid contamination, the pharmacist should fill sterile filtered solutions into presterilized containers closed with appropriate fitments and closed under laminar flow, using aseptic techniques. The Parenteral Drug Association has produced several audiovisual teaching materials for aseptic techniques and processing. The reader should refer to these guidelines for reference.

## Gas

Gas sterilization of heat-sensitive materials may be carried out by exposure to ethylene oxide (EtO) gas in the presence of moisture. EtO gas for sterilization use is available commercially, diluted with either carbon dioxide or halogenated hydrocarbons. EtO sterilization requires careful consideration of conditions required to effect sterility. Temperature and pressure conditions are quite nominal in contrast to wet or dry heat; however, careful control of exposure time, EtO concentration, and moisture is essential.

Gas sterilization requires that specialized, but not necessarily elaborate, equipment be used. Gas autoclaves may range from very large walk-in units to small units on the scale of a laboratory bench that are suitable for small hospitals, laboratories, or pharmacies. Users of gas autoclaves must keep in mind the possibility of human toxicity and take care to restrict exposure to EtO during the loading, venting, and unloading of the sterilizer. EtO sterilization produces irritating by-products that remain as residues in or on the articles sterilized. Residues include ethylene glycol and ethylene chlorohydrin (when in contact with chloride ions), in addition to EtO itself. Aeration of the sterilized articles for at least 72 hours, preferably at 40°C to 50°C, will minimize such residues.

Ambient aeration time for sterilized polyethylene bottles should be about 48 hours. EtO is recommended for the sterilization of solid materials that will not withstand heat sterilization. The FDA has recommended maximum residues in the parts-per-million range for EtO, ethylene glycol, and ethylene chlorohydrin.

Extreme caution is necessary when using EtO gas sterilization. The previously accepted 12:88 mixture of EtO to Freon has been replaced with 100 percent EtO for environmental reasons. This gas is explosive, and all workers also should be protected from accidental exposure because of concern for carcinogenicity and other toxic reactions to EtO. This method at present is used as a last resort when no other methods can be used.

## Radiation

Sterilization by exposure to ionizing radiation is an acceptable procedure for components of ophthalmic preparations or,

indeed, for the total product, such as certain ophthalmic ointments. Sources of radiation are twofold and include linear electron accelerators and radioisotopes. The linear accelerators produce high-energy electrons with very little penetrating power. Radioisotopes, particularly <sup>60</sup>Co (a source for gamma irradiation), are employed more widely than linear electron accelerators for sterilization. Sterilization by radiation may produce untoward effects, such as chemical changes in product components as well as changes in color or physical characteristics of package components. Gamma sterilization is currently the method used in place of EtO for sterilizing most of the packaging components. Gamma sterilization of containers may alter the surface characteristics, and this can increase degradation of drug molecules and/or some of the excipients used in the formulation. Some plastic manufacturers have developed special grades of polypropylene resin that are stabilized to withstand gamma irradiation.

## OPHTHALMIC PREPARATION CHARACTERISTICS

### CLARITY

Ophthalmic solutions, by definition, contain no undissolved ingredients and are essentially free from foreign particles. Filtration can enhance clarity in some cases. It is essential that the filtration equipment be clean and well rinsed to avoid introduction of particulate matter into the solution by equipment designed to remove it. Operations performed in clean surroundings, the use of laminar-flow hoods, and proper nonshedding garments will contribute collectively to the preparation of clear solutions essentially free from foreign particles. In many instances the same filtration step can produce both clarity and sterility. If viscosity-imparting polymers are used, a polish-filtration step may be necessary before the final filtration.

Both container and closure must be thoroughly clean, sterile, and non-shedding, so that neither one introduces particulate matter to the solution during prolonged contact for the duration of the shelf-life. Normally this is established by thorough stability testing, which also will indicate whether insoluble particles (by-products of drug degradation) have been generated. Solution formulations may also contain viscosity-imparting polymers that can diminish clarity. In these situations it may be important to both define the visual clarity of the product and monitor its stability. The *European Pharmacopoeia* describes visual clarity and recommends standards that can be used for clarity specifications.<sup>3</sup>

### STABILITY

The stability of a drug in an ophthalmic product depends on a number of factors, including the chemical nature of the drug substance, whether it is in solution or suspension, product pH, method of preparation (particularly temperature exposure), solution additives, and type of packaging. A pharmaceutical manufacturer strives for a shelf-life measured in years at controlled room-temperature conditions, whereas the compounding pharmacist often is uncertain about the shelf-life of his or her preparation and thus provides relatively small quantities at one time, assigns a shelf-life in terms of days or weeks, and may specify refrigerated storage as a further precaution. The attainment of optimum stability often requires some compromises in the formulation, packaging, and preparation of the final product.

The product's pH is often the stability-controlling factor for many drugs. Drugs such as pilocarpine and physostigmine are both active and comfortable in the eye at a pH of 6.8; however, at this pH, chemical stability (or instability) can be measured in days or months. Either drug will lose a substantial amount of chemical stability in less than a year. On the other hand, at a pH of 5.0, both drugs are stable for a period of several years. (With regard to eye comfort at acidic pH, see the later discussion under Buffer and pH.)

In addition to optimal pH, if oxygen sensitivity is a factor, adequate stability may require inclusion of an antioxidant or special packaging. Plastic packaging, such as the low-density polyethylene containers (e.g., the DropTainer from Alcon) that are convenient for patient use, may prove detrimental to stability by permitting oxygen permeation, resulting in oxidative decomposition of the drug substance. Development of an epinephrine solution with 2 to 3 years' stability in a plastic package requires the use of a pH of about 3.0 for protection from oxidation, whereas an epinephrine borate solution formulated at a pH of about 7.0, which is more comfortable to the patient, requires an antioxidant system and the use of glass packaging. The prodrug of epinephrine, dipivefrin, significantly increases ocular bioavailability and is effective at one-tenth the concentration of epinephrine. The structure of the chemical derivative protects the active epinephrine portion from oxidation, so that it can be packaged in plastic. However, the labile ester linkage introduced in the prodrug requires that it be formulated at a pH of about 3.0 to minimize hydrolysis; even with this precaution, the shelf-life of dipivefrin stored at room temperature can be extended to no longer than 18 months.

Pharmaceutical manufacturers conduct comprehensive stability programs to assure the assigned expiration dating for each product. In addition to monitoring the standard chemical and physical stability of the pharmaceutical, they test the stability of the preservative by chemical means or by actual challenge of its efficacy with appropriate test organisms. Sterility is not a stability parameter *per se*, but each container-closure system can be tested by microbial challenge to assure integrity of the package against environmental contamination before opening.

Some of the newer classes of ophthalmic drugs, like prostaglandins, are very hydrophobic and have very low concentrations. For example, in the product Xalatan, latanoprost is present at 0.005 percent, and in the product Travatan, travoprost is present at 0.004 percent. Active agents at such low concentrations present a challenge for formulators, because the loss of even small amounts of drug (e.g., from adsorption losses to packaging) can become significant. Pharmacia's Xalatan requires refrigerated storage, and as indicated earlier, temperature cycling also can reduce the concentration of active drug. It is important that the pharmacist knows the properties of the drug substance, in order to maintain product quality throughout the shelf-life of the product.

## BUFFER AND PH

Ideally, ophthalmic preparations should be formulated at a pH equivalent to the tear fluid value of 7.4. Practically, formulators seldom achieve this. Most active ingredients used in ophthalmology are salts of weak bases and are most stable at an acid pH. This property generally holds for suspensions of insoluble corticosteroids.

Optimum pH adjustment generally requires a compromise on the part of the formulator, who should select not only a pH that is optimal for stability but a buffer system that has adequate capacity to maintain pH within the stability range for the duration of the product shelf-life. Buffer capacity is the key in this situation.

It generally is accepted that a low (acid) pH *per se* necessarily will not cause stinging or discomfort on instillation. If the overall pH of the tears, after instillation, reverts rapidly to pH 7.4, discomfort is minimal. On the other hand, if the buffer capacity is sufficient to resist adjustment by tear fluid and the overall eye pH remains acid for an appreciable period of time, then stinging and discomfort may result. Consequently, buffer capacity should be adequate for stability but minimized, so far as possible, to allow only momentary disruption of the overall pH of the tear fluid. Special care in formulating intraocular products is required regarding their pH and buffer capacity. The corneal endothelium can tolerate much less deviation from physiological conditions, compared to the external corneal epithelium.<sup>55</sup>

## TONICITY

Tonicity refers to the osmotic pressure exerted by salts in aqueous solution. An ophthalmic solution is isotonic with another solution when the magnitudes of the colligative properties of the solutions are equal. An ophthalmic solution is considered isotonic when its tonicity is equal to that of a 0.9 percent sodium chloride solution (290 mOsm). However, the osmotic pressure of the aqueous intraocular fluid is slightly higher than that of normal tears, measuring about 305 mOsm.

In actuality the *external* eye is much more tolerant of tonicity variations than was at one time suggested and usually can tolerate solutions equivalent to a range of 0.5 to 1.8 percent sodium chloride. Given a choice, one will find that isotonicity is desirable and is particularly important in intraocular solutions.<sup>56</sup> However, in certain cases a nonisotonic topical product is desirable. Tear fluid in some cases of dry eye (keratoconjunctivitis sicca) is reported to be hypertonic, and a hypotonic artificial-tear product is used to counteract this condition. Hypertonic ophthalmic products are used to relieve corneal edema, and solutions and ointments containing 2 or 5 percent sodium chloride are available for this use.

The tonicity of ophthalmic (and parenteral) solutions has been the subject of intensive investigation over the years. These studies have resulted in the accumulation and publication of a large number of sodium chloride equivalents that are useful in calculating tonicity values. See Chapter 16 for a thorough discussion of the measurement and calculation of tonicity values.

## VISCOSITY

Ophthalmic solution and suspension eyedrops may contain viscosity-imparting polymers to thicken the tear film and increase corneal contact time (i.e., reduce the rate of tear fluid drainage). For suspensions, the increased viscosity also retards the settling of particles between uses and at the same time maintains their suspension for uniform dosing. However, added viscosity may impede initial resuspension, particularly in a suspension that has a tendency to cake during storage. The hydrophilic polymers most often used for these purposes are methylcellulose, hydroxypropyl methylcellulose, hydroxyethyl cellulose, and polyvinyl alcohol—at concentrations that produce viscosities in the range of about 5 to 100 Centipoise. These polymers also themselves appear as the active ingredients in artificial-tear solutions for dry eye therapy because of their lubrication and moisturizing. Viscosity agents can have several disadvantages, in that they sometimes produce blurring of vision and can leave a residue on the eyelids. These effects are most often seen at the higher end of the viscosity range. The added viscosity can make filtration more difficult, particularly for the small pore-size filters used to sterilize solutions.

Newer ophthalmic dosage forms, such as gel-forming solutions and semisolid aqueous gels with their increased viscosity and gel elasticity, significantly improve drug bioavailability and duration of effect. With these advances, the frequency of dosing can be reduced and patient compliance improved. These newer dosage forms incorporate novel polymer systems with special rheological properties to enhance their effect. Their complex rheology and intricate dependence on environment, however, increase the complexity of the sterile manufacturing process.

## ADDITIVES

Most ophthalmic dosage forms contain additives or pharmaceutical excipients as inactive ingredients. Because of the need for tissue compatibility in ophthalmics, particularly in intraocular products, however, the use of additives is perhaps less common.

The most common inactive ingredient is the product's vehicle. For topical dosage forms, Purified Water USP is used. Because of the requirement for nonpyrogenicity, Water for Injection USP is used for intraocular products. While a mineral oil and petrolatum combination is the vehicle used for ophthalmic

ointments, nonaqueous liquids are rarely used in topical eye-drops because of their potential for ocular irritation and poor patient tolerance. Some mineral and vegetable oils have served as vehicles for very moisture-sensitive or poorly water-soluble drugs. Use of the purest grade of oil, such as that used for parenteral products, is a requirement.

Multiple-dose topical ophthalmic products commonly contain microbiological preservatives, which will be discussed in a later section. Other commonly used additives in topical eye products are ingredients to adjust pH and tonicity, and to buffer pH, in addition to the viscosity agents previously discussed. Ingredients to adjust pH and tonicity and to buffer pH are essentially the same as those used in parenteral products. Less commonly used additives are antioxidants, such as sodium bisulfite, ascorbic acid, and acetylcysteine.

Topical eye products sometimes incorporate surfactants to disperse insoluble ingredients or to aid in solubilization. Formulators use them in the smallest concentration possible to achieve the desired function, because they can be irritating to sensitive ocular tissues. Nonionic surfactants are preferable, because they are generally less irritating than ionic surfactants. Polysorbate 80 is the surfactant used to prepare an ophthalmic emulsion. Polyoxyl 40 stearate and polyethylene glycol function to solubilize a drug in an anhydrous ointment so that it can be filter-sterilized. Formulators often add surfactants to stabilize more hydrophobic drugs, for example, preventing loss to adsorption on the container walls. For example, the nonionic surfactant like polyoxyl 40 hydrogenated castor oil (HCO-40) stabilizes travoprost, a prostaglandin derivative.<sup>57</sup> Similarly, Cremophore EL stabilizes diclofenac in the Voltaren formulation marketed by Novartis.

The FDA has published a list of all inactive ingredients used in approved drug products on its Internet website at [www.fda.gov/cder](http://www.fda.gov/cder). The list includes dosage forms and concentration ranges.

## PACKAGING

Currently, almost all commercially available ophthalmic products are packaged in plastic containers. Obvious advantages—ease of use, little breakage, less spillage—have led to universal acceptance of these plastic packaging components, consisting of bottle, fitment, and closure. Alcon was the first company to introduce these packaging components, identified as a DropTainer for ophthalmic products, in the late 1940s and then saw them adopted by the industry as the standard for packaging topical ophthalmic products. These bottles are generally of low-density polyethylene, either without any colorants or with opacifying agents or other colorants for light protection. Polypropylene or high-density polyethylene resins are also used to meet specific product requirements. The fitments determine drop size of the product and may contain additional features to prevent streaming of product at the time of use. Caps or closures are generally made from polypropylene and basically seal the container to prevent contamination or leakage of the product.

The FDA and other health authorities are also concerned about leachable impurities extracted either from the packaging components themselves or even occasionally from the label adhesives or ink used in printing the labels. Normally, as a part of a stability program, actual package-formulation compatibility studies are required, including monitoring any extractables that come out in the product as a function of the duration of storage. Selection of compatible packaging material has become a critical issue for newer drug products, especially those in which the concentration of active is extremely low, like prostaglandins, described earlier. The prostaglandin travoprost, the active ingredient in Travatan, required reengineering of the total packaging, starting with the resin (syndiotactic polypropylene) to stabilize the drug, as well as altering size and shape to maintain squeezability of the bottle.<sup>58</sup> Travoprost was found not to be stable when stored in low-density polyethylene containers, the compound being lost to adsorption onto and into surfaces,

even at room temperature. Consequently, chemical assay of marketed product must be conducted in a manner that does not deplete the concentration.

Specialized containers, like those developed by Merck for their timolol/pilocarpine combination product, maintain two solutions in different chambers, adjusted separately to provide optimal chemical stability. At the time of dispensing the product, fractions of both solutions are combined and reconstituted by the pharmacist. For example, the final timolol/pilocarpine product, once reconstituted, would be at a nearly physiological pH, would provide pilocarpine as stable for one month at room temperature, and will be found comfortable to patients. Alcon also has developed a proprietary package<sup>59</sup> that can keep unstable or reactive components separate during storage, and that permits the pharmacist, at the time of dispensing to the patient, to rupture a diaphragm, allowing the disparate fractions to be mixed. After mixing, the product is expected to remain stable for a month at room temperature. This container is designed to handle either liquid/liquid two-part or solid/liquid two-part components.

Pharmacists also should be aware of unit-dose products currently available in form-fill-seal containers that are preservative free. These products are discarded after single use. These products are most suited for patients who are sensitive or allergic to common preservatives and require chronic administration of a product. Specialized manufacturing technology involves melting a plastic resin to form the container walls, filling with the drug solution (usually 0.2 to 0.8 mL), and then sealing to maintain sterility. At the time of use the tip is broken off, the solution is dosed, and then the package is discarded. For technical reasons relating to manufacturing and filling capabilities, as well as for the need to minimize evaporation rate, these containers contain an excess volume of the product. The disadvantage is that patients may desire to use the entire volume and risk using an accidentally contaminated product. Recently, some unit-dose containers have been modified to allow the product to be recapped after use. These containers are designed and labeled to be discarded after a single day's use (12 hours) in order to reduce the risk of significant contamination, yet make them more economical for the patient.

In only a very few instances are glass containers still in use, usually because of stability limitations. Large-volume intraocular solutions of 250 and 500 mL have been packaged in glass, but even these parenteral-type products are beginning to be packaged in specially fabricated polyethylene/polypropylene containers or flexible bags. Type 1 glass vials with appropriate stoppers are used for intraocular ophthalmic products administered by injection. These packaging components should meet the same requirements as parenteral products. Products injected intraocularly also are required to meet endotoxin limits. Readers should refer to Chapter 26, Parenteral Preparations, and Chapter 27, Pharmaceutical Compounding – USP <797> Sterile Preparations for more details.

Plastic packaging, usually low-density polyethylene, is by no means interchangeable with glass, however. Plastic packaging is permeable to a variety of substances, including light and air. The plastic package may contain a variety of extraneous substances such as mold-release agents, antioxidants, reaction quenchers, and the like, which may leach out of the plastic and into the contained solution. Label glues, inks, and dyes also may penetrate polyethylene. Conversely, confined volatile or lipophilic materials may permeate from solution into or through plastic walls. Sterilization, depending on the method, may influence the resin properties; for example, gamma irradiation may increase acid extractables or generate sites that may degrade certain drugs. For these products EtO gas sterilization may be the only remaining option. However, gas sterilization also may degrade active molecules or leave harmful residuals, and certainly requires aeration under forced air to remove the traces of the gas and volatile residues. Whatever process is selected will need to be validated and monitored, assuring the process neither degrades the active ingredient nor generates toxic residues.

**Table 28-1. Ophthalmic Cap Color Coding**

Color	Pharmaceutical Class
Yellow or blue	$\beta$ -blockers
Gray	Nonsteroids
Pink	Steroids
Brown or tan	Anti-infectives
Orange	Carbonic anhydrase inhibitors
Turquoise	Prostaglandins
Red	Mydriatics
Green	Miotics

Patients may be prescribed more than one ophthalmic medication for the same or different conditions, and this can lead to confusion as to which medication is for which use. Historically, red caps have been used for mydriatic drops and green caps for miotic drops, such as pilocarpine. The FDA now requires the use of certain colored caps on several additional types of ophthalmic drugs as a result of a cooperative effort between the FDA, the ophthalmic industry, and the Academy of Ophthalmology. The intent is to help patients prevent medication errors and improve patient compliance. The pharmacist should counsel the patient or caregiver about the purpose of the cap color coding and the importance of opening only one container at a time so that the cap is replaced on the correct container. A listing of the current coding is provided in Table 28-1.

Glass containers (using type 1 glass) remain a convenient package material for extemporaneous preparation of ophthalmic solutions. Type 1 glass should be used. The container, well rinsed with sterile distilled water, can also be sterilized by autoclaving. Presterilized droppers normally are available, presterilized and packaged in a convenient blister pack.

Invariably, packaging of ophthalmic ointments consists of metal tubes with an ophthalmic tip. Autoclaving with either heat or EtO can conveniently sterilize such tubes. In rare cases of metal reactivity or incompatibility, it may be necessary to package ointments in tubes lined with epoxy or vinyl plastic.

Regardless of the form of packaging, consumer protection requires that some type of tamper-evident feature be included. The common tamper-evident feature used on most ophthalmic preparations is the moisture- or heat-sensitive shrink band. Some form of identification on the band should be present, so that its disruption or absence constitutes a warning that tampering, either accidental or purposeful, has occurred.

The eyecup, an ancillary packaging device, fortunately seems to have gone the way of the community drinking cup. Use of an eyecup will inevitably spread or aggravate eye infections. Pharmacists should discourage their use, just as they should take the time to instruct patients in the proper use and care of eye medications. While ophthalmic administration may seem simple enough, it can be a foreign and difficult task for many people. The suggestions and precautions given earlier (under Types of Ophthalmic Dosage Forms) may be useful in instructing patients.

## ANTIMICROBIAL PRESERVATIVES<sup>60</sup>

A preservative is a substance or mixture of substances added to a product formulation to prevent the growth of, or to destroy, microorganisms introduced accidentally once the container is opened for use.<sup>61,62</sup> Addition of the preservative is not intended to be a means of preparing a sterile solution, for which other appropriate techniques exist (discussed elsewhere).

Preservatives are used for topical ophthalmic products packaged in multiple-dose containers unless the formulation itself is self-preserving, as is the case with some antimicrobial products, like the ophthalmic solution Vigamox (moxifloxacin). FDA regulations (21 CFR 200.50) allow unpreserved ophthalmic liquid

products to be packaged in multiple-dose containers only if they are packaged and labeled in a manner that affords adequate protection and minimizes the hazards resulting from accidental contamination during patient use. This can be accomplished by using a reclosable container with a minimum number of doses, which is to be discarded after 12 hours from initial opening and which should be labeled appropriately.

Solutions intended for intraocular use should not contain preservatives because of the risk of irritation and damage to these delicate tissues. Medicines intended for chronic topical applications in patients who cannot tolerate preservatives should also be free of preservatives. Unit-dose ophthalmic solutions are especially useful for patients with sensitivity to preservatives who nevertheless require daily medication, such as glaucoma patients or individuals requiring chronic application of palliatives for dry eye. Ophthalmic solutions prepared and packaged for a single application (i.e., a unit dose) need not contain a preservative, because they are not intended for reuse.

The need for proper control of ophthalmic solutions to prevent serious contamination was recognized in the 1930s. The first preservative recommended for use in ophthalmics was chlorobutanol, as an alternative to daily boiling.

The selection of an ophthalmic preservative can be difficult in part because of the relatively small number of suitable candidates. There is, of course, no such thing as an ideal preservative; however, the following criteria may be useful in preservative selection.

1. The agent should have a broad spectrum, being active against Gram-positive and Gram-negative organisms as well as fungi. The agent should exert a rapid bactericidal activity, particularly against known virulent organisms such as *Ps. aeruginosa* strains.
2. The agent should be stable over a wide range of conditions, including autoclaving temperatures and pH range.
3. Other components of the preparation as well package systems should be compatible with the agent.
4. The preservative should cause neither toxicity nor irritation, within a reasonable margin of safety.

Only through evaluating preservative substances can as a part of the total ophthalmic preparation in the proposed package can producers establish the adequacy of the preservative. Criteria for preservative effectiveness in ophthalmic products are official compendial requirements in the *US Pharmacopeia*, *European Pharmacopeia*, and the *Japanese Pharmacopoeia*. Health authorities expect that products will meet these preservative effectiveness criteria throughout their approved shelf-lives, in the final packaging, and at the recommended storage conditions.<sup>2-4</sup>

In addition to its effectiveness as an immediate measure, formulators must also ascertain a preservative's adequacy or stability as a function of time. They often accomplish this by measuring both chemical stability and preservative effectiveness over a given period of time and under varying conditions.

Many of these test procedures are not totally applicable to the preparation of an extemporaneous ophthalmic solution. In such a situation the pharmacist must make selections based upon known conditions and physical and chemical characteristics, guided by those used in commercial ophthalmic preparations. In these circumstances it would be prudent to prepare only minimum volumes for short-term patient use.

The choice of preservatives suitable for ophthalmic use is surprisingly narrow. The classes of compounds available for such use are described in Table 28-2.<sup>63</sup> In each case or category there are specific limitations and shortcomings.

## QUATERNARY AMMONIUM COMPOUNDS

Benzalkonium chloride (BAC) is a typical quaternary ammonium compound and is the most common preservative used in ophthalmic preparations, being present in over 65 percent of commercial ophthalmic products. Note the structure of BAC is

**Table 28-2. Ophthalmic Preservatives<sup>63</sup>**

Type	Typical Structure	Concentration Range	Incompatibilities
Quaternary ammonium compounds	$\left[ \begin{array}{c} R_2 \\   \\ R_1 - N^+ - R_1 \\   \\ R_1 \end{array} \right] Y^-$	0.004–0.02 %, 0.01% most common	Soaps Anionic materials Salicylates Nitrates
Organic mercurials (thimerosal example)		0.001–0.01%	Certain halides with phenylmercuric salts
Parahydroxy benzoates (methyl ester example)		Maximum 0.1%	Adsorption by macromolecules; marginal activity
Chlorobutanol		0.5 %	Stability is pH-dependent; activity concentration is near solubility
Aromatic alcohols		0.5–0.9 %	Low solubility in water; marginal activity

a slight departure from the general one provided in Table 28-2 in which there are three small alkyl chains on one longer alkyl chain (the R's). For BAC one of the R1's is a benzyl group. Despite its widespread use, the compound has definite limitations. As a cationic surface-active material of high molecular weight, it is not compatible with anionic compounds. It is incompatible with salicylates and nitrates, and may be inactivated by high-molecular-weight nonionic compounds. Conversely, BAC has excellent chemical stability and very good antimicrobial characteristics. Given the alternatives, it is often better to modify a formulation to eliminate the incompatibility than to include a compatible but less effective preservative. The presence of a surfactant, for example, may require higher levels of BAC to achieve an adequate level of preservation.

The literature on BAC is somewhat mixed; however, this is to be expected given the wide variation in test methods and, indeed, the chemical variability of BAC itself. The official substance is defined as a mixture of alkyl benzyldimethylammonium chlorides, including all or some of the group ranging from  $n\text{-C}_8\text{H}_{17}$  through  $n\text{-C}_{16}\text{H}_{33}$ . The  $n\text{-C}_{12}\text{H}_{25}$  homologue content is at least 40 percent on an anhydrous basis.

Reviews<sup>64</sup> of BAC indicate that it is well suited for use as an ophthalmic preservative. Certain early negative reports have been shown to be erroneous; in some cases adverse tissue reactions were attributed to BAC when, in fact, a totally different compound was used as the test material. Although BAC is the most common quaternary preservative, others occasionally mentioned include benzethonium chloride and cetyl pyridinium chloride. All are official compounds. More recently,

quaternary ammonium functionality has been attached to soluble, reasonably high-molecular-weight polymers. These agents possess good antimicrobial effectiveness with fewer compatibility problems than the official quaternary preservatives.

Search for milder, safer, gentler preservatives for ophthalmic products, specifically artificial-tear and chronic-use products, has been a challenge for many companies. As a result of this research, some commercial products now incorporate these improved agents as preservatives. Alcon has introduced many lens care and ophthalmic products preserved with polyquaternium-1 (polyquad), a newer preservative of the same class as BAC but with less cytotoxicity. More effective than BAC, these agents also are effective at a lower concentration. Their concentration in the product can range from 0.005 percent to 0.0005 percent and yet still meet compendial preservative efficacy requirements. Polyquad has been used widely in many lens care and artificial-tear products.

#### OXIDIZING AGENTS

Systems based on either sodium perborate or a stabilized oxychloro complex are being used as preservatives based on their ability to generate a mild oxidative and cytotoxic effect in aqueous media. Sodium perborate produces hydrogen peroxide as the oxidative species, and the stabilized oxychloro complex is a mixture of oxychloro species but primarily comprises chlorite and a trace of chlorine dioxide. Once in the eye, the active agents in either system are spontaneously reduced to harmless by-products and have been marketed as so-called disappearing preservatives in OTC products for dry eye treatment.

## ORGANIC MERCURIALS

It is generally stated that phenylmercuric nitrate or phenylmercuric acetate, in 0.002 percent concentration, should replace BAC as a preservative for salicylates and nitrates, and in solutions of salts of physostigmine and epinephrine that contain 0.1 percent sodium sulfite. The preferred range of concentrations employed is 0.002 to 0.004 percent. Phenylmercuric borate sometimes is used in place of the nitrate or acetate.

Phenylmercuric nitrate has the advantage over some other organic mercurials of not being precipitated at a slightly acid pH. As with other mercurials, it is slow in its bactericidal action and it also produces sensitization reactions. Phenylmercuric ion is incompatible with halides, for it forms precipitates.

The effectiveness of phenylmercuric nitrate against *Ps. aeruginosa* is questionable; researchers have found that pseudomonads survive after exposure to a concentration of 0.004 percent for longer than a week.

Development of iatrogenic mercury deposits in the crystalline lens has occurred, resulting from use of miotic eyedrops containing 0.004 percent phenylmercuric nitrate, three times daily, for periods of 3 to 6 years. Although there was no impairment of vision, the yellowish brown discoloration of the lens capsule is reportedly permanent.

Thimerosal (Merthiolate; Lilly) is an organomercurial with bacteriostatic and antifungal activity that functions as an antimicrobial preservative in concentrations of 0.005 to 0.02 percent. Its action, as with other mercurials, has been reportedly slow.

## PARAHYDROXYBENZOIC ACID ESTERS

Mixtures of methylparaben and propylparaben are sometimes used, as antimicrobial preservatives, mostly in ophthalmic ointments; the preferred maximum concentration of methylparaben is in the range of 0.1 percent, its NOEL, while that of propylparaben approaches its solubility in water (>0.04 percent). They are not considered efficient bacteriostatic agents and are slow in their antimicrobial action. Ocular irritation and stinging have been attributed to their use in ophthalmic preparations.

## SUBSTITUTED ALCOHOLS AND PHENOLS

Chlorobutanol is reportedly effective against both Gram-positive and Gram-negative organisms, including *Ps. aeruginosa* and some fungi. It is broadly compatible with other ingredients, and manufacturers normally choose a concentration of 0.5 percent. One of the products of hydrolysis is hydrochloric acid, which causes a decrease in the pH of aqueous solutions. This decomposition occurs rapidly at high temperatures and slowly at room temperature, in unbuffered solutions that were originally neutral or alkaline. Therefore, ophthalmic solutions that contain chlorobutanol should be buffered between pH 5.0 and 5.5, and generally packaged in glass containers. At room temperature it dissolves slowly in water, and although heat dissolves it more rapidly, loss by vaporization and decomposition is accelerated.

A combination of chlorobutanol and phenylethyl alcohol (0.5 percent of each) has been reported to be more effective against *Ps. aeruginosa*, *Staphylococcus aureus*, and *Proteus vulgaris* than either antimicrobial singly. In addition, dissolving chlorobutanol in phenylethyl alcohol before dissolution in water eliminates the need to heat the solution.

## OTC PRODUCTS FOR DRY EYE

Dry eye is a condition that can be either an annoying irritation in its mild form or a painful and destructive pathology in its severe form, damaging the corneal surface and interfering with vision. Possible causes of dry eye include decreased tear production, increased tear evaporation rate, or an abnormality of the tear film that decreases its natural capacity to protect and lubricate the epithelial tissues. It is one of the most common

complaints of patients seeking treatment from their eye-care doctor. This condition is somewhat unique in that it is largely treated with OTC monograph drug products, and the pharmacist is often asked to assist in its selection.<sup>65</sup> These products are variously known as artificial tears, ocular lubricants, demulcents, or emollients, and are available as solutions, gels, or ointments. Also unique is that these dry eye products are often the essential viscous-vehicle component of therapeutic ophthalmic products. Several reference books include the compositions of the various commercial dry eye products.<sup>33,34</sup>

OTC dry eye products contain water-soluble polymers as active ingredients that protect and lubricate the mucous membrane surfaces of the conjunctiva and cornea, providing temporary relief of the symptoms of dryness and irritation. The polymers thicken the tear film and decrease the rate of tear loss in addition to lubricating and protecting the tissues. Mucin is a natural lubricating component of tears, and thus, dry eye products are expected to provide a mucomimetic effect. The active-ingredient demulcent (lubricant) polymers in these products, along with their permitted concentrations and labeling, are defined in an OTC monograph issued by the FDA.<sup>66</sup> The monograph does not specify viscosity grades, and therefore, a wide range of product viscosities is available. The more viscous products can provide longer duration of relief; however, they are also more likely to blur vision and leave a residue of polymer on the eyelids. The OTC products vary in their choice of polymer or combination of polymers, concentrations, and viscosity. The majority of OTC dry eye products contain one or more of the following permitted polymers: celluloses such as hydroxypropyl methylcellulose (hypromellose) or carboxymethylcellulose sodium; polyol liquids such as glycerin, polyethylene glycol, or polysorbate 80; polyvinyl alcohol; or povidone. Dextran 70 can be used only in combination with another permitted demulcent polymer.

The inactive components of OTC dry eye products are similar to those used in therapeutic ophthalmic products and require equally careful selection, keeping in mind that the monograph products are labeled for use as often as needed and thus must be nonirritating and physiologically compatible. In the moderate to severe forms of dry eye, the product may be dosed as often as every hour, and in the especially severe cases, as often as every 15 minutes. The preferred vehicle is aqueous for replenishing natural tears and dissolving the active and inactive ingredients. The vehicle is usually adjusted to be isotonic with sodium chloride, and in some cases other salts are used as well as nonionic ingredients, such as dextrose and mannitol. Some cases of dry eye have been reported to produce tears that are hypertonic, and several products feature a slightly hypotonic formula to restore the natural tear osmotic pressure. The products generally are adjusted or buffered to provide a pH of about 7.4, but rarely outside of the range of about 7.0 to 8.0.

Storage of solutions of some polymers, notably polyvinyl alcohol, can lead to a more acidic pH. The preservative chlorobutanol also produces an acidic pH as it degrades in solution. The bicarbonate included in some products is a more physiologically compatible buffer that requires a hermetically sealed secondary package for stability. Some products include both monovalent and divalent chloride salts in their vehicles in an attempt to mimic the electrolyte composition of natural tears.

The majority of dry eye products contain a preservative and are packaged in multiple-dose plastic ophthalmic containers. As in therapeutic products, BAC is the most widely used preservative. Newer preservatives having improved compatibility with ocular tissues, such as Polyquad, are increasingly in use, as well as the “disappearing” preservatives sodium perborate and Purite. Sodium perborate forms hydrogen peroxide, which can be irritating in the eye but quickly degrades to oxygen and water. Purite is a stabilized oxychloro complex that degrades to sodium chloride and water when exposed to long-wavelength ultraviolet light.

Preservative-free products are also available and are gaining popularity, particularly for patients with chronic dry eye

conditions and those who are sensitive to preservatives. These products are packaged in form-fill-seal unit-dose containers, but manufacturing considerations dictate that they contain enough product for several doses while bearing labels indicating that they are to be discarded after a single dose. This problem has led to the introduction of a modified package with a reclosable cap allowing its use as a small-volume multiple-dose container for preservative-free products when for safety reasons they are labeled to be discarded no longer than 12 hours after first opening.

The large majority of dry eye products are solution dosage forms administered as eyedrops, but gel-like and ointment dosage forms are also available. People who suffer with dry eye or who have a defect in lid closing that causes increased tear evaporation benefit from the these ointments, which consist primarily of a mixture of petrolatum and mineral oil that imparts emollient properties. Lanolin is sometimes added to the base to provide some water miscibility. The ratio of oils can be varied for consistency and melting temperature. Patients primarily use the ointments as a night-time medication, because they usually cause a blurring of vision. Several products bearing labels identifying them as gels or liquid gels are aqueous-based dosage forms containing one or more of the permitted lubricant polymers. The gel dosage form identifier is used to designate a more viscous product; however, the dosage directions read the same as for the eyedrop products (instill one or two drops as needed), as this dosage statement is the only one permitted for dry eye products marketed using the permitted lubricant polymers under the OTC monograph.

One disadvantage of most OTC dry eye products is their relatively short duration of effect. Several products have become available that incorporate novel delivery system technology into these products to prolong the duration of the lubricant and protectant effects of the monograph active ingredients. One product, AquaSite,<sup>67</sup> incorporates the polymer polycarbophil, and in a more recent product, Systane,<sup>68</sup> a modified hydroxypropyl guar polymer forms a gel-like matrix when the product components interact with the tear fluid.

## CONTACT LENSES AND THEIR CARE

### HISTORICAL BACKGROUND<sup>69-71</sup>

Evidence suggests that the concept of altering corneal power was first envisioned by Leonardo da Vinci early in the sixteenth century. In the next century, more than a hundred years later, René Descartes described a device, a glass-filled tube in direct contact with the cornea, capable of implementing this concept, though it prohibited blinking and so was not a practical solution. In the early nineteenth century the British astronomer Sir John Herschel described the mathematics of these devices and proposed a means of treating very irregular corneas by using a glass capsule filled with a gelatin solution. Not until 1888 was the original concept executed by the artificial-eye maker, Albert Müller. He made a glass protective shell for the cornea of a lagophthalmic patient who had carcinoma of the upper lid. The patient wore the device for 20 years, and corneal clarity was maintained.

But perhaps the first contact lenses, scleral lenses resting on the bulbar conjunctiva beyond the limbal ring, were fabricated and fit by the German ophthalmologist A.E. Fick, working in Zurich late in the nineteenth century. Contact lenses without scleral portions (corneal lenses) were in existence at least as early as 1912, when they were manufactured by Carl Zeiss. Glass prostheses produced by Fick and others, while conceptually a step forward, suffer from reasonably rapid deterioration in the tear fluid. However, they had the advantage that the glass was readily wetted by tears.

Experimentation in the twentieth century led J. Dallos, working in Budapest, to perceive the importance of tear flow underneath the contact lens. Dallos also took impressions of

human eyes to improve the fidelity of the ground lens to the shape of the cornea. The first contact lenses, scleral lenses made of plastic in the late 1930s with polymethyl methacrylate (PMMA) from Rohm and Haas, are attributed to W. Mullen and T. Obrig. The advantages of durability and weight reduction far outweighed the slight differences in optical properties. And in 1948, K. Tuohy filed a patent for a plastic corneal contact lens. With the advent of PMMA, a flush-fitting shell became possible, a concept developed in England in the 1950s by Ridley. The first corneal lenses to have any measure of commercial success were developed in the early 1950s by F. Dickinson and W. Sohnges. Its thickness was about 0.2 mm, considered to be fairly thick. Thinner lenses, of about 0.1 mm, were introduced in the early 1960s.

The first soft contact lenses consisted of silicone, an elastomer nearly devoid of water but with good permeability to oxygen and carbon dioxide. However, the first soft contact lenses to be commercialized were of hydroxyethyl methacrylate hydrogels, developed by O. Wichterle and D. Lim in Czechoslovakia in the early 1960s. Continuous improvements have progressed to the present day, including milestones such as silicone acrylate rigid gas-permeable (RGP) lenses in the 1970s, disposable inexpensive lenses in the 1980s, and daily disposable and silicone hydrogel lenses in the 1990s.

With the advent of commercialized, relatively comfortable, inexpensive corneal contact lenses, the need for lens care products developed beginning in the 1950s and, as summarized below, a great variety of functionality now exists, depending on the requirements of the individual products.

From a regulatory perspective, during the period from their approval by the FDCA of 1938 until the US Medical Device Amendments to the FDCA of 1976, contact lenses and contact lens care products were regulated as drugs. Although during this period a device was defined in the FDCA, many medical devices were thought to be “used for the cure, mitigation, or prevention of disease,” leading to their classification as drugs. With increased activity in industry and significance of biomedical devices in maintaining health, congressional awareness arose regarding the advantages for greater regulation. The amendments made provision for three classes of device, with different requirements for each. Those with least risk were assigned to class I, and those associated with increasing risk, to a progressively higher class. If safety and efficacy of a device could be reasonably assured by “general controls” (including restrictions on design, production, storage, maintenance, and use), then the device was assigned to class I, which may be exempted from the requirement for a 510(k) (the section of the FDCA that allows for clearance of class II medical devices; see later) but still require company or product registrations. Under the 1976 amendments to the FDCA, contact lenses and lens care products were reclassified as class III devices, requiring a premarket approval application and approval by the FDA before marketing.

However, by 1990, following years of experience with certain devices in the marketplace and recognition that little purpose was being served duplicating regulatory investigation of substantially equivalent safe and effective devices, Congress passed new legislation. The US Safe Medical Devices Act of 1990 authorized reclassification of certain contact lens and lens care products as class II devices, requiring special controls in the form of a 510(k) submission and clearance. The products covered by this reclassification include solutions, dry products, tablets, and disinfecting units used in caring for and disinfecting soft (hydrophilic) and RGP contact lenses. In March 1994, the down-classification of two types of daily-wear contact lenses, from class III to class II, was implemented by a rule in the *Federal Register*. In July of 1997 a similar down-classification of certain contact lens care products, including multipurpose solutions and in-eye contact lens solutions, was implemented by a rule in the *Federal Register*. Extended-wear contact lenses remain governed by class III regulations.

**Table 28-3. Contact Lens Classes, Characteristics, and Support Products**

Lens Type	Chemical Classification	Major Characteristics	Typical Support Products
Hard, rigid, hydrophobic	PMMA (polymethyl methacrylate)	Negligible gas permeability, low water content, medium wettability	Wetting solutions Soaking solutions Cleaning solutions Combination Artificial tears
Soft, flexible, hydrophilic	HEMA (hydroxyethyl methacrylate)	High water content, low gas permeability, good wettability	Cleaning solutions Disinfection solutions
Flexible hydrophobic	Silicone rubber	Good gas permeability; poor wettability	Wetting solutions Cleaning solutions
	Silicone vinylpyrrolidone	Good gas permeability; good wettability	Soaking solutions
Rigid, hydrophilic	CAB (cellulose acetate butyrate)	Good gas permeability; good wettability	Wetting solutions Cleaning solutions Soaking solutions Rewetting solutions

### CONTACT LENSES, CURRENT ART

As a consequence of these years of development, the consumer currently can choose from an enormous selection of contact lenses and lens materials. There are basically four classes of lenses, and the identification of these classes is both by polymer type and lens characteristics: hard contact lenses, RGP contact lenses, soft hydrophilic contact lenses, and silicone-based flexible hydrophobic lenses. These classes are summarized in Table 28-3. Hard contact lenses are generally fabricated from PMMA or polysilicone acrylate polymers or co-polymer blends containing one of these materials. RGP contact lenses are generally consist of more polarizable and oxygen-permeable materials such as cellulose acetate butyrate, *t*-butyl styrene, or silicone polymers or co-polymers. These lenses generally provide visual acuity superior to that of the more flexible soft contact lenses. The US Adopted Names (USAN) designates these hydrophobic lens types with less than 10 percent water by the suffix *focon*. However, RGP lenses have a low oxygen permeability and so should be removed and cleaned after a day's wear; moreover, because of greater lens awareness, especially a new wearer, should wear them routinely (i.e., not intermittently). They are durable, however, and so may be preferred because the replacement schedule is extended. RGP lenses with higher oxygen transmissibility tend to be preferred, especially in comparison with hard contact lenses, because the improved exchange of gases assists in maintaining the health of the cornea.

The third class of contact lenses, soft hydrophilic lenses, is fabricated from such a wide variety of materials and their blends that the FDA has grouped them according to two parameters, ionicity and water content (either low or high, less than or greater than 50 percent water):

- Group I includes the nonionic polymers of low water content, such as polymacon, a simple poly(hydroxyethyl methacrylate) (HEMA),
- Group II includes the nonionic polymers of high water content, such as alphafilcon A (a co-polymer of five monomeric units: HEMA, vinyl pyrrolidone, ethylene dimethacrylate, hydroxycyclohexyl methacrylate, and a substituted vinyl carbonate),
- Group III includes ionic polymers of low water content, such as bufilcon (a terpolymer of HEMA, dimethyl oxobutyl acrylamide, and the trimethacrylate ester of ethyl *t*-butane triol with some level of hydrolysis of the esters to the free acid) or ocufilcon A (a terpolymer with HEMA, methacrylic acid, and ethylene dimethacrylate), and
- Group IV includes ionic polymers of high water content, such as a higher water content ocufilcon B/C or etafilcon (a terpolymer of HEMA, the salt of methacrylic acid, and the trimethacrylate ester of ethyl *t*-butane triol).

The final class of contact lenses, considered either a group of harder soft lenses or a group of softer RGP lenses with high oxygen solubility and transmission, is that of the silicone hydrogel lenses. These silicone and fluorosilicone materials are candidates for continuous extended-wear applications.

Such diverse functionalities provide distinct properties in addition to water content, ranging from oxygen and metabolite transport, hardness, and flexibility, through processability, to durability and stability. More complete lists of the materials used in contact lens manufacture are available, but in general the USAN Council designates these hydrophilic lens types with greater than 10 percent water by the suffix *filcon*.<sup>72-74</sup> While the nomenclature adequately distinguishes monomer components, and the alphabetical trailing designation indicates differences in ratios of monomer units, one must remember that differences in crosslinker (often ethylene glycol dimethacrylate), initiator, catalyst, filler, or color additive are not delineated.

While this is a reasonable overview of the categories of choices for the materials composing contact lenses, it is still an incomplete list with regard to the properties that concern both the consumer and his or her practitioner in selecting a contact lens. In addition to the chemical composition, the following choices are necessary: (1) duration of wear (daily vs. continuous), (2) lens replacement schedule (daily vs. biweekly vs. monthly vs. quarterly), (3) lens design (spherical, toric, orbifocal), (4) colored or clear, (5) means of manufacture (lathe-cut or cast-molded), (5) edge design (which can affect lens motion, overall fit, comfort, and acuity) and lens thickness, (6) fitting characteristics, like the selection available for base curves and lens diameter, and (7) any surface treatment or conditioning. With this multiplicity of choices and the subtlety of competing requirements, the recommendation of the practitioner is vital.

But ultimately, the consumer's personal metrics—comfort, convenience, and cost—also remain significant factors in lens selection rates. For example, patients with drier eyes are more likely to prefer group I lenses.

In addition to their use in vision correction, soft contact lenses, like collagen shields, find occasional use for therapeutic purposes, serving as bandages providing protection in treatment of bullous keratopathy (or other forms of corneal edema or other corneal irregularities or sources of cicatrization) or for lid abnormalities, and with ulcers, chemical burns, grafts, or dry eye. They are also efficacious in sustaining the delivery of therapeutic agents, as discussed previously. Patients will have to care for lenses that are used for these therapeutic purposes with the same preparations as those needed for lenses prescribed for refractive correction.

In summary, both doctors and consumers of contact lenses have a broad range of alternatives. Current lens materials and

the solutions to maintain them (next section) provide a wide selection of properties suitable for individual ocular health requirements and preferences.

## CONTACT LENS CARE PRODUCTS

### General Considerations

With the previous two sections for background, we are ready to discuss those preparations produced for the care of contact lenses. For all of the specialized solutions to be discussed, it is generally necessary (1) to adjust pH, tonicity (osmolality), surface and interfacial tensions, and viscosity; (2) preserve and maintain sterility; (3) assure stability and shelf-life; and (4) package and sterilize appropriately. In the United States these solutions are class II medical devices.<sup>71</sup>

### Wetting Solutions

These are lubricating and cushioning preparations designed to furnish a hydrophilic coating over the characteristically hydrophobic surface of PMMA, silicon, acrylate, and other rigid lens surfaces. Typically, wetting solutions include an acceptable viscosity-imparting agent, a surfactant, and a preservative. The surface-activity and viscosity effects may be obtained from a single compound. Agents commonly used include cellulose derivatives, polyvinyl pyrrolidone, polyvinyl alcohol, and polyethylene glycol derivatives. The need for surface-active agents, which facilitate wetting of lenses and spreading of tears, is greater for hard contact lenses because of their hydrophobic surface characteristics. Preservatives include those acceptable for ophthalmic use, including polyquad and a polyhexylmethylene biguanide, called PHMB or DYMED.

### Cleaning Solutions

Cleaning solutions commonly are used to remove surface contaminants—lipids, protein, organic salts, and the like. Cleaning is accomplished by the use of surfactants that preferably are nonionic or amphoteric. Viscosity-imparting agents generally are not included. Some cleaning agents also include a mild abrasive: silica for RGPs or plastic particles for soft lenses.

Adequate cleaning of hydrophilic lenses is a far more complex and challenging problem than for hard-lens cleaning. Because of their permeability characteristics, contaminants penetrate into the lens structure and may bind chemically or physically to the HEMA or ionic portions of the lens material. Contaminants may be surface films or crystals, amorphous aggregates of protein material, cellular debris, or insoluble inorganic salts.

Cleaning products generally are specific to the lens material and require FDA clearance, with proof of cleaning efficacy and safety. Cleaners are based on surface activity, enzyme action, or even abrasant action, in which case the abrasant material must be softer than the lens itself. Adequate daily cleaning of hydrophilic lens material can enhance disinfection but in some cases may not be necessary, given the choices of today's powerful disinfecting solutions and enzymatic cleaners, available in either a tableted or liquid form. Most recently, daily-wear planned-replacement lenses have found wide acceptance. Conventionally their successful use is reliant on enzymatic cleaning together with special disinfectants. However, extended-wear lenses, soiling at a lower rate, require only rewetting drops.

The significance of adequate cleaning cannot be overstated. Improperly or inadequately cleaned and maintained lenses are perhaps the most important contributors to complications associated with the wear of contact lenses such as discomfort, loss of visual acuity, conjunctivitis, and keratitis.

There are two types of cleaning solutions, daily and weekly cleaners. Weekly-cleaning solutions may include proteolytic enzymes like subtilisin, or a broad-spectrum less toxic enzyme like pancreatin (which contains protease, lipase, and amylase activity), or concentrated surfactants. Daily-cleaning solutions achieve cleaning using less aggressive surface-active agents and polymers, often nonionic but nonsolubilizing agents that will be

less toxic if carried over into the eye. Examples include Tween 20 or 80 (types of polysorbate detergents) and tyloxapols (surfactants). A daily cleaning solution even containing a nontoxic enzyme is available (SupraClens).

The goal is to provide thorough cleaning of the lenses for the benefits described previous without causing any degradation of the lenses.

### Disinfecting Systems

Disinfection of the first hydrophilic lens approved by the FDA was accomplished using a heating device that generated steam from a saline solution. The latter was either prepared by the user or available from the manufacturer. Subsequent to the so-called thermal systems, requiring heating at 80°C for 10 minutes, disinfection solutions were developed that met the requirements for FDA approval while not damaging the more delicate soft lens materials. Because of the sorption characteristics of hydrophilic lens materials, many of the accepted ophthalmic preservatives are unsatisfactory for use in soft-lens disinfecting systems, including the ubiquitous BAC. Once again, however, the use of a quaternary disinfectant covalently bonded to a soluble, relatively high-molecular-weight polymer has met with some success. These have to a large extent replaced chemical antimicrobial agents like sorbic acid, thimerosal (containing mercury), and hydrogen peroxide, among many others. Perhaps the most common in current use are a cationic polymer, polyquad, and a polyhexylmethylene biguanide.

In addition to possessing satisfactory disinfecting activity, such a preparation must be isotonic, be in an acceptable pH range, be nonreactive (nonbinding) with lens materials, and over a normal use period induce or bring about no physical, chemical, or optical changes in the lens. It is, of course, sterile and safe for use in the eye, even though direct instillation into the eye is not intended.

### Soaking Solutions

Soaking or storage solutions, as the name suggests, serve in storage and hydration of hard or RGP lenses but, most importantly, in disinfection of such lenses. Disinfection should be rapid and as complete as possible, making use, once again, of acceptable ophthalmic preservative substances. Soaking solutions typically contain chlorhexidine (gluconate), benzalkonium, or quaternary/polymer compounds, enhanced by sodium edetate. Soaking solutions are intended to be rinsed off lenses before insertion.

### Rewetting Solutions

Solutions intended to rewet hard or RGP lenses *in situ* are referred to as rewetting solutions or lubricating drops. Such preparations are intended to reinforce the wetting capacity of the normal tear film. Early products of this type tended to be somewhat viscous wetting solutions, acceptable for direct instillation into the eye. More recent preparations mimic tears more accurately, and their viscosity may be rather low, to improve user acceptability, or adjusted to be responsive and to improve retention and duration of the wetting characteristics.

### Multipurpose Solutions

By combining the actions of two or more of the solutions just described, these products simplify regimens, improve compliance, generally increase the comfort of contact lens products, and greatly increase the convenience of using contact lenses. For soft contact lenses, multipurpose solutions have to combine only the functions of cleaning and disinfection, whereas a complete multipurpose solution for a hard or RGP lens must also provide some level of wetting. Suffice it to say that these solutions, which contain an intricate balance of ingredients, have grown in popularity significantly because of the greatly increased level of convenience they provide. Their efficacy often precludes the need for separate cleaning solutions for many patients.

## GUIDELINES FOR SAFETY AND EFFICACY TESTING

The FDA periodically issues or updates guidelines describing recommended test procedures for contact lens care products. The reader is advised to review the most recent guidelines for appropriate requirements.

Current guidelines cover all lens care products. Applicable guidelines are determined by the type of product (e.g., saline solution, cleaning solution, multipurpose solution, and rewetting drops) and the claim (e.g., disinfection in a regimen as opposed to a stand-alone process). Safety testing includes determinations of cytotoxicity, oral toxicity, potential for sensitization, and single to multiple exposure in an animal (rabbit) eye. The tests designated depend on the active ingredient (e.g., if it is a new entity or has been in previous products) and its concentration (e.g., if it is the same or different from that used in a currently approved product). Efficacy of preservation, disinfection, and cleaning, compatibility with lens or lens types, and clinical trials are also required, with their type and scope dependent on product type, characteristics, ingredients, and claims.

## SUMMARY

There has been considerable progress in ophthalmic pharmaceuticals and in lens care products during the last decade. Very substantial advances have occurred in designing vehicles and packaging for highly potent active ingredients presented at very low concentrations; in increasing ophthalmic bioavailability and controlling factors influencing ophthalmic drug absorption; in the design of implants and means of delivering them for providing therapeutic agents to the retina and other deep ophthalmic tissues; and in devising robust yet delicately balanced multipurpose solutions for contact lens wearers. Continuing advances in the general field of ophthalmic pharmaceuticals and pharmacokinetics can be expected to assist in maintaining and improving ocular health.

CONVENTIONAL TOPICAL DOSAGE FORMS—SEMISOLIDS 571

OTHER DOSAGE FORMS FOR APPLICATION TO THE SKIN AND ITS APPENDAGES 572

RECTAL, VAGINAL, AND URETHRAL ROUTES OF ADMINISTRATION 574

### INTRODUCTION

The application of medicinal substances to the skin and its appendages (e.g., nails) or various body orifices is a concept as old as humanity. The papyrus records of ancient Egypt describe a variety of such medications for external use. Galen described the use in Roman times of a forerunner to today's vanishing creams.

Medications are applied in a variety of forms reflecting the ingenuity and scientific imagination of pharmacists through the centuries. New modes of drug delivery have been developed to remedy the shortcomings of earlier vehicles or, more recently, to optimize drug delivery. Conversely, some external medications have fallen into disuse because of changes in the practice of medicine.

Medications are applied to the skin or its appendages or inserted into body orifices in liquid, semisolid, or solid form. Accordingly, emphasis in this chapter has been placed on (1) the epidermal, dermal, and transdermal (percutaneous) routes, and (2) the rectal, vaginal, and urethral routes and their corresponding formulations. Nasal and intranasal products, ophthalmics, and topical aerosol products will not be discussed in this chapter.

### THE SKIN AND ITS APPENDAGES

#### ANATOMIC AND PHYSIOLOGIC ASPECTS

##### The Skin

The skin often has been referred to as the largest of the body organs: an average adult's skin has a surface area of about 2 m<sup>2</sup>. It is probably the heaviest organ of the body. Its accessibility and the opportunity it affords to maintain applied preparations intact for a prolonged time have resulted in its increasing use as a route of drug administration, whether for local, regional, or systemic effects.

Anatomically, human skin may be described as a stratified organ with three distinct tissue layers: the epidermis, the dermis, and the subcutaneous fat layer (Figure 29-1).

Epidermis, the outermost skin layer, consists of stratified squamous epithelial cells. Keratinized, flattened remnants of these actively dividing epidermal cells accumulate at the skin surface as a relatively thin region (about 10–20 μm thick) termed the stratum corneum, or horny layer. The horny layer is itself lamellar with the keratinized cells overlapping one another, linked by intercellular bridges and compressed into about 15 layers. The lipid-rich intercellular space in the stratum corneum consists of lamellar matrices with alternating hydrophilic layers and lipophilic bilayers formed during the process of keratinization. The region behaves as a tough but flexible coherent membrane.

The stratum corneum also is markedly hygroscopic—far more so than other keratinous materials, such as hair or nails. Immersed in water, the isolated stratum corneum swells to about three times its original thickness, absorbing about four to five times its weight in water in the process. The stratum corneum functions as a protective physical and chemical barrier and is only slightly permeable to water. It retards water loss from underlying tissues, minimizes ultraviolet light penetration, and limits the entrance of microorganisms, medications, and toxic substances from without. The stratum corneum is abraded continuously. Thus, it tends to be thicker in regions more subject to abrasion or the bearing of weight. Its regeneration is provided by rapid cell division in the basal cell layer of the epidermis. Migration or displacement of dividing cells toward the skin surface is accompanied by differentiation of the epidermal cells into layers of flat, laminated plates, as noted above. An acidic film, (pH ranging between 4 and 6.5, depending on the area tested) made up of emulsified lipids, covers the surface of the stratum corneum.

The dermis can be described as a gel structure involving a fibrous protein matrix, embedded in an amorphous, colloidal, ground substance. Protein, including collagen and elastin fibers, is oriented approximately parallel to the epidermis. The dermis supports and interacts with the epidermis, facilitating its conformation to underlying muscles and bones. Blood vessels, lymphatics, and nerves are found within the dermis, although only nerve fibers reach beyond the dermal ridges or papillae into the germinative region of the epidermis. Sweat glands and hair follicles extending from the dermis through the epidermis provide discontinuities in an otherwise uniform integument.

The subcutaneous fat layer serves as a cushion for the dermis and epidermis. Collagenous fibers from the dermis thread between the accumulations of fat cells, providing a connection between the superficial skin layers and the subcutaneous layer.

##### THE SKIN'S APPENDAGES – HAIR, SEBACEOUS GLANDS, AND SWEAT GLANDS

Human skin has numerous surface openings (i.e., hair follicles and sweat glands) extending well into the dermis (see Figure 29-1). Hair follicles, together with the sebaceous glands that empty into the follicles, make up the pilosebaceous unit. Human hair consists of compacted keratinized cells formed by the follicles. The hair follicles, surrounded by sensory nerves, are able to provide a sensory function. Human hair varies enormously within the same individual, even within the same specific body area. Follicular density varies considerably as well, from values of about 250 follicles per cm<sup>2</sup> for the scalp to 50 per cm<sup>2</sup>, or less, for the thigh and other relatively nonhirsute areas. Follicular density is determined genetically (no new follicles are formed after birth). One characteristic human trait is that although most of the body hairs never develop beyond the rudimentary vellus state, the only hairless areas are confined,

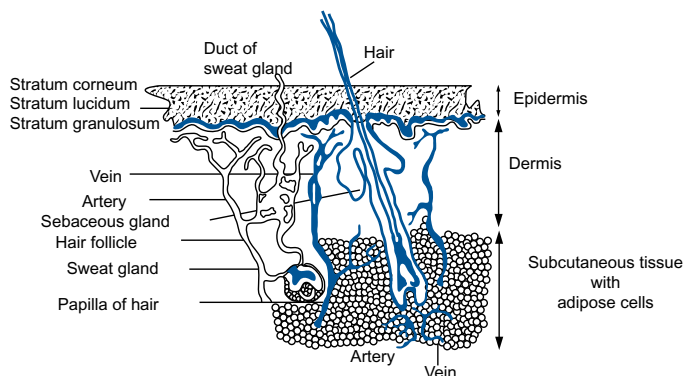

Figure 29-1. Vertical section of human skin.

primarily, to the palmar and plantar surfaces. Individual hairs can vary in microscopic appearance, diameter, cuticle appearance, and even presence or absence of medulla.

Sebaceous glands are similar anatomically and functionally but vary in size and activity according to location. Population in the scalp, face, and anogenital areas may vary from 400 to 900 per  $\text{cm}^2$ . Fewer than 100/ $\text{cm}^2$  are found in other areas. Sebaceous glands are richly supplied with blood vessels.

Sebaceous cells synthesize and accumulate lipid droplets. This accumulation results in enlarged cells that fragment to form sebum. Sebum is made up of a mixture of lipids: triglycerides (57.5 percent), wax esters (26 percent), squalene (12 percent), cholesterol esters (3.0 percent), and cholesterol (1.5 percent).

The sebaceous gland, containing sebum, cell debris, and microorganisms such as *Propionibacterium acnes*, is connected to the pilosebaceous canal by a duct of squamous epithelium. When access to the surface is blocked and bacteria multiply, the result is the comedo of acne.

Sweat glands are classified as either apocrine or eccrine. Apocrine glands are secretory but are not necessarily responsive to thermal stimulation. Such glands do not produce sweat in the normal sense of the word. Apocrine glands, however, often are associated with eccrine sweat glands, particularly in the axilla. Eccrine sweat glands are coiled secretory glands, equipped with a blood supply, extending from the dermis to the epidermal surface. Eccrine sweat glands function to regulate heat exchange in humans. As such, they are indispensable to survival. About 3 million eccrine glands are distributed over the human body. Distribution varies from less than 100 to more than 300 per  $\text{cm}^2$ .

### THE SKIN'S APPENDAGES—NAILS

Nails facilitate our ability to use our fingers and toes to grasp and manipulate objects, protect our fingers and toes from physical trauma, and, from a cosmetic perspective, may be indicative of our socioeconomic status. Thus, human nail functionality extends beyond that of corresponding structures (i.e., nails, hooves, and claws) in other animals. The nail unit includes the nail folds, nail matrix, nail bed, and the skin under the free edge of the nail plate, i.e., the hyponychium. The nail plate (about 0.25–0.6 mm thick) consists of about 25 layers of highly interconnected keratinized cells and detaches from the nail bed at the hyponychium. Unlike the stratum corneum of the skin, the nail plate has been described as a substantially crosslinked, minimally lipoidal hydrogel with poor permeability to drug molecules.

## DRUG DELIVERY TO THE SKIN AND ITS APPENDAGES—BASIC PRINCIPLES

### THE SKIN

Drugs are applied to the skin to elicit one or more of four general effects: an effect on the skin surface, an effect within the

stratum corneum, a more deep-seated effect requiring penetration into the epidermis and dermis, or a systemic effect resulting from delivery of sufficient drug through the epidermis and the dermis to the vasculature to produce therapeutic systemic concentrations.

Drug activity on the skin surface may be in the form of a protective film (e.g., a zinc oxide cream or a sunscreen), an action against surface microorganisms, or a cleansing effect. Surface films may be somewhat occlusive and provide a moisturizing effect by diminishing loss of moisture from the skin surface. In such instances the film or film formation *per se* fulfills the objective of product design. The action of antimicrobials against surface flora requires more than simple delivery to the site. The vehicle must facilitate contact between the surface organisms and the active ingredient. Skin cleansers employ soaps or surfactants to facilitate the removal of superficial soil.

Drug effects within the stratum corneum are seen with certain sunscreens; *p*-aminobenzoic acid is an example of a sunscreensing agent that both penetrates and is substantive to stratum corneum cells. Skin moisturization takes place within the stratum corneum. Whether it involves the hydration of dry outer cells by surface films or the intercalation of water in the lipid-rich, intercellular laminae, the increased moisture results in the softening of the skin. Keratolytic agents, such as salicylic acid, act within the stratum corneum to cause a breakup or sloughing of stratum corneum cell aggregates. This is particularly important in conditions of abnormal stratum corneum such as psoriasis, a disease characterized by thickened, scaly plaques.

The stratum corneum also may serve as a *reservoir phase* or depot, wherein topically applied drug accumulates due to partitioning into or binding with skin components. This interaction can limit the subsequent migration of the penetrant unless the interaction capacity of the stratum corneum is surpassed by providing excess drug. The drug depot may also serve to sustain the flux of drug into the living epidermis and beyond. Examples of drugs that exhibit significant skin interaction include benzocaine, estrogens, scopolamine, and corticosteroids.

Given the mechanical resistance offered by the stratum corneum to topically applied drugs, the penetration of a drug into the viable epidermis and dermis may be difficult to achieve. But, once transepidermal permeation or percutaneous absorption has occurred, the continued diffusion of drug into the dermis is likely to result in drug transfer into the microcirculation of the dermis and then into general circulation. Nonetheless, it is possible to formulate drug delivery systems that provide substantial localized delivery without achieving correspondingly high systemic concentrations. Limited studies in man of topical triethanolamine salicylate, minoxidil, and retinoids—among others—demonstrate the potential of this approach.

Unwanted systemic effects stemming from the inadvertent transdermal penetration of drugs have been reported for a wide variety of compounds (e.g., benzocaine, hexachlorophene, lindane, corticosteroids, or *N,N*-diethyl-*m*-toluamide) over the years. With the commercial introduction of transdermal drug delivery systems for numerous drugs (e.g., clonidine,  $17\beta$ -estradiol, fentanyl, lidocaine, methylphenidate, nitroglycerin, nicotine, oxybutynin, rivastigmine, rotigotine, scopolamine, selegiline, and testosterone), transdermal penetration is now generally regarded as an opportunity rather than a nuisance.

Nonetheless, for a drug to qualify as a candidate for systemic delivery after topical application, it must satisfy additional requirements beyond the exhibition of good skin permeation. Successful candidates for transdermal drug delivery should be nonirritating and nonsensitizing to the skin. Since relatively little drug may reach systemic circulation over a relatively long time, drug candidates should be relatively potent drugs. In addition, the limitation to relatively potent drugs can ease problems of formulation, since the amount of drug that can be incorporated in the formulation may be limited by physicochemical considerations, such as solubility.

Percutaneous absorption involves the transfer of drug from the skin surface into the stratum corneum, under the aegis of a concentration gradient, and its subsequent diffusion through the stratum corneum and underlying epidermis, through the dermis, and into the microcirculation. The skin behaves as a passive barrier to diffusing molecules. Evidence for this includes the fact that the impermeability of the skin persists long after the skin has been excised. Furthermore, Fick's law is obeyed in the vast majority of instances.

Molecular transport through the various strata of the skin is limited by the diffusional resistances encountered in each of the regions. The total diffusional resistance ( $R_{skin}$ ) to drug permeation through the skin can be described as the sum of diffusional resistances offered by each of the successive regions of the skin:

$$R_{skin} = \sum (R_{sc} + R_e + R_{pd})$$

where  $R$  is the diffusional resistance, and the subscripts *sc*, *e*, and *pd* refer to the stratum corneum, epidermis, and papillary layer of the dermis, respectively. In addition, resistance to transfer into the microvasculature limits the systemic delivery of drug.

By and large, the greatest resistance to drug penetration is met in the stratum corneum (i.e., diffusion through the stratum corneum tends to be the rate-limiting step in percutaneous absorption).<sup>3</sup>

The role of hair follicles and sweat glands in percutaneous absorption must be considered, though their effect is minimized by the relatively small fractional areas occupied by these appendages (at least in humans). On the other hand, liposomal vehicles and microbead (3–10  $\mu\text{m}$  diameter) suspensions appear to accumulate selectively in pilosebaceous and perifollicular areas. In the very early stages of absorption, transit through the appendages may be comparatively large, particularly for lipid-soluble molecules and those whose permeation through the stratum corneum is relatively low. Surfactants and volatile organic solvents, such as ethanol, have been found to enhance drug uptake via the transfollicular route.

Rather than characterizing drug transfer into and through the skin in terms of the diffusional resistances encountered, one could define permeation in terms of the *pathways* followed by the diffusing species. Drug permeation through the intact skin of humans involves either an intercellular or transcellular path in the stratum corneum, for the most part, rather than the so-called shunt pathways (i.e., the transglandular or transfollicular routes).

The conventional wisdom is that for the most part, lipophilic compounds transfer preferentially into the lipoidal intercellular phase of the stratum corneum, while relatively more hydrophilic compounds transfer into the intracellular domain of the stratum corneum. One should keep in mind that the often-postulated biphasic character of the horny layer—with hydrophilic cells in a lipophilic matrix—is overly simplistic: the hydrophilic cells themselves are enclosed within lipid bilayer membranes, while the lipophilic matrix comprises intercellular lipids that are, in fact, present in lamellar structures that “sandwich in” hydrophilic layers. The intercellular pathway is *bicontinuous*, consisting of both a nonpolar and a polar diffusion pathway between the corneocytes. Thus, attempts to predict permeability constants from oil:water or solvent:water partition coefficients have had limited success.

The stratum corneum can be regarded as a passive diffusion membrane but not an inert system; it often has an affinity for the applied substance. The adsorption isotherm often is linear in dilute concentration ranges. The correlation between external and surface concentrations is given in terms of the tissue:solvent distribution coefficient  $K_m$ :

$$K_m \text{ is the } \frac{\text{solute absorbed per cm}^3 \text{ of tissue}}{\text{solute in solution per cm}^3 \text{ of solvent}} = \frac{C_m}{C_s}$$

The integrated form of Fick's law is given as

$$J_s = \frac{K_m DC_s}{\delta}$$

and

$$K_p = \frac{K_m D}{\delta}$$

where  $K_p$  is the permeability coefficient,  $J_s$  is the steady state flux of solute,  $C_s$  is the concentration difference of solute across the membrane,  $\delta$  is the membrane thickness, and  $D$  is the average membrane diffusion coefficient for the solute.

Percutaneous absorption of a drug can be enhanced by the use of occlusive techniques or by the use of so-called penetration enhancers.<sup>4–6</sup>

Occluding the skin with wraps or impermeable plastic film such as Saran Wrap prevents the loss of surface water from the skin. Since water is absorbed readily by the protein components of the skin, the occlusive wrap causes greatly increased levels of hydration in the stratum corneum. The concomitant swelling of the horny layer ostensibly decreases protein network density and the diffusional path length. Occlusion of the skin surface also increases skin temperature ( $\sim 2^\circ\text{--}3^\circ$ ), resulting in increased molecular motion and skin permeation.

Hydrocarbon bases that occlude the skin to a degree will bring about an increase in drug penetration. However, this effect is trivial compared with the effects seen with an occlusive skin wrap. Occlusive techniques are useful in some clinical situations requiring anti-inflammatory activity, and occlusive wrappings have been commonly used with steroids. Since steroid activity can be enhanced by two orders of magnitude by skin occlusion, it is possible to depress adrenal function unknowingly.

Transdermal drug delivery systems, with their occlusive backing, can effect increased percutaneous absorption as a result of increased skin temperature and hydration. Investigators have shown that exposure of the surrounding skin area to localized heating (e.g., via hot tubs and saunas) or cooling could cause extensive changes in transdermal drug bioavailability, presumably due to changes in regional cutaneous blood flow and subsequent systemic uptake.

One additional consequence of occlusion of the skin surface, whether by a transdermal delivery system or a hydrophobic film, is that an aqueous film may form at the formulation-skin interface. This aqueous film or interface could result in decreased transfer efficiency and, in the case of a transdermal delivery system, a loss of adhesion. Accordingly, the suppression of perspiration could enhance vehicle-skin partitioning efficiency and drug permeation.

The term “penetration enhancer” has been used to describe substances that facilitate drug absorption through the skin. Penetration enhancers with a direct effect on skin permeability include solvents, surfactants, and miscellaneous chemicals, such as urea and *N,N*-diethyl-*m*-toluamide (Table 29-1). While most such materials have a direct effect on the permeability of the skin, other so-called enhancers (e.g., polyols, such as glycerin and propylene glycol) appear to augment percutaneous absorption by increasing the thermodynamic activity of the penetrant, thereby increasing the effective escaping tendency and concentration gradient of the diffusing species. The mechanism of action of these enhancers is complex since these substances also may increase drug solubility. Nonetheless, the predominant effect of these enhancers is to either increase the stratum corneum's degree of hydration or disrupt its lipoprotein matrix. In either case, the net result is a decrease in resistance to drug (penetrant) diffusion. (The formulator should note that the inclusion of a penetration enhancer in a topical formulation mandates additional testing and evaluation to ensure the absence of enhancer-related adverse effects.)

Foremost among the solvents that affect skin permeability is water. Water is a factor even for *anhydrous* transdermal delivery systems due to their occlusive nature. Due to its safety and

efficacy, water has been described as the ultimate penetration enhancer. Other solvents include the classic enhancer, dimethyl sulfoxide (DMSO), which is of limited utility because of its potential ocular and dermal toxicity, its objectionable taste and odor (a consequence of its absorption and subsequent biotransformation), and the need for concentrations in excess of 70% to promote absorption. Analogs of DMSO such as decylmethyl sulfoxide are used currently in some topical formulations. In contrast to many other solvents, laurocapram (Azone) has been shown to function effectively at low concentrations ( $\leq 5\%$ ). Furthermore, laurocapram's effect on skin permeability persists long after a single application, due apparently to its prolonged retention within the stratum corneum.

Surfactants, long recognized for their ability to alter membrane structure and function, can have a substantial effect on skin permeability. However, given the irritation potential of surfactants applied chronically, their utility as penetration enhancers is limited. Their effect on permeability may be complicated further by surfactant monomer aggregation to form micelles and the concomitant solubilization of the permeant. As the impact of surfactants on skin permeability of a penetrant is problematic, the effect of their inclusion in a formulation should be evaluated using appropriate *in vitro* and *in vivo* studies.

Even though *in vitro* studies of percutaneous transport may reflect the resistance of the skin to drug diffusion, such studies cannot characterize adequately the transfer of diffusing drug into the microvasculature of the dermis and its subsequent transfer into general circulation. There is evidence in the literature of delayed dermal clearance in the aged. This may reflect, in part, a decrease in older subjects in dermal capillary loop density, a

decrease in the rate and/or extent of dermal blood perfusion, or an increase in resistance to transfer into the capillaries.

The potential effect of blood-flow-limited percutaneous absorption underscores the possible occurrence of cutaneous interactions between vasoconstrictors or vasodilators and topically applied drugs intended for a systemic effect: bioavailability could be increased or diminished as a result. The assessment of the potency of corticosteroids by corticosteroid-induced skin blanching (vasoconstriction) lends credence to this issue.

Another factor to consider is that the stratum corneum of older subjects may offer less resistance to the penetration of topically applied drugs due to the age-related increase in photochemical and mechanical damage to the skin.

Given the substantial intersubject variations that occur in diffusional resistance and in dermal clearance, it is not surprising that *in vivo* studies of percutaneous absorption often demonstrate marked intersubject differences in systemic availability of drugs. Furthermore, the tendency to employ normal, healthy, young adults in bioavailability studies may not provide data that is indicative of drug permeation through the skin of older subjects or patients. Comprehensive studies of percutaneous absorption as a function of age continue to be warranted.

Cutaneous biotransformation, i.e., catabolic enzymatic activity in the viable epidermis, is substantial. In fact, the viable epidermis is metabolically more active than the dermis. If the topically applied drug is subject to biotransformation during skin permeation, local and systemic bioavailability can be affected markedly. Enzymatic activity in the skin, or for that matter in systemic fluids and tissues, can be taken advantage of to facilitate percutaneous absorption.

The effect of regional variations in skin permeability can be marked. It has been suggested that one ought to differentiate between two species of horny layer: the palms and soles (up to 600  $\mu\text{m}$  thick), adapted for weight-bearing and friction; and the body horny layer ( $\sim 10\text{--}20$   $\mu\text{m}$  thick), adapted for flexibility, impermeability, and sensory discrimination.

Overall, data suggest the following order for diffusion of simple molecules through the skin: plantar < palmar < arms, legs, trunk, dorsum of hand < serotal and postauricular < axillary < scalp. Electrolytes in solution penetrate the skin poorly. Ionization of a weak electrolyte substantially reduces its permeability; e.g., sodium salicylate permeates poorly compared with salicylic acid. The development of iontophoretic devices in recent years may minimize this problem with ionic penetrants. For any specific molecule, the predictability of regional variations in skin permeability continues to elude investigators. Pharmacokinetic models that do not adequately reflect the anisotropicity of the skin's composition and structure, the skin's interactions with the drug and the vehicle, and the physiological parameters that affect transfer will not succeed in simulating or predicting the rate and extent of percutaneous drug absorption or transdermal delivery.

Classically, percutaneous absorption has been studied *in vivo*, using radioactively labeled compounds, or by *in vitro* techniques, using excised human or animal skin. *In vivo* studies have often made use of the skin-stripping method, which permits the estimation of the concentration or amount of the penetrating species as a function of depth of the stratum corneum. Layers of the stratum corneum can be removed or stripped successively away by the repeated application and removal of adhesive tape strips. Skin penetration of a drug and the effect of additives or formulation may be studied as a function of time and evaluated through analysis of successive individual skin strips that provide a temporal profile of skin penetration *via* appropriate dermatopharmacokinetic models.

Clearly, the evaluation of new chemical entities (NCEs) of indeterminate toxicity mandates *in vitro* testing. A diffusion cell often used for *in vitro* experiments is shown in Figure 29-2. In this system, the intact skin or the epidermis is treated as a semipermeable membrane separating two fluid media. The transport rate of a particular drug is evaluated by introducing

**Figure 29-2.** Schematic representation of a Franz diffusion cell. The top is open to ambient laboratory environment. (From Franz TJ. Percutaneous absorption. On the relevance of *in vitro* data. *J Invest Dermatol* 1975; 64: 190–195.)

the drug in solution on the stratum corneum side of the membrane, then measuring penetration by periodic sampling and analysis of the fluid in the receptor compartment.

Investigators have recognized that transport across an immersed, fully hydrated stratum corneum may not represent the absorption system or rate observed in *in vivo* studies. Percutaneous absorption across a fully hydrated stratum corneum may be an exaggeration. It may be more representative of enhanced absorption that is seen after *in vivo* skin is hydrated as a result of the application of an occlusive wrapping or material.

Numerous studies have demonstrated that *in vitro* studies of percutaneous absorption under controlled conditions are relevant to estimations of *in vivo* drug penetration. Although human skin is preferable for *in vitro* permeation studies, its availability is limited. Additional constraints apply if one is only willing to use freshly obtained viable human skin from surgical specimens or biopsies, as opposed to skin harvested from cadavers.

Concern has been voiced over the notorious variability in barrier properties of excised skin, whether animal or human. Factors responsible for the variability include the source and characteristics of the donor skin (e.g., elapsed time from death to harvesting of the skin, age and gender of the donor, and health of the skin prior to the donor's death), exposure of the skin to chemicals or mechanical treatment (e.g., shaving or clipping prior to harvesting of the skin), etc. The availability of a *living skin equivalent*—comprising a bilayered system of human dermal fibroblasts in a collagenous matrix, upon which human corneocytes have formed a stratified epidermis—offers an alternative, less variable, model for evaluating human skin permeation and biotransformation.

Skin-flap methods represent *in vivo* and *in vitro* techniques for evaluating percutaneous absorption in animals or animal models: the general approach entails the surgical isolation of a skin section of an animal such that the blood supply is singular; this ensures that drug can be collected and assayed in the vascular perfusate as it undergoes absorption from the skin surface. The perfused skin flap can be maintained in the intact animal or mounted in an *in vitro* perfusion system, all the while maintaining its viability.

Animals also have been used to detect contact sensitization, measure antimetabolic drug activity, measure phototoxicity, and evaluate the comedogenic and comedolytic potential of substances. In each of these test procedures, be it a safety test or assay model, the animal is considered a substitute for humans. It is, therefore, important to realize that the animal is not man, even though man is the ultimate test animal. Animal testing

presents the investigator with unique advantages; lack of appreciation of the variables involved can destroy these advantages.

Any evaluation of a study of percutaneous absorption in animals must take species variation into consideration. Just as percutaneous absorption in man will vary considerably with skin site, so will absorption in various animal species. There is a consensus that rhesus monkeys and miniature pigs are good *in vivo* models for human percutaneous absorption, while smaller laboratory animals (e.g., mouse, rat, and rabbit) are not. Nonetheless, it should be stressed that percutaneous absorption studies in animals, either *in vivo* or *in vitro*, only can be approximations of activity in humans. The effect of species variation, site variability (about which little is known in animals), skin condition, experimental variables, and, of major importance, the vehicle, must be kept in mind.

In recent years, *in silico* or *in numero* modeling or computer simulation of percutaneous absorption has been advocated as a link between *in vitro* and *in vivo* studies. A number of relatively simplistic dermatopharmacokinetic models have been developed that do provide the formulator with some insight into transdermal drug delivery, in spite of the biological and physicochemical complexity of drug transport into and through the skin. By and large, these models are analogous to the classical pharmacokinetic models that have been employed to assess *in vivo* drug uptake and disposition. Some of the dermatopharmacokinetic models proposed differ from more classically oriented models in that drug transport in the vehicle and in the epidermis, particularly the stratum corneum, is modeled in accordance with Fickian diffusion. Thus, the formulator can anticipate the effect of variables such as the thickness of the applied (vehicle) phase, alterations in drug partitioning between the vehicle and the stratum corneum, and the frequency of re-application on the overall appearance of drug systemically as a function of time following topical application.

The study of the targeted delivery of drugs to follicles and/or sebaceous glands has become necessary in view of the selective uptake or deposition of antiacne drugs, such as tretinoin in pilosebaceous units. Fortunately, the anatomical and physiological correspondence of hamster ear pilosebaceous units to those in humans has facilitated studies of the cutaneous and pilosebaceous disposition of drugs following topical application.

## UNGUAL AND PERUNGUAL DRUG DELIVERY

The properties of the nail unit (e.g., thickness and hydration) and the applied drug (e.g., molecular size, shape, electrical charge, and lipophilic-hydrophilic character) are critical factors affecting ungual and perungual drug delivery. Nonetheless, the hardness and rigidity of the nail plate—coupled with its relatively slow growth rate—generally do not bode well for drug absorption into and through the nail. Given the prevalence of disorders of the nail unit (e.g., fungal infections and psoriasis) in the general population, their refractoriness to treatment, and issues of safety and toxicity of long-term dosing of systemically administered drugs for these disorders, mechanistic studies of topical drug delivery and delivery system formulation need to be continued.

## THE FORMULATION OF DOSAGE FORMS AND DELIVERY SYSTEMS FOR TOPICAL DRUG APPLICATION?

The array of formulations and compositions employed for topical application confounds attempts at categorization. Considerable overlap is evident in the terminology used for topical products. Although the rheological properties of topical formulations have been suggested as a basis for discrimination among types of formulations, definitive differentiation and boundaries among formulation types are difficult to establish. Nonetheless, a distinction can be made between drug *dosage forms* and drug *delivery systems*. Dosage forms contain the active drug

ingredient in association with nondrug (usually inert) excipients that comprise the vehicle or formulation matrix. A conventional dosage form tends to be empirical in composition; its formulator's focus tends to emphasize stability and esthetics rather than efficacy. On the other hand, delivery systems involve a holistic approach to formulation that is optimized for the drug's relevant biopharmaceutic and pharmacokinetic characteristics in the patient population. Thus, a delivery system is formulated with functionality and efficacy in mind, not just stability and aesthetics.

## CONVENTIONAL DOSAGE FORMS

### The Skin

In many (if not most) clinical situations, the rate-limiting step is penetration of the drug across the skin barrier (i.e., percutaneous penetration through the skin alone). Diffusion of the drug from its vehicle should not be, unknowingly, the rate-limiting step in percutaneous absorption. Such a rate limitation or control may, of course, be an objective and the endpoint of specific drug optimization, but inappropriate formulation can reduce substantially the effectiveness of a topical drug substance.

In the formulation of a vehicle for topical drug application, many factors (drug stability, intended product use, site of application, and product type) must be considered in formulating a dosage form or delivery system that will release the drug readily when placed in contact with the skin. Further, the release characteristics of the vehicle depend on the physical-chemical properties of the specific drug substance to be delivered to the skin: drug release from a vehicle is a function of the drug's concentration and solubility in the vehicle, and the drug's partition coefficient between the vehicle and the skin. A vehicle optimized for delivery of hydrocortisone may be quite inappropriate for delivery of a different steroid.

Ostrenge *et al.*<sup>1</sup> discussed the significance of vehicle composition on the percutaneous absorption of fluocinonide acetonide and fluocinonide 21-acetate (fluocinonide) (see Figure 29-3). These investigators used propylene glycol/isopropyl myristate partition coefficients, *in vitro* (human) skin penetration, and finally *in vivo* vasoconstrictor studies to evaluate formulation variables. They concluded that

In general, an efficacious topical gel preparation is one in which (a) the concentration of diffusible drug in the vehicle for a given labeled strength is optimized by ensuring that all of the drug is in solution, (b) the minimum amount of solvent is used to dissolve the drug completely

**Figure 29-3.** *In vivo* response as a function of vehicle composition (24-hour vasoconstriction). (From Ostrenge J *et al.* Significance of vehicle composition. I. Relationship between topical vehicle composition, skin permeability, and clinical efficacy. *J Pharm Sci* 1971; 60: 1175–1179.)

and yet maintain a favorable partition coefficient and (c) the vehicle components affect the permeability of the stratum corneum in a favorable manner.

The effect of propylene glycol concentration on *in vivo* vasoconstrictor activity is illustrated strikingly in Figure 29-3.

Experimental work of the kind described by Ostrenge, Steinmetz, and Poulsen provides a means of optimizing drug release from a vehicle and penetration of the drug into the skin. The formulator must then proceed to develop a total composition in which the drug is stable and causes no irritation to sensitive skin areas. Safety, stability, and effective preservative efficacy must be combined with optimum drug delivery in the total formulation.

The work of Chiang, Weiner, and others<sup>2</sup> on the physicochemical stability of topical drug-delivery systems *postapplication* has facilitated the exploration of additional formulation factors that are crucial to the success of topical formulations. Flynn notes that the functionality of topical drug delivery systems stands in stark contrast to that of transdermal drug-delivery systems; while both delivery systems are open systems kinetically due to the formulation–skin interface, they differ to a considerable extent *thermodynamically* because most topical formulations are left open to the air postapplication, while transdermal delivery systems are self-contained closed systems.

One study focused on a topical delivery system for minoxidil. The vehicle was a 60:20:20 ethanol:propylene glycol:water system, with just enough propylene glycol to maintain 2 percent minoxidil in solution, following evaporation of the more volatile ethanol and water. Minoxidil fluxes across human cadaver skin, measured as a function of minoxidil concentration, increased as the initial concentration of drug increased, but only to about 3 percent (Figure 29-4). At initial minoxidil concentrations greater than 3 percent, transport was disproportionately low, relative to initial concentration, due to early precipitation of the drug.

Evaporation and loss of volatile formulation components, such as water or ethanol postapplication, can be expected to affect topical drug-delivery system composition and performance. Chiang *et al.*<sup>2</sup> have shown that so-called nonvolatile excipients, e.g., propylene glycol, evaporate after topical application. Skin permeation by excipients also may occur after application leading to further compositional changes in the applied film on the skin surface. The impact of this evaporative and absorptive loss of adjuvants increases as the volume of the applied formulation is reduced. As Chiang *et al.*<sup>2</sup> note, “the momentary compositions, and thus delivery capabilities, of real vehicles are significantly influenced by the amounts applied.”

**Figure 29-4.** Minoxidil flux ( $\times 10^4$  mg/cm<sup>2</sup>/h) through human cadaver skin as a function of minoxidil concentration in the topically applied formulation. (Data from Chiang C-M *et al.* Bioavailability assessment of topical delivery systems: effect of vehicle evaporation upon *in vitro* delivery of minoxidil from solution formulations. *Int J Pharm* 1989; 55: 229–236.)

## CONVENTIONAL TOPICAL DOSAGE FORMS—SEMISOLIDS

### THE USP CLASSIFICATION OF OINTMENT BASES

#### Ointments

The USP defines ointments as semisolid preparations intended for external application to the skin or mucous membranes. They usually, but not always, contain medicinal substances. The types of ointment bases used as vehicles for drugs are selected or designed to facilitate drug transfer into the skin. Ointments also contribute emolliency or other quasi-medicinal benefits. The USP recognizes four general classes of ointment bases: hydrocarbon bases (i.e., oleaginous bases), absorption bases, water-removable bases, and water-soluble bases. The selection of the optimum vehicle based on the USP classification *per se* may require compromises. For example, stability or drug activity might be superior in a hydrocarbon base; however, patient acceptability is diminished because of the greasy nature of the base. The water solubility of the polyethylene glycol bases may be attractive, but the glycol(s) may be irritating to traumatized tissue. For some drugs, activity and percutaneous absorption may be superior when using a hydrocarbon base; however, it may be prudent to minimize percutaneous absorption by the use of a less occlusive base. In other instances, activity and percutaneous absorption may be enhanced by using a hydrophilic base. These problematic aspects of bioavailability of drugs in topical formulations are discussed above.

#### HYDROCARBON (OLEAGINOUS) BASES

Hydrocarbon bases are usually petrolatum *per se* or petrolatum modified by waxes or liquid petrolatum to change viscosity characteristics. Liquid petrolatum gelled by the addition of polyethylene also is considered a hydrocarbon ointment base, albeit one with unusual viscosity characteristics.

Hydrocarbon ointment bases are classified as oleaginous bases along with bases prepared from vegetable fixed oils or animal fats. Bases of this type include lard, benzoated lard, olive oil, cottonseed oil, and other oils. Such bases are emollient but generally require addition of antioxidants and other preservatives. They are now largely of historic interest.

Petrolatum USP is a tasteless, odorless, unctuous material with a melting range of 38°C to 60°C; its color ranges from amber to white (when decolorized). Petrolatum often is used externally, without modification or added medication, for its emollient qualities.

Petrolatum used as an ointment base has a high degree of compatibility with a variety of medicaments. Bases of this type are occlusive and nearly anhydrous and thus provide optimum stability for medicaments such as antibiotics. The wide melting range permits some latitude in vehicle selection, and the USP permits addition of waxy materials as an aid in minimizing temperature effects.

Hydrocarbon bases, being occlusive, increase skin hydration by reducing the rate of loss of surface water. Bases of this kind may be used solely for such a skin-moisturizing or emollient effect. Skin hydration, on the other hand, may increase drug activity, as discussed earlier.

A gelled mineral oil vehicle (Plastibase) represents a unique member of this class of bases that comprises refined natural products: When approximately 5 percent of low-density polyethylene is added to liquid petrolatum and the mixture is then heated and subsequently shock-cooled, a soft, unctuous, colorless material resembling white petrolatum is produced. The mass maintains unchanged consistency over a wide temperature range. It neither hardens at low temperatures nor melts at reasonably high temperatures. Its useful working range is between -15°C and 60°C. Excessive heat (above 90°C), will destroy the gel structure.

On the basis of *in vitro* studies, drugs may be released faster from a gelled mineral oil vehicle than from conventional petrolatum. This quicker release has been attributed to easier diffusion of drug through a vehicle with lower microscopic viscosity (i.e., a vehicle that is essentially a liquid) than through petrolatum.

Despite the advantages that hydrocarbon or oleaginous vehicles provide in terms of stability and emolliency, such bases have the considerable disadvantage of greasiness. The greasy or oily material may stain clothing and is difficult to remove. In terms of patient acceptance, hydrocarbon bases (i.e., ointments) rank well below emulsion bases such as creams and lotions.

#### ABSORPTION BASES

Absorption bases are hydrophilic, anhydrous materials or hydrophilic bases that have the ability to absorb additional water. The former are anhydrous bases, which absorb water to become water-in-oil (W/O) emulsions; the latter are W/O emulsions, which have the ability to absorb additional water. The word absorption in this context refers only to the ability of the base to absorb water.

Hydrophilic petrolatum USP is an anhydrous absorption base. Its W/O emulsifying property is conferred by the inclusion of cholesterol. This composition is a modification of the original formulation, which contained anhydrous lanolin. The lanolin was deleted because of reports of allergy; cholesterol was added. Inclusion of stearyl alcohol and wax adds to the physical characteristics, particularly firmness and heat stability.

Absorption bases, particularly the emulsion bases, impart excellent emolliency and a degree of occlusiveness on application. The anhydrous types can be used when the presence of water would cause stability problems with specific drug substances (e.g., antibiotics). Absorption bases also are greasy when applied and are difficult to remove. Both of these properties are, however, less pronounced than with hydrocarbon bases.

Commercially available absorption bases include Aquaphor (Beiersdorf) and Polysorb (Fougera). Nivea Cream (Beiersdorf) is a hydrated emollient base. Absorption bases, either hydrophilic or anhydrous, are seldom used as vehicles for commercial drug products. The W/O emulsion system is more difficult to deal with than the more conventional oil-in-water (O/W) systems, and there is, of course, reduced patient acceptance because of greasiness.

#### WATER-REMOVABLE (WATER-WASHABLE) BASES

Water-removable bases are O/W emulsion bases, commonly referred to as *creams*, and represent the most commonly used type of ointment base. By far the majority of commercial dermatologic drug products are formulated in an emulsion (or cream) base. Emulsion bases are washable and are removed easily from skin or clothing. Emulsion bases can be diluted with water, although such additions are uncommon.

As a result of advances in cosmetic chemistry the formulator of an emulsion base is faced with a bewildering array of potential ingredients. A glance at the cosmetic literature and such volumes as the *International Cosmetic Ingredient Dictionary and Handbook* impresses one with the enormous number and variety of emulsion-base components, particularly surfactants and oil-phase components. Many of these substances impart subtle but distinct characteristics to cosmetic emulsion systems. While desirable, many of these characteristics are not really necessary in drug dosage forms or delivery systems. Furthermore, the likelihood of drug-excipient interactions, either physical or chemical, increases substantially (as does the cost) as the number of formulation components is increased. Thus, the formulator of topical products should minimize the number of excipients in the formulation. Nonetheless, emulsion bases typically include antimicrobial preservatives, stabilizers (such as antioxidants, metal chelating agents, or buffers), and humectants (e.g., glycerin or propylene glycol), in addition to the emulsifiers, in order to ensure stability and efficacy.

Soaps and detergents (i.e., emulsifiers) have, overall, a damaging effect on the skin. Both anionic and cationic surfactants can cause damage to the stratum corneum in direct proportion to concentration and duration of contact. Nonionic surfactants appear to have much less effect on the stratum corneum.

### WATER-SOLUBLE BASES

Soluble ointment bases, as the name implies, are made up of soluble components or may include gelled aqueous solutions. The latter often are referred to as gels, and in recent years have been formulated specifically to maximize drug availability.

Major components, and in some instances the only components, of water-soluble bases are the polyethylene glycols (PEGs). Patch tests have shown that these compounds are innocuous, and long-term use has confirmed their lack of irritation. PEGs are relatively inert, nonvolatile, water-soluble or water-miscible liquids or waxy solids identified by numbers that are an approximate indication of molecular weight. Polyethylene glycol 400 is a liquid superficially similar to propylene glycol, while polyethylene glycol 6000 is a waxy solid.

Polyethylene glycols of interest as vehicles include the 1500, 1600, 4000, and 6000 products, ranging from soft, waxy solids (polyethylene glycol 1500 is similar to petrolatum) to hard waxes. Polyethylene glycols, particularly 1500, can be used as a vehicle *per se*; however, better results often are obtained by using blends of high- and low-molecular-weight glycols, as in polyethylene glycol ointment NF. The water-solubility of polyethylene glycol vehicles does not ensure availability of drugs contained in the vehicle. Because hydrated stratum corneum is an important factor in drug penetration, the use of polyethylene glycol vehicles, which are anhydrous and nonocclusive, actually may hinder percutaneous absorption due to dehydration of the stratum corneum.

Aqueous gel vehicles containing water, propylene, and/or polyethylene glycol and gelled with a carbomer or a cellulose derivative also are classed as water-soluble bases. Bases of this kind, sometimes referred to as *gels*, may be formulated to optimize delivery of a drug, particularly steroids. In such a preparation propylene glycol is often used for its solvent properties as well as for its antimicrobial or preservative effects.

Gelling agents used in these preparations may be nonionic or anionic. Nonionics include cellulose derivatives, such as methylcellulose or hypromellose (hydroxypropyl methylcellulose). Sodium carboxymethylcellulose is an anionic cellulose derivative.

Carbomers are the NF designation for various polymeric acrylic acids, crosslinked with carbohydrates or polyalcohol derivatives that are dispersible but insoluble in water. When the acid dispersion is neutralized with a base, a clear, stable gel is formed. Carbomers for which monographs appear in the NF include carbomers 910, 934, 934P, 940, 941, and 1342, as well as the more complex carbomer copolymer, carbomer homopolymer, and carbomer interpolymer.

Other gelling agents employed in topical formulations include sodium alginate and the propylene glycol ester of alginic acid (Kelcoloid). Sodium alginate is a hydrophilic colloid that functions satisfactorily between pH 4.5 and 10; addition of calcium ions will gel fluid solutions of sodium alginate.

Gels can also be formed or stabilized by the incorporation of finely divided solids such as colloidal magnesium aluminum silicate (Veegum) or colloidal (fumed) silicon dioxide (Aerosil, Cab-O-Sil). These inorganic particulates can function as emulsifiers and suspending agents as well as gellants. Their compatibility with alcohols, acetone, and glycols makes them particularly useful in topical gel formulations.

### PREPARATION

Ointment preparation or manufacture depends on the type of vehicle and the quantity to be prepared. The objective is the same (i.e., to disperse the drug uniformly throughout the

vehicle). Normally, the drug materials are either in finely powdered form or in solution before being dispersed in the vehicle.

### INCORPORATION OF DRUG BY LEVIGATION

The incorporation of a drug powder in small quantities of an ointment (i.e., 30–90 g) can be accomplished by using a spatula and an ointment tile (either porcelain or glass). The drug material is levigated thoroughly with a small quantity of the vehicle or a miscible liquid component of the formulation (e.g., propylene glycol; light mineral oil) to form a concentrate. The concentrate then is diluted geometrically with the remainder of the base.

If the drug substance is water soluble, it can be dissolved in water and the resulting solution incorporated into the vehicle by use of a small quantity of lanolin, if the base is oleaginous. Generally speaking, an amount of anhydrous lanolin equal in volume to the amount of water used will suffice.

On a larger scale, mechanical mixers (e.g., Hobart mixers and pony mixers) are used. The drug substance in finely divided form usually is added slowly or sifted into the vehicle contained in the rotating mixer. When the ointment is uniform, the finished product may be processed through a roller mill to ensure complete dispersion and reduce any aggregates.

An alternative procedure involves preparing and milling a concentrate of the drug in a portion of the base. The concentrate then is dispersed in the balance of the vehicle, using a mixer of appropriate size. Occasionally, the base may be melted for easier handling and dispersing. In such cases the drug is dispersed and the base slowly cooled, using continuous agitation to maintain dispersion.

### EMULSION FORMULATIONS

Emulsions are prepared generally by combining the “oil”-soluble ingredients (e.g., petrolatum, waxes, and fats) and heating the admixture to about 75°C (i.e., a temperature at which the oil-phase ingredients are molten). The “water”-soluble ingredients are combined separately and heated to slightly above 75°C. The aqueous phase then is added to the oil phase, slowly and with constant agitation. When the emulsion is formed, the mixture is allowed to cool, maintaining slow agitation.

At this stage in the process the medicinal ingredients usually are added as a concentrated slurry, which usually has been milled to reduce any particle aggregates. Volatile or aromatic materials generally are added when the finished emulsion has cooled to about 35°C. At this point, additional water may be added to compensate for any evaporative losses occurring during exposure and transfer at the higher temperatures of emulsion formation.

While the product remains in the tank in bulk, quality-control procedures are performed (e.g., for pH, active ingredients). If control results are satisfactory, the product is filled into the appropriate containers.

## OTHER DOSAGE FORMS FOR APPLICATION TO THE SKIN AND ITS APPENDAGES

### POULTICES (CATAPLASMS)

Poultices, or cataplasms, represent one of the most ancient classes of pharmaceutical preparations. A poultice is a soft, moist mass of meal, herbs, seed, etc., usually applied hot in a cloth. The consistency is gruel-like, which is probably the origin of the word poultice.

Cataplasms were intended to localize infectious material in the body or to act as counterirritants. The materials tended to be absorptive, which, together with heat, accounts for their popularity. None is now official in the USP. The last official product was Kaolin Poultice NF IX.

### PASTES

The USP defines pastes as semisolid dosage forms that contain one or more drug substances intended for topical application.

Pastes are divided into fatty pastes (e.g., zinc oxide paste) and those made from a single-phase aqueous gel (e.g., carboxymethylcellulose sodium paste). Another official paste is triamcinolone acetonide dental paste.

The term *paste* is applied to ointments in which large amounts of solids have been incorporated (e.g., zinc oxide paste). In the past, pastes have been defined as concentrates of absorptive powders dispersed (usually) in petrolatum or hydrophilic petrolatum. These fatty pastes are stiff to the point of dryness and are reasonably absorptive considering they have a petrolatum base. Pastes often are used in the treatment of oozing lesions, where they act to absorb serous secretions. Pastes also are used to limit the area of treatment by acting both as an absorbent and a physical dam.

Pastes adhere reasonably well to the skin and are poorly occlusive. For this reason they are suited for application on and around moist lesions. The heavy consistency of pastes imparts a degree of protection and may, in some instances, make the use of bandages unnecessary. Pastes are less macerating than ointments.

Because of their physical properties pastes may be removed from the skin by the use of mineral oil or a vegetable oil. This is particularly necessary when the underlying or surrounding skin is traumatized easily.

## POWDERS

Powders for external use usually are described as dusting powders. Such powders should have a particle size of not more than 150  $\mu\text{m}$  (i.e., less than 100-mesh) to avoid any sensation of grittiness, which could irritate traumatized skin. Dusting powders usually contain starch, talc, and zinc stearate. Absorbable dusting powder USP is composed of starch treated with epichlorohydrin, with not more than 2.0% magnesium oxide added to maintain the modified starch in impalpable powder form; since it is intended for use as a lubricant for surgical gloves, it should be sterilized (by autoclaving) and packaged in sealed paper packets.

The fineness of powders often is expressed in terms of mesh size, with impalpable powders generally in the range of 100- to 200-mesh (149 to 75  $\mu\text{m}$ ). Determination of size by mesh analysis becomes increasingly difficult as particle size decreases below 200-mesh.

## DRESSINGS

Dressings are external applications resembling ointments, usually used as a covering or protection. Petrolatum gauze is a sterile dressing prepared by adding sterile, molten, white petrolatum to precut sterile gauze in a ratio of 60 g of petrolatum to 20 g of gauze. Topical antibacterials are available in the form of dressings.

## CREAMS

Creams are viscous liquid or semisolid emulsions of either the O/W or W/O type. Pharmaceutical creams are classified as water-removable bases in the USP and are described under *Ointments*. In addition to ointment bases, creams include a variety of cosmetic-type preparations. Creams of the O/W type include shaving creams, hand creams, and foundation creams; W/O creams include cold creams and emollient creams.

## PLASTERS

Plasters are substances intended for external application, made of such materials and of such consistency as to adhere to the skin and attach to a dressing. Plasters are intended to afford protection and support and/or to furnish an occlusive and macerating action and to bring medication into close contact with the skin. Medicated plasters, long used for local or regional drug delivery, are the prototypical transdermal delivery system.

Plasters usually adhere to the skin by means of an adhesive material. The adhesive must bond to the plastic backing and to

the skin (or dressing) with proper balance of cohesive strengths. Such a proper balance provides for removal (adhesive breakage at the surface of application), thus leaving a clean (skin) surface when the plaster is removed.

## THE EVOLUTION OF TRANSDERMAL DRUG DELIVERY SYSTEMS FROM CONVENTIONAL TOPICAL FORMULATIONS

Conventional medicated topicals (e.g., creams and ointments) seldom permit substantial systemic uptake of the drug or drugs incorporated therein. This is a consequence, in part, of the limited persistence or residence time of the topical formulation on the skin surface. In effect, a drug does not remain in contact with the absorbing surface long enough for sufficient drug to transfer into the skin and, ultimately, into systemic circulation. Furthermore, there is the concomitant problem of the gradual depletion of drug from the region of the topical formulation immediately adjacent to the skin surface and the corresponding reduction in the concentration gradient for drug transfer from the topical formulation to the skin.

The emergence of adhesive transdermal drug delivery systems (TDDSs) in the early 1980s permitted skin residence times to increase from hours to days. The novel matrix- or reservoir-formulations employed in these TDDSs also provided for the maintenance of relatively uniform concentrations of diffusible drug in the formulation, thereby preventing the formation of drug-depleted regions within the topical formulation and helping to ensure relatively constant drug-release rates over an extended period of time. As noted above, skin occlusion by the water-impermeable backing film of TDDSs further facilitates TDDS systemic efficacy by increasing skin hydration and temperature, with a corresponding increase in the rate and extent of skin permeation. The inclusion of skin-penetration enhancers in medicated topicals serves to decrease diffusional resistance and increase transport.

Nonetheless, these—by now—*conventional* TDDSs have their limitations: the increased residence time of occlusive TDDSs on the skin surface leads to an increased incidence of skin maceration and adverse cutaneous reactions. In addition, effective skin permeation is limited to relatively small (<1 kDa) lipophilic drug molecules. Thus, increasingly more attention is being placed on alternative TDDSs—e.g., electrically modulated systems and mechanical systems—which circumvent the need for partitioning and diffusion of the drug out of the formulation matrix and into and through the skin. *Electrically modulated* systems, or *electrotransport* systems, facilitate drug transport by an external electrical field. Electrotransport mechanisms include *iontophoresis*, *electroosmosis*, and *electroporation*. *Mechanically* (physically) modulated systems are exemplified by systems employing *phonophoresis* or those using *microneedle arrays* to achieve transdermal drug delivery.

## ELECTRICALLY MODULATED TRANSDERMAL DELIVERY SYSTEMS

For some poorly absorbed (ionic) compounds, parenteral administration appears to be the only viable option for regional or systemic delivery, because chemical penetration enhancers (Table 29-1) often do not function well for these compounds. Given the increased risk of adverse reactions associated with the use of such enhancers, the increased evaluation of iontophoretic devices for the enhancement of topical drug delivery has been of great interest. Iontophoretic drug delivery implies the delivery of ionic drugs into the body by means of an electric current. While the stratum corneum forms the principal barrier to electrical conductivity—due, in part, to its lower water content—the skin also acts as a capacitor. Thus, biological tissues such as the skin provide for a reactive electrical circuit. Ionic transport through the skin in the presence of a uniform electric field can be described, in part, in accordance with the Nernst-Planck equation

$$J_i = -D \frac{dC}{dx} + \frac{DzeEC}{kT}$$

where  $J_i$  is the flux of ions across the membrane,  $C$  is the concentration of ions with valence  $z$  and electron charge  $e$ ,  $dC/dx$  is the concentration gradient,  $E$  is the electric field,  $k$  is Boltzmann's constant, and  $T$  is the absolute temperature. Thus, the ionic flux is the sum of the fluxes that arise from the concentration gradient and the electric field. Given the complexity of the skin's composition, the thickness of the stratum corneum, and the occurrence of electroosmotic effects, the Nernst-Planck equation is only a first approximation of the overall transdermal flux of a solute. Faraday's law

$$\frac{Q}{t} = \frac{t_j i}{|z| F}$$

further characterizes the iontophoretic flux  $Q/t$  in terms of the current  $i$  (in amperes) and its duration  $t$  (in seconds), the transference number parameter  $t_j$ , and the Faraday constant  $F$ . Additional factors that influence the rate and extent of iontophoretic delivery through the skin include pH and ionic strength of the drug solution.

Although iontophoretic techniques have been shown to increase percutaneous absorption of ionizable or ionic drugs (including lidocaine, salicylates, and peptides and proteins, such as insulin) markedly, the clinical safety and efficacy of drug-delivery systems employing iontophoretic technology have yet to be evaluated fully.

Problematic aspects of electrotransport include cutaneous irritation or erythema and the effect of the electrical field on the integrity and stability of the formulation. Electrically induced alterations in the formulation generally arise as a result of iontophoresis (due to the increased flux of ions) or electroosmosis (due to the electrically induced convective transport of water molecules and associated electrically neutral solutes). The use of pulsed or intermittent current electrotransport systems has been suggested as an alternative to continuous current systems. *Electroporation*—the use of pulsed electrical current to provoke the transient formation of pores in biomembranes—also has been suggested as an alternative, or complement, to iontophoresis. In any event, the potential of electrically modulated drug-delivery systems for the effective transdermal delivery of large, polar, or ionic molecules (e.g., proteins, peptides, DNA) necessitates continued research in this field. One encouraging advance in this area is the development of flexible wafer-thin arrays of conductive layers or filaments for drug delivery systems that are less bulky and potentially more acceptable to patients.

### MECHANICALLY MODULATED TRANSDERMAL DELIVERY SYSTEMS

*Phonophoresis*, or *sonophoresis*, is defined as the movement of drug molecules through the skin under the influence of ultrasound. In general, ultrasound frequencies 1 to 3 MHz and intensities of 0.01 to 2 W/cm<sup>2</sup> have been used with varying degrees of effectiveness,<sup>36</sup> although high-frequency, low-intensity ultrasound has been observed to increase transdermal drug flux and decrease percutaneous diffusional lag times. A more recent analysis of ultrasound-enhanced transdermal transport indicates that low-frequency sonophoresis is much more important than high-frequency sonophoresis in enhancing transport. Various thermal and nonthermal changes have been implicated to explain phonophoretically induced increases in drug transport through the skin. Although the effect of temperature increases on molecular diffusivity and flux is clear, nonthermal effects of ultrasound (e.g., cavitation) are less clear. Transient ultrasound-induced cavitation (i.e., the generation and oscillation of gas bubbles) in the stratum corneum apparently perturbs barrier permeability and solute transport in the aqueous regions of the stratum corneum. Evidence for this is the lack of correlation between phonophoretic permeability and permeant lipophilicity.

**Figure 29-5.** Electron micrograph of a microneedle array for transdermal drug delivery. (Courtesy of Georgia Institute of Technology; ©Georgia Tech Res Corp.)

Both hollow and solid drug-coated microneedle arrays (Figure 29-5) have been proposed as painless adjuncts to transdermal delivery systems. Microneedles (e.g., 150- $\mu$ m long) can penetrate the stratum corneum, thereby facilitating drug access to the living epidermis and dermis and ultimately to systemic circulation. In one embodiment of this approach, silicon microneedles—prepared by reactive ion etching microfabrication techniques originally developed for integrated circuits—leave holes about 1  $\mu$ m in diameter when removed from the skin. Other materials (e.g., stainless steel) have been proposed for transdermal needle array systems but are still undergoing evaluation for safety and efficacy. Possible problems with microneedle arrays include extent and duration of access of the perforated cutaneous tissue to pathogens and potentially hazardous chemicals on the skin surface.

### NAILS

Conventional topical drug formulations for nail disorders have been limited, for the most part, to semisolids such as creams and ointments. The use of agents such as urea and salicylic acid to hydrate and soften the nail plate, thereby facilitating unguinal drug delivery, has not been uniformly successful. The most promising approaches to date involve the development of drug-containing nail lacquers or varnishes (transungual delivery systems) akin to cosmetic nail polishes. These formulations generally consist of a solution of the drug(s) in a quick-drying solution of a film-forming polymer. Following application of the drug-containing lacquer to the nail plate, the solvent evaporates, leaving the drug(s) in an adherent polymer film on the surface of the nail. Subsequent drug diffusion from the polymer film into the nail plate and the nail bed would be expected to yield effective unguinal concentrations of the drug, as long as drug partitioning from the polymer film into the nail unit was substantial enough. Thus, formulation factors to be considered include drug content and solubility in the nail lacquer, relative affinity of the drug for the polymer film and the nail unit, the diffusivity of the drug in the polymer film and the nail unit components, and the degree of hydration of the nail plate (this can be influenced by the polymer film-induced reduction of water loss to the environment from the nail surface).<sup>8,9</sup>

## RECTAL, VAGINAL, AND URETHRAL ROUTES OF ADMINISTRATION

### ANATOMIC AND PHYSIOLOGIC ASPECTS OF THE RECTAL, VAGINAL, AND URETHRAL ROUTES OF ADMINISTRATION

#### The Rectal Route

The rectum is about 150 mm in length, terminating in the anal opening; its surface area is about 200 to 400 cm<sup>2</sup>. In the absence of fecal matter, the rectum contains a small amount of fluid

(1 to 3 mL) of low buffering capacity. Fluid pH is purported to be about 7.2; because of the low buffer capacity, rectal pH will vary with the pH of the drug product or drug dissolved in it.

The bioavailability of rectally administered drugs is a relatively recent concern despite the antiquity of this dosage form; little was known about drug absorption or drug activity via suppository administration until recent years. Rectally instilled preparations, whether suppositories, foams, or solutions (enemas), tend to be confined to the rectum and sigmoid colon if the volume is less than about 50 mL. Foams tend to dissipate or spread to a lesser extent than solutions, particularly large-volume solutions (~100 to 200 mL). Although large-volume fluid formulations—solutions or enemas—may allow drug to reach the ascending colon, substantial intra- and intersubject variation is evident. Surveys of the literature indicate that rectal drug absorption from suppositories can be erratic and may be substantially different from absorption following oral administration. With only a few recent exceptions, suppository studies are based on either *in vivo* or *in vitro* data, with few attempts to correlate *in vitro* results with *in vivo* studies.

Major factors affecting the absorption of drugs from suppositories administered rectally are the following: anorectal physiology, suppository vehicle, and the physicochemical properties of the drug.

Most rectal suppositories today are torpedo-shaped, with the apex, or pointed end, tapering to the base, or blunt end, following the recommendation of H. S. Wellcome in 1893 that rectal suppositories should be inserted with the thicker end foremost so that when the anal sphincter contracts, expulsion is prevented. In the intervening 100 years or so, no study has correlated rectal suppository insertion with anorectal physiology until that of Abd-El-Maeboud *et al.*,<sup>10</sup> who found that ease of insertion, retention, and lack of expulsion were enhanced when the suppository was inserted base or blunt end up. This was ascribed to reversed vermicular contractions of the external anal sphincter, which facilitate movement of the suppository upward into the rectum.

The rectal epithelium is lipoidal in character. The lower, middle, and upper hemorrhoidal veins surround the rectum. Only the upper vein conveys blood into the portal system; thus, drugs absorbed into the lower and middle hemorrhoidal veins will bypass the liver. Absorption and distribution of a drug therefore are modified by its position in the rectum, in the sense that at least a portion of the drug absorbed from the rectum may pass directly into the inferior vena cava, bypassing the liver.

Spreading characteristics of rectal formulations may be affected considerably by intraluminal rectal pressure—due, in part, to the weight of abdominal organs and to respiratory activity—and by periodic contractile activity of the rectal wall.

Based on available data, the bioavailability of a drug from a suppository dosage form depends on the physicochemical properties of the drug as well as the composition of the base. The drug-dissolution rate and, where appropriate, the partition coefficient and aqueous phase should be known.

For suppository formulation the relative solubility of the drug in the vehicle is a convenient comparison measure. Lipid-soluble drugs present in low concentration in a cocoa butter base will have little tendency to partition and diffuse into rectal fluids. Drugs that are only slightly soluble in the lipid base will partition readily into the rectal fluid. The partition coefficient between suppository base and rectal fluid thus becomes a useful measure. In water-soluble bases, assuming rapid dissolution, the rate-limiting step in absorption would be transport of the drug through the rectal mucosa.

In the absence of evidence of any substantial carrier-mediated uptake mechanisms, the predominant mechanism of colorectal mucosal permeation appears to involve transcellular passage across cell membranes in accordance with the pH-partition hypothesis. Ease of access to the rectal mucosa has encouraged the evaluation of absorption enhancers. A wide variety of substances have been investigated for their ability to enhance rectal

permeability to drugs. Agents such as EDTA have been used to chelate  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in the vicinity of paracellular tight junctions and, thus, alter epithelial permeability. Other promoters of rectal absorption (e.g., bile salts and nonsteroidal anti-inflammatory agents, including aspirin, salicylic acid, and diclofenac) appear to exert their influence by affecting water influx and efflux rates across the rectal mucosa. Surfactants not only may modify membrane permeability but also may enhance wetting or spreading of the base and dissolution of the drug. In any event, it should be evident that whatever the mechanism, enhancing the rectal absorption of drugs—especially those that undergo presystemic elimination—could result in substantially reduced dosage requirements and decreased risk of adverse reactions.

Clearly, the bioavailability of a drug administered rectally depends on the nature of the drug and the composition of the vehicle or base. The physical properties of the drug can be modified to a degree, as can the characteristics of the base selected as the delivery system. Preformulation evaluations of physicochemical properties then must be confirmed by *in vivo* studies in animals and ultimately in the primary primate, the human. Dogs are probably the animal of choice in evaluating rectal drug availability. (The pig is a closer physiological match, but size and manageability argue in favor of the dog.) Blood and urine samples can be obtained from the dog, and rectal retention can be accomplished with facility. Smaller animals have been used; rabbits, rats, and even mice have been employed, but dosing and sampling become progressively more difficult.

Human subjects provide the ultimate measure of drug bioavailability. Subjects are selected on the basis of age, weight, and medical history. Subjects usually are required to fast overnight and evacuate the bowel prior to initiation of the study. Fluid volume and food intake usually are standardized in studies of this kind.

Given the difficulty of standardizing pharmacological endpoints, the usual measure of rectal drug bioavailability is the concentration of the drug in blood and/or urine as a function of time. A control group using oral drug administration provides a convenient means of comparing oral and rectal drug availability. While there is general agreement about drug absorption from the rectum, there is less agreement on dosage adequacy and the relationship between oral and rectal dosage. This state of affairs argues in favor of adequate studies to establish proper dosage and verify bioavailability.

### The Vaginal Route

Passive drug absorption via the vaginal mucosa, as with other mucosal tissues, is influenced by absorption site physiology, absorption site pH, and the solubility and partitioning characteristics of the drug. The vaginal epithelial surface usually is covered with an aqueous film—emanating from cervical secretions—whose volume, pH, and composition vary with age, stage of the menstrual cycle, and location. Postmenarche, a vaginal pH gradient is evident, with the lowest values (pH ~4) near the anterior fornix and the highest (pH ~5) near the cervix. Vaginal pH increases with menstrual, cervical, and uterine secretions.

Following intravaginal administration, some drug absorption from the intact vaginal mucosa is likely, even when the drug is employed for a local effect. In fact, extensive drug absorption can occur from the vagina. Furthermore, systemic drug concentrations following vaginal dosing may be significantly higher than those after peroral administration of an equivalent dose; a reflection, in part, of decreased first-pass biotransformation following vaginal absorption. Nonetheless, the notion persists that the vaginal epithelium is relatively impermeable to drugs.

The widespread extemporaneous compounding of progesterone vaginal suppositories as well as the marketing of an intrauterine progesterone drug delivery system (Progestasert, Alza), has focused interest on systemic drug absorption following intravaginal administration. However, only limited reports of research on *in vitro* and *in vivo* aspects of vaginal absorption have appeared in the literature to date.

## The Urethral Route

Minimal information has been published to date on the biopharmaceutical aspects of the urethral route of administration. Nonetheless, drug absorption from the urethral lumen via the urethral mucosa could be expected to be governed by the same principles that apply to drug absorption across other mucosal surfaces. The functional length of the urethra (from the bladder neck) in females is approximately 3 cm; in the male, approximately 4 to 5 cm.

## RECTAL, VAGINAL, AND URETHRAL DOSAGE FORMS AND DELIVERY SYSTEMS

### Conventional Dosage Forms—Suppositories

Suppositories are solid dosage forms of various weights and shapes, usually medicated, for insertion into the rectum, vagina, or urethra. After insertion, suppositories soften, melt, disperse, or dissolve in the cavity fluids.

The use of suppositories dates from the distant past, this dosage form being referred to in writings of the early Egyptians, Greeks, and Romans. Suppositories are suited particularly for administration of drugs to the very young and the very old, a notion first recorded by Hippocrates.

**Rectal Suppositories.** The USP describes rectal suppositories for adults as tapered at one or both ends and usually weighing about 2 g each. Infant rectal suppositories usually weigh about one-half that of adult suppositories. Drugs having systemic effects, such as sedatives, tranquilizers, and analgesics, are administered by rectal suppository; however, the largest single-use category is probably that of hemorrhoid remedies dispensed over the counter. The 2-g weight for adult rectal suppositories is based on use of cocoa butter as the base; when other bases are used, the weights may be greater or less than 2 g. An interesting variation on molded rectal suppositories is the so-called rectal “rocket,” for the treatment of hemorrhoidal conditions.<sup>11</sup>

**Vaginal Suppositories.** The USP describes vaginal suppositories, or pessaries, as usually globular or oviform and weighing about 5 g each. Vaginal medications are available in a variety of physical forms, e.g., creams, gels, or liquids, which depart from the classical concept of suppositories.<sup>12,13</sup> Vaginal tablets, or inserts prepared by encapsulation in soft gelatin, however, do meet the definition and represent convenience both of administration and manufacture.

**Urethral Suppositories.** Urethral suppositories, or bougies, are not described specifically in the USP, either by weight or dimension. Traditional values, based on the use of cocoa butter as a base, are as follows for these cylindrical dosage forms: diameter: 5 mm; length: 50 mm female, 125 mm male; weight: 2 g female, 4 g male. An intraurethral insert containing the prostaglandin alprostadil is available for the treatment of erectile dysfunction. The commercial formulation, described as a sterile micropellet (1.4 mm in diameter and 6 mm long), consisting of the drug and polyethylene glycol 1450, is inserted 3 cm deep into the urethra by use of a hollow applicator.

**Suppository Bases (Vehicles).** The ideal suppository base should meet the following general specifications:

- The base is nontoxic and nonirritating to mucous membranes.
- The base is compatible with a variety of drugs.
- The base melts or dissolves in rectal fluids.
- The base should be stable on storage; it should not bind or otherwise interfere with release or absorption of drug substances.

Rectal suppository bases can be classified broadly into two types: fatty and water soluble or water miscible. The traditional cocoa butter vehicle is immiscible with aqueous tissue fluids but melts at body temperature. Water-soluble or water-miscible vehicles also have been used. In general, formulators have been

reluctant to use glycerinated gelatin as a rectal suppository base because of its relatively slow dissolution. More typical of this class is the polyethylene glycol vehicle. Drug absorption from such dissimilar bases can differ substantially.

The USP lists the following as usual suppository bases: cocoa butter, cocoa butter substitutes (primarily vegetable oils modified by esterification, hydrogenation and/or fractionation), glycerinated gelatin, hydrogenated vegetable oils, mixtures of polyethylene glycols of various molecular weights, and fatty acid esters of polyethylene glycol.

**Cocoa Butter and Other Fatty Bases.** Theobroma oil, or cocoa butter, is a naturally occurring triglyceride. About 40 percent of the fatty acid content is unsaturated. As a natural material there is considerable batch-to-batch variability. A major characteristic of theobroma oil is its polymorphism (i.e., its ability to exist in more than one crystal form). While cocoa butter melts quickly at body temperature, it is immiscible with body fluids; this may inhibit the diffusion of fat-soluble drugs to the affected sites. Oleaginous vehicles, such as cocoa butter, seldom are used in vaginal preparations for esthetic reasons: many women consider them messy and prone to leakage.

If, in the preparation of suppositories, the theobroma oil is overheated (heated to about 60°), molded, and chilled, the suppositories formed will melt below 30°C. The fusion treatment of theobroma oil requires maximum temperatures of 40°C to 50°C to avoid a change in crystal form and melting point. Theobroma oil, heated to about 60°C and cooled rapidly, will crystallize in an alpha configuration characterized by a melting point below 30°C. The alpha form is metastable and will slowly revert to the beta form, with the characteristic melting point approaching 35°C. The transition from alpha to beta is slow, taking several days. The use of low heat and slow cooling allows direct crystallization of the more stable beta crystal form.

Certain drugs will depress the melting point of theobroma oil. This involves no polymorphic change, although the net effect is similar. Chloral hydrate is an example of a drug with a rectal dose (0.5 to 1.0 g, as a hypnotic agent) that causes a substantial melting-point depression. This effect can be countered by addition of a higher-melting wax, such as white wax or synthetic spermaceti. The amount to be added must be determined by temperature measurements. The effect of such additives on bioavailability also must be considered.

Various cocoa butter substitutes (e.g., hard fat and hydrogenated vegetable oil) are available commercially that offer a number of advantages over cocoa butter, such as decreased potential for rancidity and phase transition (melting and solidification) behavior tailored to specific formulation, processing, and storage requirements. However, as with cocoa butter, these semisynthetic glyceride mixtures are also subject to polymorphic transformations. Batch-to-batch variations of the physical properties of all of these bases, whether cocoa butter or cocoa butter substitutes, can play havoc with the final products' characteristics. The formulator should ensure that the melting and congealing behavior of these bases and the formulations prepared from them is evaluated thoroughly.

**Water-Soluble or Dispersible Suppository Bases.** These are of comparatively recent origin. The majority are composed of polyethylene glycols or glycol-surfactant combinations. Water-miscible suppository bases have the substantial advantage of lack of dependence on a melting point approximating body temperature. Problems of handling, storage, and shipping are simplified considerably.

Polymers of ethylene glycol are available as polyethylene glycol polymers (Carbowax, polyglycols) of assorted molecular weights. Suppositories of varying melting points and solubility characteristics can be prepared by blending polyethylene glycols of 1000, 4000, or 6000 molecular weight.

Polyethylene glycol suppositories, while prepared rather easily by molding, cannot be prepared satisfactorily by hand-rolling. The drug-glycol mixture is prepared by melting and then is cooled to just above the melting point before pouring into dry

unlubricated molds. Cooling to near the melting point prevents fissuring caused by crystallization and contraction. The USP advises that labels on polyethylene glycol suppositories should instruct patients to moisten the suppository before inserting it.

Water-miscible or water-dispersible suppositories also can be prepared using selected nonionic surfactant materials. Polyoxyl 40 stearate is a white, water-soluble solid, melting slightly above body temperature. A polyoxyethylene derivative of sorbitan monostearate is water-insoluble but dispersible. In using surfactant materials the possibility of drug-base interactions must be borne in mind. Interactions caused by macromolecular adsorption may have a significant effect on bioavailability.

PEG-based water-miscible suppository bases are exemplified by a low-melting formulation employing 96 percent PEG 1000 and 4 percent PEG 4000 and a more heat-stable formulation with 75 percent PEG 1000 and 25 percent PEG 4000. Both may be prepared conveniently by molding techniques.

Water-dispersible bases may include polyoxyethylene sorbitan fatty acid esters. These are either soluble (Tween, Myrj) or water-dispersible (Arlacel), used alone or in combination with other wax or fatty materials. Surfactants in suppositories should be used only with recognition of reports that such materials may either increase or decrease drug absorption.

**Hydrogels**, defined as macromolecular networks that swell but do not dissolve in water, have been advocated as bases for rectal and vaginal drug delivery. The swelling of hydrogels (i.e., the absorption of water), is a consequence of the presence of hydrophilic functional groups attached to the polymeric network. Cross-links between adjacent macromolecules result in the aqueous insolubility of these hydrogels.

The use of a hydrogel matrix for drug delivery involves the dispersal of the drug in the matrix, followed by drying of the system and concomitant immobilization of the drug. When the hydrogel delivery system is placed in an aqueous environment (e.g., the rectum or the vagina), the hydrogel swells, enabling the drug to diffuse out of the macromolecular network. The rate and extent of drug release from these hydrogel matrices depend on the rate of water migration *into* the matrix and the rate of drug diffusion *out of* the swollen matrix.

Hydrogels employed for rectal or vaginal drug administration have been prepared from polymers such as polyvinyl alcohol, hydroxyethyl methacrylate, polyacrylic acid, or polyoxyethylene. Although hydrogel-based drug-delivery systems have yet to appear in suppository or insert form commercially, research efforts in this direction are increasing, given their potential for controlled drug delivery, bioadhesion, retention at the site of administration, and biocompatibility.

**Glycerinated Gelatin.** Glycerinated gelatin is composed of water and the drug (10 percent w/w), glycerin (70 percent), and gelatin (20 percent). It is usually used as a vehicle for vaginal suppositories because rectal use may be associated with an osmotic laxative effect. Nonetheless, if rectal use is desired, a firmer suppository can be obtained by increasing the gelatin content to about 30 percent. PEG 400 or propylene glycol may be substituted for the glycerin if drug solubility is a problem. The type of gelatin employed is dependent on the drug's ionic compatibility: Type A gelatin is cationic, i.e., acidic in reaction, while Type B gelatin is anionic, i.e., alkaline in reaction. Glycerinated gelatin suppositories are prepared by dissolving the drug in the water, adding the glycerin or glycol, and then, with the aid of heat, dispersing the gelatin in the resultant solution. These suppositories must be formed by molding. If not for immediate use, they should contain a preservative such as methylparaben or propylparaben.

**Suppository Preparation.** Suppositories are prepared by rolling (hand-shaping), molding (fusion), and cold compression.

**Rolled (Hand-Shaped) Suppositories.** Hand-shaping suppositories is the oldest and the simplest method of preparing this dosage form. The manipulation requires considerable skill, yet avoids the complications of heat and mold preparation.

The general process can be described as follows:

Take the prescribed quantity of the medicinal substances and a sufficient quantity of grated theobroma oil. In a mortar, reduce the medicating ingredients to a fine powder or, if composed of extracts, soften with diluted alcohol and rub until a smooth paste is formed. The correct amount of grated theobroma oil then is added, and a mass resembling a pill is made by thoroughly incorporating the ingredients with a pestle, sometimes with the aid of a small amount of wool fat. When the mass has become plastic under the vigorous kneading of the pestle, it quickly is loosened from the mortar with a spatula, pressed into a roughly shaped mass in the center of the mortar, and then transferred with the spatula to a piece of filter paper that is kept between the mass and the hands during the kneading and rolling procedure. By quick, rotary movements of the hands, the mass is rolled to a ball, which immediately is placed on a pill tile. A suppository cylinder is formed by rolling the mass on the tile with a flat board, partially aided by the palm of the other hand, if weather conditions permit. The suppository *pipe* often will show a tendency to crack in the center, developing a hollow core. This occurs when the mass has not been kneaded and softened sufficiently, with the result that the pressure of the roller board is not carried uniformly throughout the mass but is exerted primarily on the surface. The length of the cylinder usually corresponds to about four spaces on the pill tile for each suppository, thus making the piece, when cut, practically a finished suppository except for the shaping of the point. When the cylinder has been cut into the proper number of pieces with a spatula, the conical shape is given it by rolling one end on the tile with a spatula, or in some cases even by shaping it with the fingers to produce a rounded point.

**Compression-Molded (Fused) Suppositories.** This method of suppository preparation also avoids heat. The suppository mass, such as a mixture of grated theobroma oil and drug, is forced into a mold under pressure, using a wheel-operated press. The mass is forced into mold openings, pressure is released, and the mold removed, opened, and replaced. On a large scale, cold-compression machines are hydraulically operated, water-jacketed for cooling, and screw-fed. Pressure is applied via a piston to compress the mass into mold openings.

**Fusion or Melt Molding.** In this method the drug is dispersed or dissolved in the melted suppository base. The mixture then is poured into a suppository mold, allowed to cool, and the finished suppositories removed by opening the mold. Using this procedure, one to hundreds of suppositories can be made at one time.

Suppository molds are available for the preparation of various types and sizes of suppositories. Molds are made of aluminum alloy, brass, or plastic and are available with anywhere from six to several hundred cavities.

The method of choice for commercial suppository production (Figure 29-6) involves the automated filling of molds or preformed shells by a volumetric dosing pump that meters the melt from a jacketed kettle or mixing tank directly into the molds or shells. Strips of preformed shells pass beneath the dosing pump and are filled successively, passed through cooling chambers (to promote solidification), sealed, and then packaged. Quality control procedures (e.g., weight, fill volume, and leakage) are conducted readily in-line.

**Injection Molding.** An alternative to the melt-and-pour processes described above is that of injection molding. This process is distinctive in that it makes use of the injection-molding technique developed for the fabrication of plastics. Polyethylene glycols are the excipients of choice in this process, with polyethylene oxide, povidone, or silicon dioxide added to adjust viscosity or plasticity. Long-chain saturated carboxylic acids also have been added to reduce the hygroscopicity inherent with the use of the polyethylene glycols. Typically, the molten excipient admixture is extruded or injected under pressure into precision-machined multicavity molds, followed by the ejection of the molded units from the mold cavities. Advantages claimed for this method include the wide range of shapes and

**Figure 29-6.** A cross-section of the Sarong SpA semiautomatic equipment for the production of suppositories in preformed plastic or foil shells. The fully jacketed piston-type dosing pump (1) meters the suppository melt in the jacketed tank (2) into preformed shells that pass directly beneath injection nozzles. The strips of filled preformed shells continue into a cooling chamber (3) prior to sealing and cartoning.

sizes that can be prepared at very high production rates with great precision.

Suppositories usually are formulated on a weight basis so that the medication replaces a portion of the vehicle as a function of specific gravity. If the medicinal substance has a density approximately the same as theobroma oil, it will replace an equal weight of oil. If the medication is heavier, it will replace a proportionally smaller amount of theobroma oil.

For instance, tannic acid has a density of 1.6 compared with cocoa butter (see Table 29-2). If a suppository is to contain 0.1 g tannic acid, then  $0.1 \text{ g} \div 1.6$ , or 0.062 g, cocoa butter should be replaced by 0.1 g of drug. If the blank weight of the suppository is 2.0 g, then  $2.0 - 0.062 \text{ g}$ , or 1.938 g, cocoa butter is required per suppository. The suppository will actually weigh  $1.938 \text{ g} + 0.1 \text{ g}$ , or 2.038 g. Table 29-2 indicates the density factor, or the density compared with cocoa butter, of many substances used in suppositories.

It is always possible to determine the density of a medicinal substance relative to cocoa butter, if the density factor is not available, by mixing the amount of drug for one or more suppositories with a small quantity of cocoa butter, pouring the mixture into a suppository mold and carefully filling the mold with additional melted cocoa butter. The cooled suppositories are weighed, providing data from which a working formula can be calculated as well as the density factor itself.

When using suppository bases other than cocoa butter, such as a polyethylene glycol base, it is necessary to know either the density of the drug relative to the new base or the densities of both the drug and the new base relative to cocoa butter. The density factor for a base other than cocoa butter is simply the ratio of the blank weights of the base and cocoa butter.

For instance, if a suppository is to contain 0.1 g tannic acid in a polyethylene glycol base, then  $0.1 \text{ g} \div 1.6 \times 1.25$ , or 0.078 g, polyethylene glycol base should be replaced by 0.1 g drug (the polyethylene glycol base is assumed to have a density factor of 1.25). If the blank weight is 1.75 g for the polyethylene glycol base, then  $1.75 \text{ g} - 0.078 \text{ g}$ , or 1.672 g, of base is required per suppository. The final weight will be 1.672 g base + 0.1 g drug, or 1.772 g.

**Table 29-2. Density Factors for Cocoa Butter Suppositories**

Medication	Factor
Alum	1.7
Aminophylline	1.1
Aminopyrine	1.3
Aspirin	1.3
Barbital	1.2
Belladonna extract	1.3
Benzoic acid	1.5
Bismuth carbonate	4.5
Bismuth salicylate	4.5
Bismuth subgallate	2.7
Bismuth subnitrate	6.0
Boric acid	1.5
Castor oil	1.0
Chloral hydrate	1.3
Cocaine hydrochloride	1.3
Digitalis leaf	1.6
Gallic acid	2.0
Glycerin	1.6
Ichthammol	1.1
Iodoform	4.0
Menthol	0.7
Morphine hydrochloride	1.6
Opium	1.4
Paraffin	1.0
Peruvian balsama	1.1
Phenobarbital	1.2
Phenola	0.9
Potassium bromide	2.2
Potassium iodide	4.5
Procaine	1.2
Quinine hydrochloride	1.2
Resorcinol	1.4
Salicylic acid	1.3
Sodium bromide	2.3
Spermaceti	1.0
Sulfathiazole	1.6
Tannic acid	1.6
White wax	1.0
Witch hazel fluid extract	1.1
Zinc oxide	4.0
Zinc sulfate	2.8

<sup>a</sup> Density adjusted taking into account white wax in mass.

When the dosage and mold calibration are complete, the drug-base mass should be prepared using minimum heat. A water bath or water jacket usually is used. The melted mass should be stirred constantly but slowly to avoid air entrapment. The mass should be poured into the mold openings slowly. Prelubrication of the mold will depend on the vehicle. Mineral oil is a good lubricant for cocoa butter suppositories. Molds should be dry for polyethylene glycol suppositories.

After being poured into tightly clamped molds, the suppositories and mold are allowed to cool thoroughly, using refrigeration on a small scale or refrigerated air on a larger scale. After thorough chilling, any excess suppository mass should be removed from the mold by scraping, the mold opened, and the suppositories removed. It is important to allow cooling time adequate for

suppository contraction. This aids in removal and minimizes splitting of the finished suppository.

**Packaging and Storage.** Suppositories often are packaged in partitioned boxes that hold the suppositories upright. Glycerin and glycerinated gelatin suppositories often are packaged in tightly closed screw-capped glass containers. Although many commercial suppositories are wrapped individually in aluminum foil or PVC-polyethylene, strip-packaging is commonplace.

Alternatively, suppositories may be molded directly into their primary packaging. In this operation the form into which the suppository mass flows consists of a series of individual molds formed from plastic or foil. After the suppository is poured and cooled, the excess is trimmed off, and the units are sealed and cut into 3s or 6s, as desired. Cooling and final cartoning then can be carried out.

Suppositories with low-melting ingredients are best stored in a cool place. Theobroma oil suppositories, in particular, should be refrigerated.

## CONTRACEPTIVES

Contraceptives — in the context of this chapter — are employed in the form of creams, jellies, or aerosol foams, intended for vaginal use to protect against pregnancy. Contraceptive creams and jellies are designed to melt or spread, following insertion, over the vaginal surfaces. These agents act to immobilize spermatozoa.

Creams and jellies for contraceptive use may contain spermicidal agents such as nonoxynol 9, or they may function by a specific pH effect. A pH of 3.5 or less has an appreciable spermicidal effect. It is important to note that a final *in situ* pH of 3.5 or less is required; thus, the dilution effect and pH change brought about by vaginal fluids must be considered. To achieve the proper pH effect and control, buffer systems composed of acid and acid salts, such as lactates, acetates, and citrates, are commonly used.

## PRESERVATIVES IN TOPICAL FORMULATIONS

Antimicrobial preservative substances are included in topical formulations to maintain the potency and integrity of product forms and to protect the health and safety of the consumer. The USP addresses this subject in its monograph *Microbiological Examination of Non-Sterile Products: Acceptance Criteria for Pharmaceutical Preparations and Substances for Pharmaceutical Use*. The USP designates acceptance criteria for total aerobic microbial count and total combined yeasts and mold

in topical formulations. The significance of microorganisms in nonsterile products should be evaluated in terms of the use of the product, the nature of the product, and the potential hazard to the user. Specific requirements are cited for cutaneous products (including transdermal formulations), which should be tested for the presence of *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Products intended for vaginal administration should also be tested for *Candida albicans*.

# Chapter 30

## Oral Solid Dosage Forms

Ahmed Adel Sakr, PhD and Fars K. Alanazi, PhD

**TABLETS** 581

Medicinal substances are most frequently administered orally, by means of solid dosage forms, such as tablets and capsules. Large scale production methods used for their manufacture, as is described in this chapter, require the incorporation of other materials, in addition to the active ingredients. These additives are usually included in the formulation to facilitate handling, enhance the physical appearance, improve stability, and aid in the delivery of the medicament to the blood stream after administration. These materials, as well as the employed production methods, have been shown to potentially influence the absorption and/or bioavailability of the drugs.<sup>1</sup> In addition, the physicochemical characteristics of the drug substances may influence the physiological bioavailability from solid dosage forms.<sup>2</sup>

### TABLETS

According to the USP, tablets are solid dosage forms, containing medicinal substances with or without suitable diluents. They may be classed, according to the method of manufacture, as compressed tablets or molded tablets. The vast majority of all tablets manufactured today are made by compression, and compressed tablets are the most widely used dosage form. Compressed tablets are prepared by the application of high pressures, utilizing steel punches and dies, to powders or granulations. Recently, punching of laminated sheets, electronic deposition methods, and three-dimensional printing methods have been used to make tablets. Tablets have been in widespread use, since the latter part of the 19th century, and their popularity continues. The term “compressed tablet” is believed to have been first used by John Wyeth and Brother, Inc. of Philadelphia. During this same period, molded tablets were introduced for use as hypodermic tablets, for the extemporaneous preparation of solutions for injection. Tablets remain popular as a dosage form, due to the advantages afforded both to the manufacturer (e.g., simplicity and economy of preparation, stability, and convenience in packaging, shipping, and dispensing) and to the patient (e.g., accuracy of dosage, compactness, portability, blandness of taste, and ease of administration). Although the basic mechanical approach for most tablet manufacture has remained the same, tablet technology has undergone great improvement and experimentation. Efforts are continually made to understand more clearly the physical characteristics of powder compaction and the factors affecting the availability of the drug substance from the dosage form after oral administration. Tableting equipment continues to improve in both production speed and the uniformity of tablets. Recent advances in tablet technology have been reviewed.<sup>3,4</sup>

Although tablets are frequently discoid in shape, they also may be round, oval, oblong, cylindrical, or triangular. Other geometric shapes, such as diamonds and pentagons, and hexagons have also been used. They may differ greatly in size and weight, depending on the amount of drug substance present and the intended method of administration. Most commercial tablets can be divided into two general classes: whether they are made by compression or molding. Compressed tablets are prepared by large-scale production methods, whereas molded tablets involve small-scale operations. The various tablet types and abbreviations used in referring to them are listed here.

### COMPRESSED TABLET (CT)

Compressed tablets are formed by compression and, in their simplest form, contain no special coating. They are made from powdered, crystalline, or granular materials, alone or in combination with binders, disintegrants, controlled-release polymers, lubricants, diluents, and, in many cases, colorants. The vast majority of tablets commercialized today are compressed tablets, either in an uncoated or coated state.

### Sugar-Coated Tablets (SCT)

Sugar-coated tablets are compressed tablets surrounded by a sugar coating. Such coatings may be colored and are beneficial in covering up drug substances possessing objectionable tastes or odors and in protecting materials sensitive to oxidation. These coatings were once quite common, but lost commercial appeal due to the high cost of process validation. Recently, they have made a comeback, due to patient popularity and technical advances.

### Film-Coated Tablets (FCT)

Film-coated tablets are compressed tablets covered with a thin layer or film of a water-soluble material. A number of polymeric substances with film-forming properties may be used. Film coating imparts the same general characteristics as sugar coating with the added advantage of the greatly reduced time required for the coating operation. Advances in material science and polymer chemistry have made these coatings the first-choice of formulators.

### Enteric-Coated Tablets (ECT)

Enteric-coated tablets are compressed tablets coated with substances that resist solution in gastric fluid but disintegrate in the intestine. Enteric coatings can be used for tablets containing drug substances inactivated or destroyed in the stomach, for those that irritate the mucosa, or as a means of delayed release of the medication.

### Multiple Compressed Tablets (MCT)

Multi-compressed tablets are compressed tablets made by more than one compression cycle. This process is best used when separation of active ingredients is needed for stability purposes or if the mixing process is inadequate to guarantee uniform distribution of two or more active ingredients.

### Layered Tablets

Layered tablets are prepared by compressing additional tablet granulation on a previously compressed granulation. The operation may be repeated to produce multilayered tablets of two or more layers.

### Press-Coated Tablets

Press coated tablets, also referred to as dry-coated tablets, are prepared by feeding previously compressed tablets into a special tableting machine and compressing another granulation layer around the preformed tablets. They have all the advantages of compressed tablets (i.e., slotting, monogramming, speed of disintegration), while retaining the attributes of sugar-coated tablets in masking the taste of the drug substance in the core tablets. An example of a press-coated tablet press is

the Manesty Drycota. Press-coated tablets can also be used to separate incompatible drug substances; in addition, they can provide a means of giving an enteric coating to the core tablets. Both types of multiple-compressed tablets have been widely used in the design of prolonged-action dosage forms.

### Controlled-Release Tablets (CRT)

Compressed tablets can be formulated to release the drug slowly over a prolonged period of time. Hence, these dosage forms have been referred to as “prolonged-release” or “sustained-release” dosage forms as well. These tablets, as well as capsule versions, can be categorized into three types: 1) those that respond to some physiological condition to release the drug, such as enteric coatings; 2) those that release the drug in a relatively steady, controlled manner; and 3) those that combine combinations of mechanisms to release pulses of drug, such as repeat-action tablets. Chapter 32 describes the performance of these systems in more detail. Other names for these types of tablets are; Extended Release, Sustained Release, Prolonged Release, Delayed Release, and, in the case of pulsatile tablets, Repeat Action, Pulsatile Release, or Pulse Release.

### Tablets for Solution (CTS)

Compressed tablets used for preparing solutions or imparting given characteristics to solutions must be labeled to indicate they are not to be swallowed. Examples of these tablets are Halazone Tablets for Solution and Potassium Permanganate Tablets for Solution.

### Effervescent Tablets

In addition to the drug substance, effervescent tablets contain sodium bicarbonate and an organic acid, such as tartaric or citric. In the presence of water, these additives react, liberating carbon dioxide that acts as a disintegrator and produces effervescence. Except for small quantities of lubricants present, effervescent tablets are soluble.

### Compressed Suppositories or Inserts

Occasionally, vaginal suppositories, such as Metronidazole tablets, are prepared by compression. Tablets for this use usually contain lactose as the diluent. In this case, as well as for any tablet intended for administration by means other than swallowing, the label must indicate the manner in which it is to be used.

### Buccal and Sublingual Tablets

Buccal and sublingual tablets are small, flat, oval tablets. Tablets intended for buccal administration by inserting into the buccal pouch (the space between the lip and gum in the mouth) may dissolve or erode slowly; therefore, they are formulated and compressed with sufficient pressure to give a hard tablet. Progesterone tablets may be administered in this way. Some newer approaches have employed materials that act as bioadhesives to increase absorption of the drug. Other approaches use tablets that melt at body temperatures. The matrix of the tablet is solidified, while the drug is in solution. After melting, the drug is automatically in solution and available for absorption, thus, eliminating dissolution as a rate-limiting step in the absorption of poorly soluble compounds. Sublingual tablets, such as those containing nitroglycerin, isoproterenol hydrochloride, or erythryl tetranitrate, are placed under the tongue. Sublingual tablets dissolve rapidly, and the drug substances are absorbed readily by this form of administration.

### MOLDED TABLETS OR TABLET TRITURATES (TT)

Tablet triturates are usually made from moist material, using a triturate mold that gives them the shape of cut sections of a cylinder. Such tablets must be completely and rapidly soluble. The problem arising from compression of these tablets is the failure to find a lubricant that is completely water-soluble.

### Dispensing Tablets (DT)

Dispensing tablets provide a convenient quantity of potent drug that can be incorporated readily into powders and liquids, thus, circumventing the necessity to weigh small quantities. These tablets are supplied primarily as a convenience for extemporaneous compounding and should never be dispensed as a dosage form.

### Hypodermic Tablets (BT)

Hypodermic tablets are soft, readily soluble tablets and were originally used for the preparation of solutions to be injected. Since stable parenteral solutions are now available for most drug substances, there is no justification for the use of hypodermic tablets for injection. Their use in this manner should be discouraged, since the resulting solutions are not sterile. Large quantities of these tablets continue to be made, but for oral administration. No hypodermic tablets have ever been recognized by the official compendia.

### COMPRESSED TABLETS (CT)

For medicinal substances, with or without diluents, to be made into solid dosage forms with pressure, using available equipment, it is necessary that the material, either in crystalline or powdered form, possess a number of physical characteristics. These characteristics include the ability to flow freely, cohesiveness, and lubrication. The ingredients, such as disintegrants designed to break the tablet up in gastrointestinal (GI) fluids and controlled-release polymers designed to slow drug release, ideally, should possess these characteristics or not interfere with the desirable performance traits of the other excipients. Since most materials have none or only some of these properties, methods of tablet formulation and preparation have been developed to impart these desirable characteristics to the material that is to be compressed into tablets. The basic mechanical unit in all tablet-compression equipment includes a lower punch that fits into a die from the bottom and an upper punch, with a head of the same shape and dimensions, which enters the die cavity from the top, after the tableting material fills the die cavity (Fig. 30-1). The tablet is formed by pressure applied on the punches and, subsequently, is ejected from the die. The weight of the tablet is determined by the volume of the material that fills the die cavity. Therefore, the ability of the granulation to flow freely into the die is important in ensuring a uniform fill, as well as the continuous movement of the granulation from the source of supply or feed hopper. If the tablet granulation does not possess cohesive properties, the tablet, after compression, will crumble and fall apart on handling. As the punches must move

Figure 30-1. Multi-tip punches and die. (Courtesy of Natoli.)

freely within the die and the tablet must be ejected readily from the punch faces, the material must have a degree of lubrication to minimize friction and allow the removal of the compressed tablets. There are three general methods typically used for commercial tablet preparation: the wet-granulation method, the dry granulation method, and direct compression. The method of preparation and the added ingredients are selected to give the tablet formulation the desirable physical characteristics, allowing the rapid compression of tablets. After compression, the tablets must have a number of additional attributes, such as appearance, hardness, disintegration ability, appropriate dissolution characteristics, and uniformity, which are also influenced by both the method of preparation and the added materials present in the formulation. In the preparation of compressed tablets, the formulator must also be cognizant of the effect that the ingredients and methods of preparation may have on the availability of the active ingredients and, hence, the therapeutic efficacy of the dosage form. In response to a request by physicians to change a dicumarol tablet, so it might be broken more easily, a Canadian company reformulated to make a large tablet with a score. Subsequent use of the tablet, containing the same amount of drug substance as the previous tablet, resulted in complaints that larger-than-usual doses were needed to produce the same therapeutic response. Conversely, literature reports indicate that the reformulation of a commercial digoxin tablet resulted in a tablet that, although containing the same quantity of drug substance, gave the desired clinical response at half its original dose. Methods and principles that can be used to assess the effects of excipients and additives on drug absorption have been reviewed.<sup>5-7</sup>

## TABLET INGREDIENTS

In addition to the active or therapeutic ingredient, tablets contain a number of inert materials. The latter are known as additives or excipients. They may be classified according to the part they play in the finished tablet. The first group contains those that help to impart satisfactory processing and compression characteristics to the formulation. These include diluents, binders, glidants, and lubricants. The second group of added substances helps to give additional desirable physical characteristics to the finished tablet. Included in this group are disintegrants, surfactants, colors, and, in the case of chewable tablets, flavors and sweetening agents, and, in the case of controlled-release tablets, polymers or hydrophobic materials, such as waxes or other solubility-retarding materials. In some cases, antioxidants or other materials can be added to improve stability and shelf-life. Although the term "inert" has been applied to these added materials, it has become apparent that there is an important relationship between the properties of the excipients and the dosage forms containing them.<sup>8</sup> Preformulation studies demonstrate their influence on stability, bioavailability, and the processes by which the dosage forms are prepared. The need for acquiring more information and use standards for excipients has been recognized in a joint venture of the Academy of Pharmaceutical Sciences and the Council of the Pharmaceutical Society of Great Britain. The result is called the *Handbook of Pharmaceutical Excipients*. This reference work is now distributed widely throughout the world.<sup>9</sup>

### Diluents

Frequently, the single dose of the active ingredient is small, and an inert substance is added to increase the bulk to make the tablet a practical size for compression. Compressed tablets of dexamethasone contain 0.75 mg steroid per tablet; hence, it is obvious that another material must be added to make tableting possible. Diluents used for this purpose include dicalcium phosphate, calcium sulfate, lactose, cellulose, kaolin, mannitol, sodium chloride, dry starch, and powdered sugar. Certain diluents, such as mannitol, lactose, sorbitol, sucrose, and inositol, when present in sufficient quantity, can impart properties to some compressed tablets that permit disintegration in the mouth by chewing. Such tablets are commonly called chewable tablets.

Upon chewing, properly prepared tablets disintegrate smoothly at a satisfactory rate, have a pleasant taste and feel, and leave no unpleasant aftertaste in the mouth. Diluents used as excipients for direct compression formulas have been subjected to prior processing to give them flow ability and compressibility. These are discussed in the section Direct Compression. Most formulators of immediate-release tablets tend to consistently use only one or two diluents selected from the listed group in their tablet formulations. Usually, these are selected on the basis of experience and cost factors. However, in the formulation of new therapeutic agents, the compatibility of the diluents with the drug must be considered (e.g., calcium salts used as diluents for the broad-spectrum antibiotic tetracycline) have been shown to interfere with the drug's absorption from the GI tract. When drug substances have low water solubility, it is recommended that water-soluble diluents be used to avoid possible bioavailability problems. Highly adsorbent substances (e.g., bentonite and kaolin) are avoided in making tablets of drugs used clinically in small dosage, such as the cardiac glycosides, alkaloids, and synthetic estrogens. These drug substances may be adsorbed after administration. The combination of amine bases with lactose or alkaline salts with lactose in the presence of alkaline lubricant results in tablets that discolor on aging.

Microcrystalline cellulose (Avicel) is usually used as an excipient in direct-compression formulas. However, its presence in 5-15% concentrations in wet granulations has been shown beneficial in the granulation and drying processes in minimizing case-hardening of the tablets and in reducing tablet mottling. Many ingredients are used for several different purposes, even within the same formulation (e.g., cornstarch can be used in paste form as a binder). When added in drug or suspension form, it is a good disintegrant. Even though these uses are to achieve opposite goals, some tablet formulas use cornstarch in both ways. In some controlled-release formulas, the polymer hydroxypropyl methylcellulose (HPMC) is used both as an aid to prolong the release from the tablet, as well as a film-former in the tablet coating. Therefore, most excipients used in formulating tablets and capsules have many uses, and a thorough understanding of their properties and limitations is necessary to use them rationally.

### Binders

Agents used to impart cohesive qualities to the powdered material are referred to as binders or granulators. They impart cohesiveness to the tablet formulation that ensures the tablet remain intact after compression, as well as improve the free-flowing qualities by the formulation of granules of desired hardness and size. Materials commonly used as binders include starch, gelatin, and sugars, such as sucrose, glucose, dextrose, molasses, and lactose. Natural and synthetic gums that have been used include acacia, sodium alginate, extract of Irish moss, panwar gum, ghatti gum, mucilage of isapol husks, carboxymethylcellulose, methylcellulose, polyvinylpyrrolidone, Veegum, and larch arabogalactan. Other agents considered binders under certain circumstances are polyethylene glycol, ethylcellulose, waxes, water, and alcohol. Synthetic binders, such as polyvinylpyrrolidone and HPMC are becoming more popular. The quantity of binder used has considerable influence on the characteristics of the compressed tablets. The use of too much binder or too strong a binder will make a hard tablet that will not disintegrate easily and will cause excessive wear of punches and dies. Differences in binders used for CT Tolbutamide resulted in differences in hypoglycemic effects observed clinically. Materials that have no cohesive qualities of their own require a stronger binder than those with these qualities. Alcohol and water are not binders in the true sense of the word, but, due to their solvent action on some ingredients, such as lactose, starch, and celluloses, they change the powdered material to granules, and the residual moisture retained enables the materials to adhere together when compressed. Binders are used both as a solution and in a dry form, depending on the other ingredients in the formulation and the method of preparation. However, several pregelatinized starches available are intended

to be added in the dry form, so water alone can be used as the granulating solution. The same amount of binder in solution will be more effective than if it were dispersed in a dry form and moistened with the solvent. By the latter procedure, the binding agent is not as effective in reaching and wetting each of the particles within the mass of powders. Each of the particles in a powder blend has a coating of adsorbed air on its surface, and it is this film that must be penetrated before the powders can be wetted by the binder solution. After wetting, a certain period of time is necessary to dissolve the binder completely and make it completely available for use. Since powders differ with respect to the ease with which they can be wetted and their rate of solubilization, it is preferable to incorporate the binding agent in solution. By this technique, it is often possible to gain effective binding with a lower concentration of binder. The direct-compression method for preparing tablets requires a material that is not only free-flowing but also sufficiently cohesive to act as a binder. This use has been described for a number of materials, including microcrystalline cellulose, microcrystalline dextrose, amylose, and polyvinylpyrrolidone. It has been postulated that microcrystalline cellulose is a special form of cellulose fibril in which the individual crystallites are held together largely by hydrogen bonding. The disintegration of tablets containing the cellulose occurs by breaking the intercrystallite bonds by the disintegrating medium.

**Starch Paste**—Cornstarch is used widely as a binder. The concentration may vary from 10% to 20%. It is usually prepared as it is to be used, by dispersing cornstarch in sufficient cold purified water to make a 5–10% w/w suspension and warming in a water bath with continuous stirring until a translucent paste forms. It has been observed that, during paste formation, not all of the starch is hydrolyzed. Starch paste then is not only useful as a binder, but also as a method to incorporate some disintegrant inside the granules.

**Gelatin Solution**—Gelatin is used as a 10–20% solution; gelatin solutions should be prepared freshly as needed and used while warm, or they will solidify. The gelatin is added to cold purified water and allowed to stand, until it is hydrated. It is then warmed in a water bath to dissolve the gelatin, and the solution is made up to the final volume on a weight basis to give the concentration desired.

**Cellulosic Solutions**—Various celluloses have been used as binders in solution form. Hydroxypropyl methylcellulose (HPMC) has been used widely in this regard. Typical of a number of celluloses, HPMC is more soluble in cold water than hot. It is also more dispersible in hot water than cold. Hence, to obtain a good, smooth gel that is free from lumps or “fisheyes,” it is necessary to add the HPMC in hot, almost boiling, water and, under agitation, cool the mixture down as quickly as possible, as low as possible. Other water-soluble celluloses, such as hydroxyethylcellulose (HEC) and hydroxypropylcellulose (HPC), have been used successfully in solution as binders.

Not all celluloses are soluble in water. Ethylcellulose can be used effectively, when dissolved in alcohol or as a dry binder that then is wetted with alcohol. It is used as a binder for materials that are moisture-sensitive.

**Polyvinylpyrrolidone (PVP)** can be used as an aqueous or alcoholic solution, and this versatility has increased its popularity. Concentrations range from 2% and vary considerably. It should be noted that binder solutions are usually made up to Weight, rather than volume. This is to enable the formulator to determine the weight of the solids that have been added to the tablet granulation in the binding solution. This becomes part of the total weight of the granulation and must be taken into consideration in determining the weight of the compressed tablet, which will contain the stated amount of the therapeutic agent. As can be seen by the list of binders in this chapter, most modern binders used in solution are polymeric. Because of this, the flow or spreadability of these solutions becomes important, when selecting the appropriate granulating equipment. The rheology of polymeric solutions is a fascinating subject in and of itself and should be considered for these materials.

## Lubricants

Lubricants have a number of functions in tablet manufacture. They prevent adhesion of the tablet material to the surface of the dies and punches, reduce interparticle friction, facilitate the ejection of the tablets from the die cavity, and may improve the rate of flow of the tablet granulation. Commonly used lubricants include talc, magnesium stearate, calcium stearate, stearic acid, glyceryl behenate, hydrogenated vegetable oils, and polyethylene glycol (PEG). Most lubricants, with the exception of talc, are used in concentrations below 1%. When used alone, talc may require concentrations as high as 5%. Lubricants are, in most cases, hydrophobic materials. Poor selection or excessive amounts can result in waterproofing the tablets, resulting in poor tablet disintegration and/or delayed dissolution of the drug substance. The addition of the proper lubricant is highly desirable, if the material to be tableted tends to stick to the punches and dies. Immediately after compression, most tablets have the tendency to expand and will bind and stick to the side of the die. The choice of the proper lubricant will overcome this effectively. The method of adding a lubricant to a granulation is important, if the material is to perform its function satisfactorily. The lubricant should be divided finely by passing it through a 60- to 100-mesh nylon cloth onto the granulation. In production, this is called “bolting” the lubricant. After adding the lubricant, the granulation is tumbled or mixed gently to distribute the lubricant without coating the particles too well or breaking them down to finer particles. Some research has concluded that the order of mixing of lubricants and other excipients can have a profound effect on the performance of the final dosage form. Thus, attention to the mixing process itself is just as important as the selection of lubricant materials. These process variables can be seen in the prolonged blending of a lubricant in a granulation. Overblending materially can affect the hardness, disintegration time, and dissolution performance of the resultant tablets. The quantity of lubricant varies, being as low as 0.1% and, in some cases, as high as 5%. Lubricants have been added to the granulating agents in the form of suspensions or emulsions. This technique serves to reduce the number of operational procedures and, thus, reduce the processing time. In selecting a lubricant, proper attention must be given to its compatibility with the drug agent. Perhaps the most widely investigated drug is acetylsalicylic acid. Different talcs varied the stability of aspirin significantly. Talc, with a high calcium content and a high loss on ignition, was associated with increased aspirin decomposition. From a stability standpoint, the relative acceptability of tablet lubricants for combination with aspirin was found to decrease in the following order: hydrogenated vegetable oil, stearic acid, talc, and aluminum stearate. The primary problem in the preparation of a water-soluble tablet is the selection of a satisfactory lubricant. Soluble lubricants reported to be effective include sodium benzoate, a mixture of sodium benzoate and sodium acetate, sodium chloride, leucine, and polyethylene glycol/Carbowax 4000. However, it has been suggested that formulations used to prepare water soluble tablets may represent a number of compromises between compression efficiency and water solubility. Although magnesium stearate is one of the most widely used lubricants, its hydrophobic properties can retard disintegration and dissolution. To overcome these waterproofing characteristics, sodium lauryl sulfate is sometimes included. One compound found to have the lubricating properties of magnesium stearate, without their disadvantage, is magnesium lauryl sulfate. Its safety for use in pharmaceuticals has not been established.

## Glidants

A glidant is a substance that improves the flow characteristics of a powder mixture. These materials always are added in the dry state just prior to compression (i.e., during the lubrication step). Colloidal silicon dioxide Cab-o-sil (Cabot) is the most commonly used glidant and is used in low concentrations of

1% or less. Talc (asbestos-free) is also used and may serve the dual purpose of lubricant and glidant. It is especially important to optimize the order of addition and the mixing process for these materials, to maximize their effect and to make sure their influence on the lubricant(s) is minimized.

### Disintegrants

A disintegrant is a substance or a mixture of substances added to a tablet to facilitate its breakup or disintegration after administration. The active ingredient must be released from the tablet matrix as efficiently as possible to allow rapid dissolution. Materials serving as disintegrants have been classified chemically as starches, clays, celluloses, alginates, gums, and cross-linked polymers. The oldest and still the most popular disintegrants are corn and potato starches that have been well dried and powdered.

Starch has a great affinity for water and swells when moistened, thus, facilitating the rupture of the tablet matrix. However, others have suggested that its disintegrating action in tablets is due to capillary action, rather than swelling; the spherical shape of the starch grains increases the porosity of the tablet, thus, promoting capillary action. Starch, 5%, is suggested, but, if more rapid disintegration is desired, this amount may be increased to 10% or 15%. Although it might be expected that disintegration time would decrease as the percentage of starch in the tablet increased, this does not appear to be the case for tolbutamide tablets. In this instance, there appears to be a critical starch concentration for different granulations of the chemical. When their disintegration effect is desired, starches are added to the powder blends in the dry state. A group of materials known as "super disintegrants" have gained in popularity as disintegrating agents. The name comes from the low levels (1–4%) at which they are completely effective. Croscarmellose, crospovidone, and sodium starch glycolate represent examples of a cross-linked cellulose, a cross-linked polymer, and a cross-linked starch, respectively. The development of these disintegrants fostered new theories about the various mechanisms by which disintegrants work. Sodium starch glycolate swells 7- to 12-fold in less than 30 seconds. Croscarmellose swells 4- to 8-fold in less than 10 seconds. The starch swells equally in all three dimensions, whereas the cellulose swells only in two dimensions, leaving fiber length essentially the same. It is postulated that the rate, force, and extent of swelling play an important role in those disintegrants that work by swelling. Cross-linked PVP swells little but returns to its original boundaries quickly after compression. Wicking, or capillary action, is also postulated to be a major factor in the ability of cross-linked PVP to function.<sup>10–13</sup> In addition to the starches, large varieties of materials have been used and are reported to be effective as disintegrants. This group includes Veegum HV, methylcellulose, agar, bentonite, cellulose and wood products, natural sponge, cation-exchange resins, alginic acid, guar gum, citrus pulp, and carboxymethylcellulose. Sodium lauryl sulfate, in combination with starch, has also been demonstrated to be an effective disintegrant. In some cases, the apparent effectiveness of surfactants in improving tablet disintegration is postulated as due to an increase in the rate of wetting. The disintegrating agent is usually mixed with the active ingredients and diluents after granulation. In some cases, it may be advantageous to divide the disintegrant into two portions: one part is added to the powdered formula prior to granulation, and the remainder is mixed with the lubricant and added prior to compression. Incorporated in this manner, the disintegrant serves a double purpose: the portion added to the lubricant rapidly breaks down the tablet to granules, and the disintegrant mixed with the active ingredients disintegrates the granules into smaller particles.<sup>12</sup> Veegum has been shown more effective as a disintegrator in sulfathiazole tablets, when most of the quantity is added after granulation and only a small amount before granulation. Likewise, the montmorillonite clays were found to be good tablet disintegrants, when added to prepared granulations as powder.

They are much less effective as disintegrants, when incorporated within the granules.

Factors other than the presence of disintegrants can affect the disintegration time of compressed tablets significantly. The binder, tablet hardness, and the lubricant have been shown to influence the disintegration time. Thus, when the formulator is faced with a problem concerning the disintegration of a compressed tablet, the answer may not lie in the selection and quantity of the disintegrating agent alone. The evolution of carbon dioxide is also an effective way to cause the disintegration of compressed tablets. Tablets containing a mixture of sodium bicarbonate and an acidulant, such as tartaric or citric acid, will effervesce when added to water. Sufficient acid is added to produce a neutral or slightly acidic reaction when disintegration in water is rapid and complete.

One drawback to the use of the effervescent type of disintegrator is that such tablets must be kept in a dry atmosphere at all times during manufacture, storage, and packaging. Soluble, effervescent tablets provide a popular form for dispensing aspirin and noncaloric sweetening agents.

### Coloring Agents

Colors in compressed tablets serve functions other than making the dosage form more esthetic in appearance. Color helps the manufacturer control the product during its preparation, as well as serves as a means of identification to the user. The wide diversity in the use of colors in solid dosage forms makes it possible to use color as an important category in the identification code developed by the AMA to establish the identity of an unknown, compressed tablet in situations arising from poisoning. All colorants used in pharmaceuticals must be approved and certified by the FDA. For several decades, colorants have been subjected to rigid toxicity standards, and, as a result, a number of colorants have been removed from an approved list of Food, Drug and Cosmetic Act (FD&C) colors, or "delisted." Several have been listed as well. Table 30-1 lists the colorants currently approved in the United States. Each country has its own list of approved colorants, and formulators must consider this in designing products for the international market. Any of the approved, certified, water-soluble FD&C dyes, mixtures of the same, or their corresponding lakes may be used to color tablets. A color lake is the combination by adsorption of a water-soluble dye to a hydrous oxide of a heavy metal, resulting in an insoluble form of the dye. In some instances, multiple dyes are used to give a purposefully heterogeneous coloring in the form of speckling to compressed tablets. The dyes available do not meet all the criteria required for the ideal pharmaceutical colorants. The photosensitivity of several of the commonly used colorants and their lakes has been investigated, as well as the protection afforded by a number of glasses used in packaging tablets. Another approach for improving the photostability of dyes has been in the use of ultraviolet-absorbing chemicals in the tablet formulations with the dyes. The Di-Pac line (Amstar) is a series of commercially available colored, direct-compression sugars. The most common method of adding color to a tablet formulation is to dissolve the dye in the binding solution prior to the granulating process. Another approach is to adsorb the dye on starch or calcium sulfate from its aqueous solution; the resultant powder is dried and blended with the other ingredients. If the insoluble lakes are used, they may be blended with the other dry ingredients. Frequently, during drying, colors in wet granulations migrate, resulting in an uneven distribution of the color in the granulation. After compression, the tablets have a mottled appearance, due to the uneven distribution of the color. Migration of colors may be reduced by drying the granulation slowly at low temperatures and stirring the granulation, while it is drying. The affinity of several water-soluble, anionic, certified dyes for natural starches has been demonstrated; in these cases, this affinity should aid in preventing color migration. Other additives have been shown to act as dye-migration inhibitors. Tragacanth (1%), acacia (3%),

		1984.	Modification of uses and restrictions

<sup>2</sup> The year approved is based on the date listed in the “Confirmation of Effective Date” notice for the action as published in the Federal Register.

<sup>5</sup> Color additives permitted for general use may not be used in the area of the eye, in injections or in surgical sutures, unless such use is specified in the color additive listing regulation. Currently, no color additives are listed for use in injected products, such as tattoos or permanent makeup.

<sup>7</sup> NTE—not to exceed

attapulgate (5%), and talc (7%) were effective in inhibiting the migration of FD&C Blue Nolin lactose. In using dye lakes, the problem of color migration is avoided, since the lakes are insoluble. Prevention of mottling can also be helped, by the use of lubricants and other additives that have been colored similarly to the granulation prior to their use. The problem of mottling becomes more pronounced as the concentration of colorants increases. Color mottling is an undesirable characteristic common to many commercial tablets.

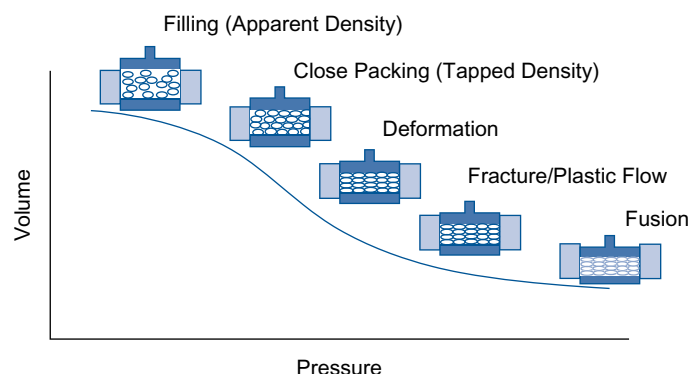

### Flavoring Agents

In addition to the sweetness that may be afforded by the diluent of the chewable tablet (e.g., mannitol or lactose) artificial sweetening agents may be included. Formerly, the cyclamates, either alone or in combination with saccharin, were used widely. With the banning of the cyclamates and the indefinite status of saccharin, new natural sweeteners are being sought. Aspartame (Pfizer), has found applications in pharmaceutical formulations. Sweeteners, other than the sugars, have the advantage of reducing the bulk volume, considering the quantity of sucrose required to produce the same degree of sweetness. Present in small quantities, they do not markedly affect the physical characteristics of the tablet granulation.

### POWDER COMPACTION

Compressed tablets became a commercially viable and efficient dosage form with the invention of tablet machines. In 1843, William Brockendon, a British inventor, author, artist, and watchmaker, received British Patent #9977 for *Shaping Pills, Lozenges, and Black Lead by Pressure in Dies*. In over 150 years of tablet manufacture, the basic process has not changed. Surpris-

ingly, improvements have been made only with regards to speed of manufacture and quality control. The process of compaction has several identifiable phases. As can be seen in Figure 30-2, when powders undergo compression (a reduction in volume), the first process to occur is a consolidation of the powders. During this consolidation phase, the powder particles adopt a more efficient packing order. The second phase of the compaction process is elastic, or reversible deformation. If the force were removed during this phase, the powder would completely recover to the efficiently packed state. For most pharmaceutical powders, this phase is very short in duration and very difficult to identify on most instrumented tablet presses. The third phase of compaction is plastic, or irreversible, deformation of the powder bed. It is this phase that is the most critical in tablet

**Figure 30-2.** The stages of powder compaction.

formation. If too much force is applied to the powder, brittle fracture occurs. If the force is applied too quickly, fracture and de-bonding during stress relaxation can occur. In 1950, Stewart reported on the importance of plastic flow and suggested that, if a material has significant plastic flow under compression, it will be more likely to form a compact. Stress-relaxation data, using the Maxwell model of viscoelastic behavior, were evaluated, in an attempt to quantify the rate of plastic deformation of some direct compression excipients. The term “contact time” was used to describe the total time for which a moving punch applies a detectable force to the die contents during the compression and decompression event, excluding ejection.

### Tablet Strength-Compression Pressure Profile

Most formulators use tablet hardness, or tensile strength, as a measure of the cohesiveness and/or the crushing strength/breaking strength of the tablet. With even the simplest of instrumented tablet presses, it is possible to plot tensile strength versus the force applied to the tablet. These plots can be useful in identifying forces that can cause fracture and can lead to a quick, tangible assessment of the compatibility of the formulation. However, there are many limitations to this method, as these plots cannot predict lamination or capping. In addition, the cohesiveness of a tablet can change upon storage, in either a positive or negative direction.

### Tablet Friability

There have been many suggestions about how tablet friability tests should be performed. Many formulators believe this is an important indicator of cohesiveness but is of limited value in predicting failure in the field.

### Changes in Bed Density During Compression

As applied stress (force) increases, elastic and plastic deformation of the particles occurs, which results in plastic flow and a reduction in inter- and intraparticulate void spaces. This lowers the overall compact density. For highly cohesive systems, the reduction in void space may yield a compact of sufficient strength for insertion into a capsules shell. However, the inherent cohesiveness for most drugs and excipients is not suitable alone for tablet manufacture. The Heckel equation is subsequently given;  $K$  can be considered equal to the reciprocal of the mean yield pressure, and  $A$  is a function of the original compact volume and is related to the densification and particle rearrangement prior to bonding:

$$\text{Log} [1/(1 - D)] = KP + A,$$

where  $D$  is the relative density at pressure  $P$ , and  $K$  and  $A$  are constants.

### Changes in Surface Area During Compression

Bulk powders change their state of packing during compaction, and individual particles fracture and/or plastically deform. During this process, the surface area of the powders and the compact, in whole change. Conventional nitrogen absorption techniques can estimate these changes. Although this can be tedious, these measurements can give a means of examining lamination tendency.

### Stress Relaxation

Stress relaxation, an experimental technique, consists of holding the compression process at a point of maximum compression and observing the compression force over various periods of time. By increasing the duration of this period (or dwell time), plastic flow is maximized, and tablet strength increases.

### Stress Transmissions during Compression

If the stresses in the upper punch, lower punch, and die wall are monitored, a general plot can be constructed, showing the relationship between these forces.

## GRANULATION METHODS

### Wet Granulation

The most widely used and most general method of tablet preparation is the wet-granulation method. Its popularity is due to the greater probability that the granulation will meet all the physical requirements for the compression of good tablets. Its chief disadvantages are the number of separate steps involved, as well as the time and labor necessary to carry out the procedure, especially on a large scale. The steps in the wet method are weighing, mixing, wet massing, screening the damp mass, drying, dry screening, lubrication, and compression. The equipment involved depends on the quantity or size of the batch and the percent active ingredient per total weight of the tablets. Wet massing can be performed by:

1. Low Shear mixers/granulators,
2. High Shear mixers/granulators,
3. Fluid-Bed granulators/dryers,
4. Spray Dryers, or
5. Extruders and Spheronizers.

Low shear mixers include the barrel, cube, twin shell, double cone, slated double cone, ribbon, sigma blade, planetary mixers, etc. (Fig. 30-3). Although these mixers continue to be used in some older pharmaceutical factories, they are replaced, now, by the high shear mixers/granulators. High shear mixers are stationary shell mixers with a large mixer scraper blade, which mixes the ingredients, eliminates dead spots, and presents the ingredients with a high speed chopper blade, which intimately

Figure 30-3. Twin Shell Blender with Intensifier Bars. (Courtesy of Patterson Kelly Buflovak LLC.)

mixes the ingredients and breaks the lumps. The advantages of the high shear mixers/granulators are: simple, robust technology, production of high density granules, rapid and efficient mixing, low liquid requirements, and equipped for drying.

There are many models/trade names of high shear mixers in the pharmaceutical market, such as the Loedige, Littleford MGT, Diosna, Fiedler, Vector, Glatt, GEA, and Hüttlin Gentlewing. Figure 30-4 shows a typical high shear mixer granulator from Vector, and Figure 30-5 shows a typical Glatt high shear mixer. A relatively new high shear mixer from Hüttlin is the Gentlewing High Shear Mixer, which is available in laboratory and large scale sizes, either top driven or bottom driven. The Gentlewing technology applies the principle of a positive displacement impeller for blending a non-Newtonian medium. The impeller shape matches the contour of the mixing container, and its angled impeller plate ensures a forced mixing of the product. Rather than using the impulse of an impeller for mixing, the Gentlewing's uniform presence throughout the product container distributes the mixing energy, at lower speeds but higher torque, evenly throughout the product, reducing segregation issues typically caused by high dynamic forces (Fig. 30-6 and Fig. 30-7).

The active ingredient, diluent, and part of the disintegrant are mixed or blended well. Solutions of the binding agent are added or sprayed to the mixed powders with stirring. The powder mass is wetted with the binding solution, until the mass has the consistency of damp snow or brown sugar. If the granulation is over-wetted, the granules will be hard, requiring considerable pressure to form the tablets, and the resultant tablets may have a mottled appearance. If the powder mixture is not wetted sufficiently, the resulting granules will be too soft, breaking down during lubrication and causing difficulty during compression. In modern high shear mixers, the end point of wet granulation is no more dependent on the experience of the operator and the "hand" feeling of the wet mass, but is measured accurately by a built in torque meter. This consistency and reproducibility

Figure 30-5. High Shear Mixer. (Courtesy of GLATT.)

from batch to batch are assured. The wet granulation mass is then forced through a 6- or 8-mesh screen. Small batches can be forced through by hand, using a manual screen. For larger quantities, one of several comminuting mills suitable for wet screening can be used. These include the Stokes oscillator, Colton rotary granulator, Fitzpatrick comminuting mill, Cone Mill, or Stokes tornado mill. In comminuting mills, the granulation is forced through the sieving device by rotating hammers, knives, or oscillating bars (Fig. 30-8–30-10). Most high-speed mixers are equipped with a chopper blade that operates independently of the main mixing blades and can replace the wet milling step (i.e., can obviate the need for a separate operation). For tablet

formulations in which continuous production is justified, extruders, such as the Reitz extruder, have been adapted for the wet-granulation process. Moist material from the wet milling step, traditionally, was placed on large sheets of paper on shallow wire trays and placed in drying cabinets with a circulating air current and thermostatic heat control. Although tray drying was the most widely used method of drying tablet granulations in the past, fluid-bed drying is now considered the standard. In drying tablet granulation by fluidization, the material is suspended and agitated in a warm air stream, while the granulation is maintained in motion. Drying tests comparing the fluidized bed and a tray dryer for a number of tablet granulations indicated that the former was 15 times faster than the conventional method of tray drying. In addition to the decreased drying time, the fluidization method is claimed to have other advantages, such as better control of drying temperatures, decreased handling costs, and the opportunity to blend lubricants and other materials into the dry granulation directly in the fluidized bed (Fig. 30-11). The application of microwave drying and infrared drying to tablet granulations has been reported as successful for most granulations tried. These methods readily lend themselves to continuous granulation operations. The study of drying methods for tablet granulations led to the development of the Rovac dryer system by Ciba Novartis pharmacists and engineers. The dryer is similar in appearance to the cone blender, except for the heating jacket and vacuum connections. By excluding oxygen and using the lower drying temperatures made possible by drying in a vacuum, opportunities for degradation of the ingredients during the drying cycle are minimized. A greater uniformity of residual moisture content is achieved, due to the moving bed, controlled temperature, and controlled time period of the drying cycle. Particle-size distribution can be controlled by varying the speed of rotation and drying tempera-

**Figure 30-8.** Fitzmill Comminutor. (Courtesy of Fitzpatrick Co.)

ture, as well as by comminuting the granulation to the desired granule size after drying. Recently, many machine manufacturers, such as Hüttlin, GEA, and Glatt, introduced the single pot technology in which the drying process can also take place in a vertical granulator specially equipped for this purpose. The drying is assisted by suitable measures, according to the product and the process, such as heated wall surfaces, gas stripping, and vacuum (Fig. 30-12).

In drying granulations, it is desirable to maintain a residual amount of moisture in the granulation. This is necessary to maintain the various granulation ingredients, such as gums, in a hydrated state. Also, the residual moisture contributes to the reduction of the static electric charges on the particles. In the selection of any drying process, an effort is made to obtain uniform moisture content. In addition to the importance of moisture content of the granulation in its handling, during the manufacturing steps, the stability of the products containing moisture-sensitive active ingredients may be related to the moisture content of the products. Previously, it was indicated that water-soluble colorants can migrate toward the surface of the granulation during the drying process, resulting in mottled tablets after compression. This is also true for water-soluble drug substances, resulting in tablets unsatisfactory as to content uniformity. Migration can be reduced by drying the granulation slowly at low temperatures or using a granulation in which the major diluent is present as granules of large particle size. The presence of microcrystalline cellulose in wet granulations also reduces migration tendencies. After drying, the granulation is reduced in particle size, by passing it through a smaller-mesh screen. Following dry screening, the granule size tends to be more uniform. For dry granulations, the screen size selected depends on the diameter of the punch. The following sizes are suggested:

**Figure 30-9.** Hammers. (Courtesy of Fitzpatrick Co.)

1. Tablets up to 3/16 inch diameter, use 20-mesh
2. Tablets 7/32 to 5/16 inch, use 16-mesh
3. Tablets 11/32 to 13/32 inch, use 14-mesh
4. Tablets 7/16 inch and larger, use 12-mesh

For small amounts of granulation, hand screens may be used and the material passed through with the aid of a stainless steel spatula. With larger quantities, any of the comminuting mills with screens corresponding to those just mentioned may be used. Note that the smaller the tablet, the finer the dry granulation to enable more uniform filling of the die cavity; large granules give an irregular fill to a comparatively small die cavity. With compressed tablets of sodium bicarbonate, lactose, and magnesium trisilicate, a relationship has been demonstrated between the particle size of the granulated material and the disintegration time and capping of the resultant tablets. For a sulfathiazole granulation, however, the particle-size distribution did not appear to influence hardness or disintegration. After dry granulation, the lubricant is added as a fine powder.

**Figure 30-10.** Screens. (Courtesy of Fitzpatrick Co.)

**Figure 30-11.** Schematic Fluid bed Dryer. (Courtesy of Glatt.)

It is screened onto the granulation through 60- or 100-mesh nylon cloth to eliminate small lumps, as well as to increase the covering power of the lubricant. As it is desirable for each granule to be covered with the lubricant, the lubricant is blended with the granulation very gently, preferably in a blender using a tumbling action, such as the Patterson Kelly Twin Shell Blender (Fig. 30-3). Gentle action is desired to maintain the uniform granule size, resulting from the granulation step. It has been claimed that too much fine powder is not desirable, because fine powder may not feed into the die evenly; consequently, variations in weight and density result. Fine powders, commonly designated as “fines,” also blowout around the upper punch and down past the lower punch, making it necessary to clean the machine frequently. Fines, however, at a level of 10–20%, are, traditionally, sought by the tablet formulator. The presence of some fines is necessary for the proper filling of the die cavity. Now, even higher concentrations of fines are used successfully in tablet manufacture. Most investigators agree that no general limits exist for the amount of fines that can be present in a granulation; it must be determined for each specific formula. Many formulators once believed (and some still believe) that over blending resulted in an increased amount of fines and, hence, caused air entrapment in the formula. The capping and laminating of tablets associated with over blending lubricants was thought to be caused by these air pockets. Most scientists now recognize that a more plausible explanation has to do with the function of the lubricants themselves. Since the very nature of a lubricant tends to make surfaces less susceptible to adhesion, over blending prevents the intergranular bonding that takes place during compaction.

### Fluid-Bed Granulation

A relatively new method for granulating evolved from the fluid-bed drying technology previously described. The concept was to spray a granulating solution onto the suspended particles,

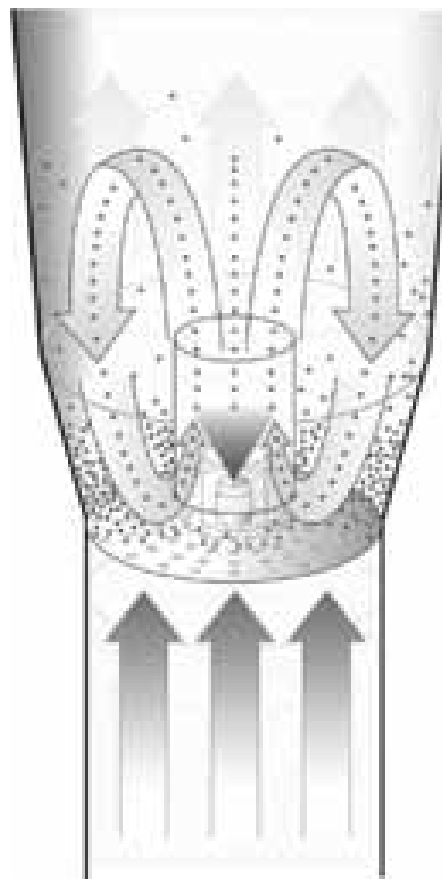

**Figure 30-12.** Single Pot Vertical Granulator. (Courtesy of Glatt.)

which then would be dried rapidly in the suspending air. The main benefit from this system is the rapid granulation and drying of a batch. The main firms that developed this technology are Glatt, Aeromatic (now GEA), Vector, and Hüttlin. The general design of these systems is the same with most companies (Fig. 30-13–30-16). In this method, particles of an inert material or the active drug are suspended in a vertical column with a rising air stream; while the particles are suspended, the common granulating materials in solution are sprayed into the column. There is a gradual particle buildup under a controlled set of conditions, resulting in a tablet granulation ready for compression after the addition of the lubricant. An obvious advantage exists, since granulating and drying can take place in a single piece of equipment. It should be noted, however, that many of the mixers discussed previously can be supplied with a steam jacket and vacuum and can provide the same advantage. In these systems, a granulating solution or solvent is sprayed into or onto the bed of suspended particles. The rate of addition of the binder, temperature in the bed of particles, temperature of the air, volume, and moisture of the air all play an important role in the quality and performance of the final product. Many scientists feel that this method is an extension of the wet-granulation method, as it incorporates many of its concepts. However, anyone who has developed a formulation in

**Figure 30-13.** Fluid Bed Top Spray Granulator. (Courtesy of Glatt.)

**Figure 30-14.** Bottom Spray Fluid Bed. (Courtesy of Glatt.)

a fluid-bed system knows that the many operating parameters involved make it somewhat more complex. In addition to its use for the preparation of tablet granulations, this technique has also been proposed for the coating of solid particles, as a means of improving the flow properties of small particles. Researchers have observed that, in general, fluid-bed granulation yields a less dense particle than conventional methods, and this can affect subsequent compression behavior. The Merck facility at Elkton, VA, was the first completely automated tablet production facility in the world. The entire tablet-manufacturing process, based on a wet-granulation method, was computer-controlled. The system weighed the ingredients, blended, granulated, dried, and lubricated to prepare a uniform granulation of specified particle size and particle-size distribution. The computer directed the compression of the material into tablets with exacting specifications for thickness, weight, and hardness. After compression, the tablets were coated with a water-based film coating. The computer controlled and monitored all flow of material. The plant represented the first totally automated pharmaceutical manufacturing facility. However, due to shifting market trends, the burdens of process validation, and changes to processes, totally automated processes are, generally, not used today. Instead, many production operations focus on computer-controlled and monitored unit operations, such as seen in various tableting machines and granulators. Equipment suppliers work closely with individual pharmaceutical companies in designing specialized and unique systems. Newer developments from the machine manufacturing industries improved the process efficiency by modifying the air distribution plate and introducing the new Diskjet with a tangential air exit, which ensures optimum exchange of materials and energy, as well as reduced process time for drying, granulating, and coating (Fig. 30-17). Total containment systems are available from Glatt, GEA, and Hüttlin. Thus, a high

**Figure 30-15.** Tangential Spray Fluid Bed. (Courtesy of Glatt.)

shear mixer is connected to a cone mill and then a fluid bed dryer. Charging and discharging take place under totally dust and contamination free conditions (Fig. 30-18).

### Dry Granulation

When tablet ingredients are sensitive to moisture or are unable to withstand elevated temperatures during drying and when the tablet ingredients have sufficient inherent binding or cohesive properties, slugging may be used to form granules. This method is referred to as dry granulation, precompression, or double-compression. It eliminates a number of steps but still includes weighing, mixing, slugging, dry screening, lubrication, and compression. The active ingredient, diluent (if required), and part of the lubricant are blended. One of the constituents, either the active ingredient or the diluent, must have cohesive properties. Powdered material contains a considerable amount of air; under pressure, this air is expelled, and a fairly dense piece is formed. The more time allowed for this air to escape, the better the tablet or slug. When slugging is used, large tablets are made as slugs, because fine powders flow better into large cavities. Also, producing large slugs decreases production time: 7/8-1 in are the most practical sizes for slugs. Sometimes, to obtain the pressure desired, the slug sizes are reduced to 3/4 in. The punches should be flat-faced. The compressed slugs are com-

**Figure 30-16.** Fluid-Bed. (Courtesy of Hüttlin GmbH, A Bosch Packaging Technology Company.)

**Figure 30-17.** Disk Jet. (Courtesy of Hüttlin GmbH, A Bosch Packaging Technology Company.)

minuted through the desirable mesh screen either by hand or, for larger quantities, through the Fitzpatrick or similar comminuting mill. The lubricant remaining is added to the granulation and blended gently, and the material is compressed into tablets. Aspirin is a good example of where slugging is satisfactory. Other materials, such as aspirin combinations, acetaminophen, thiamine hydrochloride, ascorbic acid, magnesium hydroxide, and other antacid compounds, may be treated similarly. Results comparable to those accomplished by the slugging process are also obtained with compacting mills. In the compaction method, the powder densified passes between high-pressure rollers that compress the powder and remove the air. The densified material is reduced to a uniform granule size and compressed into tablets after the addition of a lubricant. Excessive pressures that may be required to obtain cohesion of certain materials may result in a prolonged dissolution rate. Compaction mills available include the Chilsonator (Fitzpatrick), Roller Compactor (Vector), and the Compactor Mill (Allis-Chalmers; Fig. 30-19).

### Direct Compression

As its name implies, direct compression consists of compressing tablets directly from component materials, without modifying the physical nature of the materials themselves. Formerly, direct compression, as a method of tablet manufacture, was reserved for a small group of crystalline chemicals having all the physical characteristics required for the formation of a good tablet. This group includes chemicals, such as potassium salts (chlorate, chloride, bromide, iodide, nitrate, and permanganate), ammonium chloride, and methenamine. These materials possess cohesive and flow properties that make direct compression possible. Since the pharmaceutical industry is constantly making efforts to increase the efficiency of tableting operations and reducing costs by using the smallest amount of floor space and labor as possible for a given operation, increasing attention is given to this method of tablet preparation. Approaches used to make this method more universally applicable include the introduction of formulation additives capable of imparting the characteristics required for compression and the use of force-feeding devices to improve the flow of powder blends.

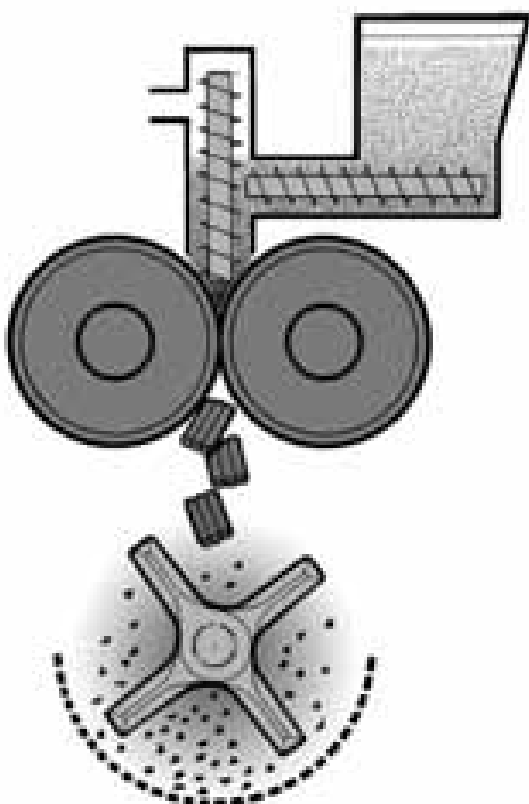

For tablets in which the drug itself constitutes a major portion of the total tablet weight, it is necessary that the drug possess those physical characteristics required for the formulation to be compressed directly. Direct compression for tablets containing 25% or less of drug substances can frequently be used by formulating with a suitable diluent that acts as a carrier or

**Figure 30-18.** Horizontal granulation line consisting of a Top Driven Granulator and a Fluid bed Dryer. (Courtesy of Glatt.)

vehicle for the drug. Direct-compression vehicles or carriers must have good flow and compressible characteristics. These properties are imparted to them by a preprocessing step, such as wet granulation, slugging, spray-drying, spheronization, or crystallization. These vehicles include processed forms of most of the common diluents, including dicalcium phosphate dihydrate, tricalcium phosphate, calcium sulfate, anhydrous lactose, spray-dried lactose, pregelatinized starch, compressible sugar, mannitol, and microcrystalline cellulose. These commercially available, direct compression vehicles may contain small quantities of other ingredients (e.g., starch) as processing aids. Dicalcium phosphate dihydrate (Di-Tab, JRS), in its unmilled form, has good flow properties and compressibility. It is a white, crystalline agglomerate insoluble in water and alcohol. The chemical is odorless, tasteless, and nonhygroscopic. Since it has no inherent lubricating or disintegrating properties, other additives must be present to prepare a satisfactory formulation. Compressible sugar consists mainly of sucrose that is processed

to have properties suitable for direct compression. It also may contain small quantities of dextrin, starch, or invert sugar. It is a white crystalline powder with a sweet taste and complete water solubility. It requires the incorporation of a suitable lubricant at normal levels for lubricity. The sugar is used widely for chewable vitamin tablets because of its natural sweetness. One commercial source is Di-Pac (Amstar), prepared by the co crystallization of 97% sucrose and 3% dextrans. Some forms of lactose meet the requirements for a direct-compression vehicle. Hydrated lactose does not flow, and its use is limited to tablet formulations prepared by the wet-granulation method. Both anhydrous lactose and spray-dried lactose have good flowability and compressibility and can be used in direct compression, provided a suitable disintegrant and lubricant are present. Mannitol is a popular diluent for chewable tablets, due to its pleasant taste and mouth feel, resulting from its negative heat of solution. In its granular form (ICI Americas), it has good flow and compressible qualities. It has low moisture content and is not hygroscopic. The excipient that has been studied extensively as a direct compression vehicle is microcrystalline cellulose (Avicel, FMC). This non-fibrous form of cellulose is obtained by spray-drying washed, acid-treated cellulose and is available in several grades, ranging in average particle size from 20 to 250  $\mu\text{m}$ . It is water-insoluble, but the material has the ability to draw fluid into a tablet by capillary action; it swells on contact and, thus, acts as a disintegrating agent. The material flows well and has a degree of self-lubricating qualities, thus, requiring a lower level of lubricant than other excipients. Recently, FMC introduced Avicel DG, which occurs as a white, odorless powder, containing 75% of microcrystalline cellulose and 25% anhydrous dibasic calcium phosphate. The wet dispersion and spray-drying of microcrystalline cellulose and anhydrous dibasic calcium phosphate results in an intimate physical combination, which cannot be achieved by traditional dry blending. JRS PHARMA introduced PROSOLV, which is coprocessed silicified microcrystalline cellulose. JRS PHARMA also introduced to the pharmaceutical excipient market PROSOLV EASY TAB, which is composed of coprocessed microcrystalline cellulose, colloidal silicon dioxide, sodium starch Glycolate, and sodium stearyl fumarate, which is claimed to be the ideal direct compression complete excipient. Forced-flow feeders are mechanical devices, available from pharmaceutical equipment manufacturers, designed to deaerate light and bulky material. Mechanically, they maintain a steady flow of powder moving into the die cavities under moderate pressure. By increasing the density of the powder, higher uniformity in tablet weights is obtained (Fig. 30-20, 30-21). Recently, many companies have reversed their optimism for some direct-compression systems. Some formulations made by direct compression were not as forgiving as the older, wet-granulated products were. As raw material variations occurred, especially with the drug, many companies found themselves with poorly compactable formulations. Interest in direct compression is also stimulating basic research on the flowability of powders with and without additives.

### Related Granulation Processes

**Spheronization**—Spheronization, a form of pelletization, refers to the formation of spherical particles from wet granulations. Since the particles are round, they have good flow properties when dried. They can be formulated to contain sufficient binder to impart cohesiveness for tableting. Spheronization equipment, such as the Marumerizer (Luwa) and the CFGranulator (Vector), are commercially available for small-scale manufacture, on up to commercial sized equipment. A wet granulation containing the drug substance, diluent (if required), and binder is passed, first, through an extruding machine to form rod-shaped cylindrical segments, ranging in diameter from 0.5 to 12 mm. The segment diameter and the size of the final spherical particle depend on the extruder screen size. After extrusion, the segments are placed into the Marumerizer, where they are shaped into spheres by centrifugal and frictional forces on a rotating plate. The pellets are then dried by conventional methods, mixed with suitable lubricants, and compressed into tablets or used as capsule-fill material. Microcrystalline cellulose has been shown to be an effective diluent and binder in granulations to be spheronized. The advantages of the process include the production of granules, regular in shape, size, and surface characteristics; low friability, resulting in fewer fines and less dust; and the ability to regulate the size of the spheres within a narrow particle-size distribution. Spheres can also be produced by fluid-bed granulation techniques and other specialized equipment, such as the CFGranulator (Vector). These processes, however, must begin with crystals or nonpareil seeds followed by buildup. Exact results, such as sphere density, are different for the various methods and could be important in product performance. These processes can be run as batches or continuously.

**Spray-Drying**—A number of tableting additives suitable for direct compression have been prepared by the drying process known as spray-drying. The method consists of bringing together a highly dispersed liquid and a sufficient volume of hot air to produce evaporation and drying of the liquid droplets. The feed liquid may be a solution, slurry, emulsion, gel, or paste, provided it is pumpable and capable of being atomized.

**Figure 30-21.** Forced Flow Feeder. (Courtesy of Courtesy of Bosch Packaging Technology Ltd., Manesty.)

The feed is sprayed into a current of warm filtered air. The air supplies the heat for evaporation and conveys the dried product to the collector; the air is then exhausted with the moisture. As the liquid droplets present a large surface area to the warm air, local heat and transfer coefficients are high. The spray-dried powder particles are homogeneous, approximately spherical in shape, nearly uniform in size, and frequently hollow. The latter characteristic results in low bulk density, with a rapid rate of solution. Being uniform in size and spherical, the particles possess good flowability. The design and operation of the spray-dryer can vary many characteristics of the final product, such as particle size and size distribution, bulk and particle densities, porosity, moisture content, flowability, and friability. Among the spray-dried materials available for direct compression formulas are lactose, mannitol, and flour. Another application of the process in tableting is spray-drying the combination of tablet additives as the diluent, disintegrant, and binder. The spray-dried material is then blended with the active ingredient or drug, lubricated, and compressed directly into tablets. Since atomization of the feed results in a high surface area, the moisture evaporates rapidly. The evaporation keeps the product cool and, as a result, the method is applicable for drying heat-sensitive materials. Among heat-sensitive pharmaceuticals successfully spray-dried are the amino acids; antibiotics, such as aureomycin, bacitracin, penicillin, and streptomycin; ascorbic acid, cascara extracts, and liver extracts; pepsin and similar enzymes; protein hydrolysates; and thiamin. Frequently, spray-drying is more economical than other processes, since it produces a dry powder directly from a liquid and eliminates other processing steps as crystallization, precipitation, filtering or drying, particle-size reduction, and particle classifying. By the elimination of these steps, labor, equipment costs, space requirements and possible contamination of the product are reduced. Intrinsic factor concentrate obtained from hog mucosa was previously prepared by Lederle / American Home Products, using a salt-precipitation process, followed by freeze-drying. By using spray-drying, it was possible to manufacture a high-grade material by a continuous process. The spherical particles of the product facilitated its subsequent blending with vitamin B12. Similar efficiencies have been found in processes producing magnesium trisilicate and dihydroxyaluminum sodium carbonate; both chemicals are used widely in antacid preparations. Encapsulation of chemicals can also be achieved using spray-drying equipment. The process is useful in coating one material on another to protect the interior substance or to control the rate of its release. The substance to be coated can be either liquid or solid, but must be insoluble in a solution of the coating material. The oil-soluble vitamins A and D can be coated with a variety of materials, such as acacia gum to prevent their deterioration. Flavoring oils and synthetic flavors are coated to give the so-called dry flavors.

**Spray-Congeaing**—Also called spray-chilling, spray-congealing is a technique similar to spray-drying. It consists of melting solids and reducing them to beads or powder, by spraying the molten feed into a stream of air or other gas. The same basic equipment is used as with spray-drying, although no source of heat is required. Either ambient or cooled air is used, depending on the freezing point of the product. For example, mono-glycerides and similar materials are spray-congealed with air at 50°F. A closed-loop system with refrigeration cools and recycles the air. Using this process, drugs can be dissolved or suspended in a molten wax and spray-congealed; the resultant material can then be adapted for a prolonged-release form of the drug. Among the carbohydrates used in compressed tablets, mannitol is the only one that possesses high heat stability. Mannitol melts at 167 and, either alone or in combination with other carbohydrates, can be fused and spray-congealed. Selected drugs have been shown to be soluble in these fused mixtures, and the resultant spray-congealed material possesses excellent flow and compression characteristics.

### TABLET MACHINES

As mentioned previously, the basic mechanical unit in tablet compression involves the operation of two steel punches within a steel die cavity. The tablet is formed by the pressure exerted on the granulation by the punches within the die cavity or cell. The tablet assumes the size and shape of the punches and dies used. Although round tablets are used more generally, oval, square, triangular or other irregular shapes and capsule-form may be used (Fig. 30-22). Likewise, the curvature of the faces of the punches determines the curvature of the tablets. Punch faces with ridges are used for compressed tablets scored for breaking into halves or fourths, although it has been indicated that variation among tablet halves is significantly greater than among intact tablets. However, a patented formulation for a tablet scored to form a groove that is one-third to two-thirds the depth of the total tablet thickness is claimed to give equal parts containing substantially equal amounts of the drug substance. Tablets, engraved or embossed with symbols or initials, require punches with faces embossed or engraved with the corresponding designs. The use of the tablet, sometimes, determines its shape; effervescent tablets are usually large, round, and flat, whereas vitamin tablets are frequently prepared in capsule-shaped forms. Tablets prepared using deep-cup punches are round and, when coated, take on the appearance of pills. Veterinary tablets often have a bolus shape and are much larger than those used in medical practice. The quality-control program for punches and dies, frequently referred to as tooling, instituted by large pharmaceutical companies, emphasizes the importance of their care in modern pharmaceutical production. To produce physically perfect, compressed tablets, an efficient punch-and-die program must be set up. Provisions for inspection of tooling, parameters for cost-per-product determination, product identification, and tooling specifications must all be considered. A committee of the Industrial and Pharmaceutical Technology Section of the American Pharmacists Association established a set of dimensional specifications and tolerances for standard punches and dies. Regardless of the size of the tableting operation, the attention that must be given to the proper care of punches and dies should be noted. They must be highly polished and kept free from rust and imperfections. In cases in which the material pits or abrades the dies, chromium-plated dies have been used. Dropping the punches on hard surfaces chips their fine edges. When the punches are in the machine, the upper and lower punches should not be allowed to contact each other; otherwise, a curling or flattening of the edges that is one of the causes of capping results. This is especially necessary to observe in the case of deep-cup punches. When the punches are removed from the machine, they should be washed thoroughly in warm, soapy water and dried well with a clean cloth. A coating of grease or oil should be rubbed over all parts of the dies and punches to protect them from the atmosphere. They should be stored carefully in boxes or paper tubes. Natoli wrote an excellent review

**Figure 30-22.** Punches and Dies with various shapes. (Courtesy of NATOLI.)

on tooling for pharmaceutical processing in which he addressed tooling options, standards, configurations, recent innovations, and production problems due to tooling. A significantly important part of the review is the listing of possible causes and corrective actions for tablet problems related to tooling.<sup>14</sup>

### Single-Punch Machines

The simplest tableting machines available are those having the single-punch design. A number of models are available. Although most of these are power-driven, several hand-operated models are available. Compression is accomplished on a single-punch machine. The feed shoe filled with the granulation is positioned over the die cavity, which then fills. The feed shoe retracts and scrapes all excess granulation away from the die cavity. The upper punch lowers to compress the granulation within the die cavity. The upper punch retracts, and the lower punch rises to eject the tablet. As the feed shoe returns to fill the die cavity, it pushes the compressed tablet from the die platform. The weight of the tablet is determined by the volume of the die cavity; the lower punch is adjustable to increase or decrease the volume of granulation, thus, increasing or decreasing the weight of the tablet (Figs. 30-23, 30-24). For tablets having diameters larger than 1/2 inch, sturdier models are required. This is also true for tablets requiring a high degree of hardness, as in the case of compressed lozenges. The heavier models are capable of much higher pressures and are suitable for slugging.

**Operation of Single-Punch Machines**—In installing punches and dies in a single-punch machine, insert the lower punch first, by lining up the notched groove on the punch with the lower punch set screw and slipping it into the smaller bore in the die table; the setscrew is not tightened yet. The lower punch is differentiated from the upper punch in that it has a collar

**Figure 30-23.** Manufacture of 1, 2 or 3 layer tablets (Courtesy of Bosch Packaging Technology Ltd., Manesty.)

around the punch head. Slip the die over the punch head so the notched groove (with the widest area at the top) lines up with the die setscrew. Tighten the lower punch setscrew after seating the lower punch, by pressing on the punch with the thumb. Tighten the die setscrew, making certain the surface of the die is flush with the die table. Insert the upper punch, again lining up the grooved notch with the upper punch setscrew. To be certain that the upper punch is seated securely, turn the machine over by hand, with a block of soft wood or wad of cloth between the upper and lower punches. When the punch is seated, tighten the upper punch setscrew. Adjust the pressure so the upper and lower punches will not come in contact with each other when the machine is turned over. Adjust the lower punch so it is flush with the die table at the ejection point. Install the feed shoe and hopper. After adding a small amount of granulation to the hopper, turn the machine over by hand and adjust the pressure until a tablet is formed. Adjust the tablet weight until the desired weight is obtained. The pressure will have to be altered concurrently with the weight adjustments. Remembered, as the fill is increased, the lower punch moves farther away from the upper punch, and more pressure has to be applied to obtain comparable hardness. Conversely, when the fill is decreased, the pressure has to be decreased. When all the adjustments have been made, fill the hopper with granulation and turn on the motor. Hardness and weight should be checked immediately, and suitable adjustments made if necessary. Periodic checks should be made on the tablet hardness and weight during the running of the batch, at 15- to 30-minute intervals. When the batch has been run off, turn off the power and remove loose dust and granulation with the vacuum cleaner. Release the pressure from the punches. Remove the feed hopper and the feed shoe. Remove the upper punch, the lower punch, and the die. Clean all surfaces of the tablet machine, and dry well with clean cloth. Cover surfaces with thin coating of grease or oil prior to storage. As tablets are ejected from the machine, after compression, they are usually accompanied by powder and uncompressed granulation. To remove this loose dust, the tablets are passed over a screen, which may be vibrating, and cleaned with a vacuum line.

### Rotary Tablet Machines

For increased production, rotary machines offer great advantages. A head carrying a number of sets of punches and dies revolves continuously, while the tablet granulation runs from the hopper, through a feed frame, and into the dies placed in a large, steel plate revolving under it. This method promotes a uniform fill of the die and, therefore, an accurate weight for the tablet. Compression takes place as the upper and lower punches pass between a pair of rollers, as can be seen in Figure 30-25. This action produces a slow squeezing effect on the material in the

**Figure 30-24.** Modern Single Punch Tablet Press. (Courtesy of Bosch Packaging Technology Ltd., Manesty.)

die cavity from the top and bottom, and so gives a chance for the entrapped air to escape. The lower punch lifts up and ejects the tablet. Adjustments for tablet weight and hardness can be made, without the use of tools, while the machine is in operation. One of the factors that contributes to the variation in tablet weight and hardness during compression is the internal flow of the granulation within the feed hopper. On most rotary machine models, there is an excess pressure release that cushions each compression and relieves the machine of all shocks and undue strain. The punches and dies can be readily removed for inspection, cleaning, and to insert different sets to produce a great variety of sizes and shapes. Most rotary tablet presses measure a tablet's weight either by measuring its variation in tablet height at precompression or by the force at main compression. They compress a volume of granules, captured in a die, between two rollers, using an upper and lower punch. By changing the distance between the rollers, one adjusts the force used to compress tablets. Once the distance between the rollers is set, the compression force will stay the same. Several factors affect the precise amount of granules captured within each die. For example, granule size, size distribution, and variation in punch length can have an effect. In addition, an excessively high rotational speed allows the granules insufficient time to fall into the die. Variations in the amount of granules in each die result in tablets of different weights and densities. An inconsistency in the maximum compression force can result in inconsistent tablet properties, thus, affecting the efficacy of the dosage form.

Compression to equal force (EF) is a new concept that allows tablets to be compressed at the same peak compression force, independent of tablet weight. This method relies on the use of an air piston (Fig. 30-26). The air piston is installed at the precompression and main compression station and allows the pre- and main compression rollers to be floating rather than fixed. The piston moves vertically in a cylinder filled with compressed air. The air pressure in the cylinder is preset and

Figure 30-25. Rotary Tablet Press Cycle. (Courtesy of Natoli.)

kept constant by a pressure-regulating valve and an expansion chamber. Because the surface of the cylinder and the air pressure are constant, the force is also constant, irrespectively of the position of the floating roller. If the air pressure in the cylinder is such that this maximum compression force is higher than the actual compression force, the system compresses tablets to equal thickness, leading to high variation in tablet hardness. Conversely, the press can be set to make the compression roller move up at each compression. In this arrangement, all tablets are compressed at the same peak force, providing a much reduced variation in tablet hardness. The tablet press is equipped with a linear variable displacement transducer sensor that measures compression-roller movement accurately. A heavy tablet causes the compression roller to move more, and a light tablet causes less movement. This provides a tablet weight control method, called "tablet weight control by displacement," with a linear relationship between tablet weight and displacement. Accordingly, more accurate tablet weight for smaller tablets than the conventional tablet weight control by force is assured. Floating compression rollers also provide an effective means to increase dwell at high turret revolutions. Increasing the dwell time at pre- and main compression and at high turret speed is necessary to improve deaeration and uniform distribution of compaction stress in the die prior to final compaction at high tablet output. This provides reduced risk of capping, better bonding of layers, in the case of bilayer tablets, and improved tablet tensile strength. When compressed to equal force, variations in tablet weight do not affect tensile strength. Therefore, tablets maintain a consistent clinical efficacy. Equal force tableting is also of interest when compacting coated pellets or when producing of Orally Disintegrating Tablets.

**Operation of Rotary Machines**—Before inserting punches and dies, make certain the pressure has been released from the pressure wheel. The die holes should be cleaned thoroughly, making certain the die seat is completely free of any foreign materials. Back off all die locks, and loosely insert dies into the die holes, then tap each die securely into place, with a fiber of soft metal rod through the upper punch holes. After all the dies have been tapped into place, tighten each die locks crew progressively and securely. As each screw is tightened, the die is checked to see it does not project above the die table. Insert the lower punches through the hole made available, by removing the punch head. Turn the machine by hand until the punch bore coincides with the plug hole. Insert each lower

punch in its place progressively. Insert the upper punches by dropping them into place in the head. Each punch (upper and lower) should be coated with a thin film of mineral oil before insertion into the machine. Adjust the ejection cam, so the lower punch is flush with the die table at the ejection point. After insertion of the punches and dies, adjust the machine for the tablet weight and hardness. The feed frame should be attached to the machine along with the feed hopper. Add a small amount of the granulation through the hopper and turn the machine over by hand. Increase the pressure by rotating the pressure wheel until a tablet is formed. Check the weight of the tablet, and adjust the fill to provide the desired tablet weight. Most likely, more than one adjustment of the fill will be necessary before obtaining the acceptable weight. When the fill is decreased, the pressure must be decreased to provide the same hardness in the tablet. Conversely, when the fill is increased, the pressure must be increased to obtain comparable hardness. Fill the hopper with the granulation and turn on the power. Check tablet weight and hardness immediately after the mechanical operation begins, and make suitable adjustments, if necessary. Check these properties routinely and regularly at 15- to 30-minute intervals, while the machine is in operation. When the batch has been run, turn off the power. Remove the hopper and feed frame from the machine. Remove loose granulation and dust with a vacuum line. Remove all pressure from the wheel. Remove the punches and dies in the reverse order of that used in setting up the machine. First, remove the upper punches individually, then the lower punches, and finally the dies. Wash each punch and die in alcohol, and brush with a soft brush to remove adhering material. Dry them with a clean cloth, and cover them with a thin coating of grease or oil before storing.

### High-Speed Rotary Tablet Machines

The rotary tablet machine has evolved, gradually, into models capable of compressing tablets at high production rates (see Figs. 30-27, 30-28). This has been accomplished by increasing the number of stations (i.e., sets of punches and dies) in each revolution of the machine head, improving feeding devices, and on some models installing dual compression points. Rotary machines with dual compression points are referred to as double rotary machines, and those with one compression point, single rotary. One-half of the tablets are produced 180° from the tablet chute. They travel outside the perimeter and

Figure 30-26. Rotary Tablet Compression Cycle. (Courtesy of Courtoy.)

discharge with the second tablet production. Although these models are mechanically capable of operating at production rates of more than 5000 tablets per minute, the actual speed still depends on the physical characteristics of the tablet granulation and the rate that is consistent with compressed tablets having satisfactory physical characteristics. The main difficulty in rapid machine operation is ensuring adequate filling of the dies. With rapid filling, dwell time of the die cavity beneath the feed frame is insufficient to ensure the requirements of uniform flow and packing of the dies. Various methods of force-feeding the granulation into the dies have been devised to refill the dies in the very short dwell time permitted on the high-speed machine. Presses with pre-compression rollers permit the partial compaction of material before final compaction. This provides for partial deaeration and particle

orientation of material before final compression. This helps in the direct compacting of materials and reduces laminating and capping due to entrapped air.

### Multilayer Rotary Tablet Machines

Rotary tablet machines have also been developed into models capable of producing multiple-layer tablets; the machines are able to make 1-, 2-, or 3-layer tablets (Oystar Manesty). Stratified tablets offer a number of advantages. Incompatible drugs can be formed into a single tablet by separating the layers containing them with a layer of inert material. It has permitted the formulation of time-delay medication and offers a wide variety of possibilities in developing color combinations that give the products identity. Originally, the tablets were prepared by a single-compression method. The dies were filled

**Figure 30-27.** Modern Rotary Tablet Press. (Courtesy of Courtoy.)

with the different granulations in successive layers, and the tablet was formed by a single compression stroke. The separation lines of the tablets prepared by this method tended to be irregular. In the machines now available for multilayer produc-

**Figure 30-28.** Modern Tablet Press. (Courtesy of FETTE.)

tion, the granulation receives a precompression stroke after the first and second fill, which lightly compacts the granulation and maintains a well-defined surface of separation between each layer. The operator is able to eject either precompressed layer, with the machine running, at any desired speed, for periodic weight and analysis checks. Other multiple-compression presses can receive previously compressed tablets and compress another granulation around the preformed tablet. An example of a press with this capability is the Manesty Drycota (Oystar Manesty). Pressure coated tablets can be used to separate incompatible drug substances and to give an enteric coating to the core tablets.

### Capping and Splitting of Tablets

The splitting or capping of tablets is one of great concern and annoyance in tablet making. It is quite difficult to detect, while the tablets are processed, but can be detected easily by vigorously shaking a few in the cupped hands. A slightly chipped tablet does not necessarily mean that the tablet will cap or split. There are many factors that may cause a tablet to cap or split: excess fines or powder, which traps air in the tablet mixture; deep markings on tablet punches. Many designs or "scores" on punches are too broad and deep. Hairline markings are just as appropriate as deep, heavy markings: worn and imperfect punches. Punches should be smooth and buffed. Nicked punches often cause capping. The development of fine feather edges on tablets indicates wear on punches: worn dies. Dies should be replaced or reversed. Dies that are chrome plated or have tungsten carbide inserts wear longer and give better results than ordinary steel dies; too much pressure. By reducing the pressure on the machines, the condition may be corrected; unsuitable formula. It may be necessary to change the formula; moist and soft granulation. This type of granulation will not flow freely into the dies, thus, giving uneven weights and soft or capped tablets; poorly machined punches. Uneven punches are detrimental to the tablet machine itself and will not produce tablets of accurate weight. One punch out of alignment may cause one tablet to split or cap on every revolution.

### Instrumented Tablet Presses

Compressional and ejectional forces involved in tablet compression can be studied by attaching strain gauges to the punches and other press components involved in compression. The electrical output of the gauges has been monitored by telemetry or use of a dual-beam oscilloscope equipped with camera. Instrumentation permits a study of the compaction characteristics of granulations, their flowabilities, and the effect of formulation additives, such as lubricants, as well as differences in tablet press design. Physical characteristics of tablets, such as hardness, friability, disintegration time, and dissolution rate, are influenced not only by the nature of the formulation, but by the compressional force as well. The rate and duration of compaction forces can be quantified. The rate of force application has a profound effect on powder consolidation within the die and, hence, efficiency of packing and powder compaction. The rate of release of force, or decompression, has a direct effect on the ability of the tablet to withstand relaxation. A prominent hypothesis, fostered by suggestion that capping and laminating of tablets is caused by too-rapid stress relaxation or decompression. This explains why slowing a tablet press and using tapered dies is useful in such situations. Most prominent pharmaceutical scientists have embraced this theory and have largely discounted air entrapment as a cause of capping and laminating. As compaction force rises, the steel tooling actually compresses in accommodation to the forces applied. The forces used to produce a tablet are considerable and should be monitored and understood. Therefore, definition of the compressional force and duration of force (dwell time), giving a satisfactory tablet for a formulation, provides an in-process control for obtaining both tablet-to-tablet and lot-to-lot uniformity. Instrumentation

has led to the development of on-line, automatic, electromechanical tablet weight-control systems capable of continuously monitoring the weights of tablets as they are produced. Most commercial presses today can be delivered with some sort of instrumentation attached. When tablet weights vary from preset limits, the monitor will automatically adjust the weight control mechanism to re-establish weights within acceptable limits. If the difficulty continues, the unit will activate an audible warning signal or an optional shut-down relay on the press. Most production model tablet presses come equipped with complete instrumentation (optional) and with options for statistical analysis and print out of compression/ejection signals. The techniques and applications of press instrumentation have been reviewed.<sup>15</sup>

### Contamination

Although good manufacturing practices used by the pharmaceutical industry for many years have stressed the importance of cleanliness of equipment and facilities for the manufacture of drug products, the penicillin contamination problem resulted in renewed emphasis on this aspect of manufacturing. Penicillin, as either an airborne dust or residual quantities remaining in equipment, is believed to have contaminated unrelated products in sufficient concentrations to cause allergic reactions in individuals hypersensitive to penicillin. This resulted in the industry spending millions of dollars to change or modify buildings, manufacturing processes, equipment, and standard operating procedures to eliminate penicillin contamination.

With this problem has come renewed emphasis on the dust problem, material handling, and equipment cleaning in dealing with drugs, especially potent chemicals. Any process using chemicals in powder form can be a dusty operation; the preparation of compressed tablets and encapsulation fall in this category. In the design of tablet presses attention is being given to the control and elimination of dust generated in the tableting process. In modern presses, shown in Figures 30-27 and 30-28, the pressing compartment is completely sealed off from the outside environment, making cross-contamination nearly impossible. The pressing compartment can be kept dust-free by the air supply and vacuum equipment developed for the machine. It removes airborne dust and granular particles that have not been compressed, thus, keeping the circular pressing compartment and the upper and lower punch guides free of dust. Drug manufacturers have the responsibility to make certain that micro-organisms present in finished products are unlikely to cause harm to the patient and will not be deleterious to the product. An outbreak of *Salmonella* infections in Scandinavian countries was traced to thyroid tablets prepared from contaminated thyroid powder. This concern, eventually, led to the establishment of microbial limits for raw materials of animal or botanical origin, especially those that readily support microbial growth and are not rendered sterile during subsequent processing. Harmful micro-organisms, when present in oral products, include *Salmonella* spp, *Escherichia coli*, and certain *Pseudomonas* spp, such as *P aeruginosa*, and *Staphylococcus aureus*. The compendia have microbial limits on raw materials, such as aluminum hydroxide gel, cornstarch, thyroid, acacia, and gelatin. These represent examples of the industry's efforts to conform to the intent of current good manufacturing practice, as defined by the FDA.

### Molded Tablets or Tablet Triturates (TT)

Tablet triturates are small, discoid masses of molded powders weighing 30–250 mg each. The base consists of lactose, B lactose, mannitol, dextrose, or other rapidly soluble materials. It is desirable in making tablet triturates to prepare a solid dosage form that is rapidly soluble; as a result, they are generally softer than compressed tablets. This type of dosage form

is selected for a number of drugs, due to its rapidly dissolving characteristic. Nitroglycerin in many concentrations is prepared in tablet triturate form, since the molded tablet rapidly dissolves, when administered by placing under the tongue. Potent alkaloids and highly toxic drugs, used in small doses, are prepared as tablet triturates that can serve as dispensing tablets used as the source of the drug in compounding other formulations or solutions. Narcotics, in the form of hypodermic tablets, were originally made as tablet triturates, because they rapidly dissolve in sterile water for injection prior to administration. Today, with stable injections of narcotics available, there is no longer any justification for their use in this manner. Although many hypodermic tablets are currently made, they are used primarily for oral administration. Tablet triturates are made by forcing a moistened blend of the drug and diluent into a mold, extruding the formed mass, which is allowed to dry. This method is essentially the same as it was when introduced by Fuller in 1878. Hand molds may vary in size, but the method of operation is essentially the same. Molds consist of two plates made from polystyrene plastic, hard rubber, nickel-plated brass, or stainless steel. The mold plate contains 50–500 carefully polished perforations. The other plate is fitted with a corresponding number of projecting pegs or punches that fit the perforations in the mold plate. The mold plate is placed on a flat surface, the moistened mass is forced into the perforations, and the excess is scraped from the top surface. The mold plate is placed over the plate with the corresponding pegs and lowered. As the plates come together, the pegs force the tablet triturates from the molds. They remain on the tops of the pegs until dry, and they can be handled. In some hand molds, the pegs are forced down onto the plate holding the moist trituration.

### TABLET CHARACTERISTICS

Compressed tablets may be characterized or described by a number of specifications. These include the diameter size, shape, thickness, weight, hardness, disintegration time, and dissolution characteristics. The diameter and shape depend on the die and the punches selected for the compression of the tablet. Generally, tablets are discoid in shape, although they may be oval, oblong, round, cylindrical, or triangular. Their upper and lower surfaces may be flat, round, concave, or convex to various degrees. The concave punches, used to prepare convex tablets, are referred to as shallow, standard, and deep cup, depending on the degree of concavity. The tablets may be scored in halves or quadrants to facilitate breaking, if a smaller dose are desired. The top or lower surface may be embossed or engraved with a symbol or letters that serve as an additional means of identifying the source of the tablets. These characteristics, along with the color of the tablets, tend to make them distinctive and identifiable with the

Figure 30-29. Electric Tablet Hardness Tester. (Courtesy of Erweka.)

**Figure 30-30.** Electric Hardness Tester. (Courtesy of Key.)

active ingredient that they contain. The remaining specifications assure the manufacturer that the tablets do not vary from one production lot to another. In the case of new tablet formulations their therapeutic efficacy is demonstrated through clinical trials, and it is the manufacturer's aim to reproduce the same tablet with the exact characteristics of the tablets that were used in the clinical evaluation of the dosage form. Therefore, from the control viewpoint these specifications are important for reasons other than physical appearance.

#### Tablet Hardness or Crushing Strength

The resistance of the tablet to chipping, abrasion, or breakage under conditions of storage, transportation, and handling, before usage, depends on its hardness. In the past, a rule of thumb described a tablet to be of proper hardness if it was firm enough to break with a sharp snap, when it was held between the second and third fingers and using the thumb as the fulcrum, yet didn't break when it fell on the floor. For obvious reasons and control purposes, a number of attempts have been made to quantitate the degree of hardness. A small and portable hardness tester was manufactured and introduced in the mid-1930s by Monsanto. It now is distributed by the Stokes Div (Pennwalt) and may be designated as either the Monsanto or Stokes hardness tester. The instrument measures the force required to break the tablet, when the force generated by a coil spring is applied diametrically to the tablet. The force is measured in kilograms. The Strong-Cobb hardness tester, introduced in 1950, also measures the

**Figure 30-31.** Tablet Friability Testers. (Courtesy of Erweka.)

**Figure 30-32.** Tablet Thickness Tester. (Courtesy of Starrett.)

diametrically applied force required to break the tablet. In this instrument, the force is produced by a manually operated air pump. As the pressure is increased, a plunger is forced against the tablet placed on anvil. The final breaking point is indicated on a dial, calibrated into 30 arbitrary units. The hardness values of the Stokes and Strong-Cobb instruments are not equivalent. Another instrument is the Pfizer hardness tester, which operates on the same mechanical principle as ordinary pliers. The force required to break the tablet is recorded on a dial and expressed in either kilograms or pounds of force. Currently, the most widely used apparatuses to measure tablet hardness or crushing strength are the electrically operated equipment, which eliminates the operator variability. Newer equipment are also available with printers. Manufacturers, such as SOTAX, Key, Van Kel, Erweka, Dr. Schleuniger Pharmatron, and others, make electrically driven hardness testers (Figs. 30-29, 30-30). Hardness (or more appropriately, crushing strength) determinations are made throughout the tablet runs, to determine the need for pressure adjustments on the tableting machine. If the tablet is too hard, it may not disintegrate in the required period of time or meet the dissolution specification; if it is too soft, it will not withstand handling during subsequent processing, such as coating or packaging and shipping operations.

#### Friability

A tablet property related to hardness is friability, and the measurement is made by use of the Roche friabilator. Rather than a measure of the force required to crush a tablet, the instrument is designed to evaluate the ability of the tablet to withstand abrasion in packaging, handling, and shipping. A number of tablets are weighed and placed in the tumbling apparatus, where they are exposed to rolling and repeated shocks, resulting from free-falls within the apparatus. After a given number of rotations, the tablets are weighed, and the loss in weight indicates the ability of the tablets to withstand this type of wear (Fig. 30-31). The friability test is now included in the USP.

A similar approach is taken by many manufacturers, when they evaluate a new product in the new market package, by sending the package to distant points and back, using various methods of transportation. This is called a "shipping test." The condition of the product on its return indicates its ability to withstand transportation handling.

#### Tablet Thickness

The thickness of the tablet from production-run to production-run is controlled carefully. Thickness can vary with no change in weight, due to difference in the density of the granulation and the pressure applied to the tablets, as well as the speed

of tablet compression. Not only is the tablet thickness important in reproducing tablets identical in appearance, but also to ensure that every production lot will be usable with selected packaging components. If the tablets are thicker than specified, a given number may no longer be contained in the volume of a given size bottle. Tablet thickness also becomes an important characteristic in counting tablets using filling equipment. Some filling equipment uses the uniform thickness of the tablets as a counting mechanism. A column containing a known number of tablets is measured for height; filling is accomplished by continually dropping columns of tablets of the same height into bottles. If thickness varies throughout the lot, the result will be variation in count. Other pieces of filling equipment can malfunction, due to variation in tablet thickness, since tablets above specified thickness may cause wedging of tablets in previously adjusted depths of the counting slots. Tablet thickness is determined with a caliper or thickness gauge that measures the thickness in millimeters. Plus or minus 5% may be allowed, depending on the Standard Operating Procedures (Fig. 30-32).

### UNIFORMITY OF DOSAGE UNITS

Over the past 40 years, the limits for uniformity of dosage units have been upgraded and made stricter. The reader is advised to refer to the most recent Pharmacopeia for complying with the regulations where the test is done.

The term “uniformity of dosage unit” is defined as the degree of uniformity in the amount of the drug substance in a tablet. The uniformity of dosage units can be demonstrated by either one of two methods, Content Uniformity (CU) or Weight Variation. The most recent USP 34 is harmonized with the Japanese and European Pharmacopoeias.<sup>16</sup>

CU testing was developed to ensure the content consistency of active pharmaceutical ingredients (API) within a narrow range around the label claim in dosage units. CU is related to efficacy, especially for low drug content where manufacturing loss is the dominant problem; whereas, for potent and narrow therapeutic indexed drugs, CU is also associated with safety.

By default, all tablets and capsules, as dosage units, are requested to pass the CU acceptance criteria, by direct individual analysis of each sampled unit, otherwise weight variation (WV) procedure is to be applied, if dosage units contain 25.0 mg or 25.0% W/W of API or more, or when the process development and validation data support its application. CU by WV is determined by multiplying the composite assay results by the ratio of each individual unit weight to the average weight of the sample.

Current CU testing has a confirmatory nature and is based on calculation of acceptance value (AV) of two stage sampling plan by applying the following equation:

$$AV = (|M - \bar{x}| + ks)$$

The multiplier  $k$  is either 2.4 or 2.0, for sample sizes of 10 or 30, respectively.  $s$  is the standard deviation. The reference value  $M$  takes different values, according to the sample mean ( $\bar{x}$ ) and the target content per dosage unit at the time of manufacturing ( $T$ ). The calculated AV should be less than 15.0 ( $L_1$ ), and no single unit deviates by more than  $L_2$  % (generally, 25%) from the reference value  $M$ . Theoretically, this new concept aims to assure dosage units to have drug content not critically (within  $\pm 15\%$ ) deviating from the nominal dose value.

### Tablet Disintegration

It is recognized generally that the *in vitro* tablet disintegration test does not necessarily bear a relationship to the *in vivo* action of a solid dosage form. To be absorbed, a drug substance must be in solution, and the disintegration test is a measure only of the time required under a given set of conditions for a group of tablets to disintegrate into particles. Generally, this test is useful as a quality-assurance tool for conventional dosage forms. In the present disintegration test, the particles are those that pass

Figure 30-33. USP Disintegration Tester. (Courtesy of SOTAX.)

through a 10-mesh screen. Regardless of the lack of significance as to *in vivo* action of the tablets, the test provides a means of control in ensuring that a given tablet formula is the same as regards disintegration from one production batch to another. The disintegration test is used as a control for tablets intended to be administered by mouth, except for tablets intended to be chewed before being swallowed or tablets designed to release the drug substance over a period of time. Exact specifications are given for the test apparatus, in as much as a change in the apparatus can cause a change in the results of the test. The USP apparatus consists of a basket-rack assembly, a 1000-mL, low-form beaker, 138–160 mm in height and having an inside diameter of 97–115 mm for the immersion fluid, a thermostatic arrangement for heating the fluid between 35°C and 39°C, and a device for raising and lowering the basket in the immersion fluid at a constant frequency rate between 29 and 32 cycles per minute through a distance of not less than 53 mm and not more than 57 mm. The volume of the fluid in the vessel is such that, at the highest point of the upward stroke, the wire mesh remains at least 15 mm below the surface of the fluid and descends to not less than 25 mm from the bottom of the vessel on the downward stroke. At no time should the top of the basket-rack assembly become submerged. The time required for the upward stroke is equal to the time required for the downward stroke, and the change in stroke direction is a smooth transition, rather than an abrupt reversal of motion. The basket-rack assembly moves vertically along its axis. There is no appreciable horizontal motion or movement of the axis from the vertical.

**Basket-Rack Assembly**—The basket-rack assembly consists of six open-ended transparent tubes, each  $77.5 \pm 2.5$  mm long and having an inside diameter of 20.7–23 mm and a wall 1.0–2.8 mm thick; the tubes are held in a vertical position by two plates, each 88–92 mm in diameter and 5–8.5 mm in thickness, with six holes, each 22–26 mm in diameter, equidistant from

the center of the plate and equally spaced from one another. Attached to the under surface of the lower plate is a woven stainless steel wire cloth, which has a plain square weave with 1.8- to 2.2-mm apertures and with a wire diameter of 0.57-0.66 mm. The parts of the apparatus are assembled and rigidly held by means of three bolts passing through the two plates. A suitable means is provided to suspend the basket-rack assembly from the raising and lowering device, using a point on its axis (Fig. 30-33).

The design of the basket-rack assembly may be varied somewhat, provided the specifications for the glass tubes and the screen mesh size are maintained. The use of disks is permitted only where specified or allowed in the monograph. If specified in the individual monograph, each tube is provided with a cylindrical disk  $9.5 \pm 0.15$  mm thick and  $20.7 \pm 0.15$  mm in diameter. More details about disk design are in the USP. The endpoint of the test is indicated when any residue remaining is a soft mass with no palpably soft core. The plastic discs help force any soft mass that forms through the screen. For compressed, uncoated tablets the testing fluid is usually purified water USP at  $37^\circ\text{C}$ , but in some cases the monographs direct that Simulated Gastric Fluid TS be used. If one or two tablets fail to disintegrate, the test is repeated using 12 tablets. Of the 18 tablets then tested, 16 must have disintegrated within the given period of time. The conditions of the test are varied somewhat for coated tablets, buccal tablets, and sublingual tablets. Disintegration times are included in the individual tablet monograph. For most uncoated tablets, the period is 30 minutes, although the time for some uncoated tablets varies greatly from this. For coated tablets up to 2 hours may be required, whereas, for sublingual tablets, such as CT Isoproterenol Hydrochloride, the disintegration time is 3 minutes. This is harmonized with the corresponding texts of the European Pharmacopoeia and/or the Japanese Pharmacopoeia. (For the exact conditions of the test, consult the USP.)

### Dissolution Test

Currently, for most tablets, the monographs direct compliance with limits on dissolution, rather than disintegration. Since drug absorption and physiological availability depend on having the drug substance in the dissolved state, suitable dissolution characteristics are important properties of a satisfactory tablet. Like the disintegration test, the dissolution test for measuring the amount of time required for a given percentage of the drug substance in a tablet to go into solution under a specified set of conditions is an *in vitro* test. It is intended to provide a step toward the evaluation of the physiological availability of the drug substance, but, as described currently, it is not designed

**Figure 30-34.** USP Dissolution Tester, Paddle Method. (Courtesy of Erweka.)

**Figure 30-35.** USP Dissolution Tester, Flow Through. (Courtesy of SOTAX.)

to measure the safety or efficacy of the tablet being tested. Both the safety and effectiveness of a specific dosage form must be demonstrated, initially, by means of appropriate *in vivo* studies and clinical evaluation. Like the disintegration test, the dissolution test does provide a means of control in ensuring a given tablet formulation is the same as regards dissolution as the batch of tablets shown, initially, to be clinically effective. It also provides an *in vitro* control procedure to eliminate variations among production batches. Figures 30-34 and 30-35 show some popular commercial dissolution testers. (Refer to Chapter 6 for a complete discussion of dissolution testing.)

### Validation

In this era of increasing regulatory control of the pharmaceutical industry, manufacturing procedures cannot be discussed without the mention of some process-validation activity. By way of documentation, product testing, and, perhaps, in-process testing as well, manufacturers can demonstrate that their formulas and processes perform in the manner expected and that they do so reproducibly. Although the justification for requiring validation is found in the regulations relating to *Current Good Manufacturing Practices for Finished Pharmaceuticals*, as well as other sources, there is still much room for interpretation, and the process varies from one company to another. General areas of agreement are that the validation activity must begin in Research and Development and continue through product introduction. Documentation is the key. In general, three batches represent an adequate sample for validation. The FDA has rejected historical data or retrospective validation. They require that new products be validated from beginning to end, a process called prospective validation.<sup>17</sup>

### PROCESS ANALYTICAL TECHNOLOGY (PAT)

One definition for PAT is the “systems for continuous analysis and control of manufacturing processes based on real-time measurements, or rapid measurements during processing, of quality and performance attributes of raw and in-process materials and processes to assure acceptable end product quality at the completion of the process.”<sup>18</sup> This requires a synergy of multiple systems, including process analytical chemistry tools, information management tools, feedback process control strategies, and strategies for product/process design and optimization. The PAT initiative in pharmaceuticals began in the 1990s. In 1993, an AOAC International Symposium was held entitled “Pharmaceutical Process Control and Quality

Assessment by Non-Traditional Means.” Then, in 2001, an Advisory Committee for Pharmaceutical Science (ACPS) meeting was held and discussed PAT. This meeting prompted 20/FDA Science Board endorsement of the formation of a PAT subcommittee within ACPS.<sup>18</sup> The PAT subcommittee is comprised of four working groups: 1) benefits, technology, definitions/terminology, 2) process and analytical validation, 3) chemometrics, and 4) product/process development. These working groups are composed of people from the FDA, industry, and academia. In addition, a new journal was published to address the expanding role of PAT in the pharmaceutical industry, *The Journal of Process Analytical Technology* with its first issue in September/October 2004. It is apparent that PAT will become an important part of the pharmaceutical industry, as it has in other industries. The reason is that PAT can improve efficiency and capability of pharmaceutical processes, while verifying and improving product quality. Results the pharmaceutical industry anticipates from optimal application of PAT include reduced risk of scrap and recalls, improved process understanding with quality “by design,” improved capacity utilization and reduced cycle times, and eventual reduction in product development time. The current methods to verify product quality, final product testing at the end of manufacturing and some process operation ranges, cause low manufacturing efficiency and require a very high level of regulatory scrutiny.<sup>18</sup> For example, if a batch fails final product release testing for product quality control, these results are not known until weeks after the batch was manufactured. In that time period, multiple batches could have been manufactured with the same problems and would have to be rejected. In contrast, PAT allows for rapid identification of out of the ordinary situations, when the critical product properties are defined up front. Therefore, the time to respond to problems is greatly reduced, and much time and money can be saved. PAT also allows for statistical process control analysis (trending) of critical in-process product attributes.<sup>19</sup>

## CAPSULES

Capsules are solid dosage forms in which the drug substance is enclosed in either a hard or soft, soluble container or shell of gelatin or other suitable material. The soft gelatin capsule was invented by Mothes, a French pharmacist, in 1833. During the following year, DuBlanc obtained a patent for his soft gelatin capsules. In 1848, Murdock patented the two-piece hard gelatin capsule. More recently, capsule shells made from hydroxypropyl methylcellulose have become available commercially. These capsules contain less residual moisture than gelatin capsules and thus may have applications in filling hydrolytic drugs. In addition, these capsules offer an excellent alternative for strict vegetarians. Gelatin, however, due to its unique properties, remains the primary composition material for the manufacture of capsules. The gelatin used in the manufacture of capsules is obtained from collagenous material by hydrolysis. There are two types of gelatin, Type A, derived mainly from pork skins by acid processing, and Type B, obtained from bones and animal skins by alkaline processing. Blends are used to obtain gelatin solutions with the viscosity and bloom strength characteristics desirable for capsule manufacture.

The encapsulation of medicinal agents remains a popular method for administering drugs. Capsules are tasteless, easily administered, and easily filled either extemporaneously or in large quantities commercially. In prescription practice, the use of hard gelatin capsules permits a choice in prescribing a single drug or a combination of drugs at the exact dosage level considered best for the individual patient. This flexibility is an advantage over tablets. Some patients find it easier to swallow capsules than tablets, therefore, preferring to take this form when possible. This preference has prompted pharmaceutical manufacturers to market products in capsule form, even though the products have already been produced in tablet form.

Figure 30-36. Hard gelatin capsules showing relative size.

Although the industry prepares approximately 75% of its solid dosage forms as compressed tablets, 23% as hard gelatin capsules, and 2% as soft elastic capsules, market surveys indicated a consumer preference of 44.2% for soft elastic capsules, 39.6% for tablets, and 19.4% for hard gelatin capsules.<sup>20</sup>

## HARD GELATIN CAPSULES

The hard gelatin capsule consists of two sections, one slipping over the other, thus, completely surrounding the drug formulation. Figure 30-36 illustrates the classic capsule shape and size. These capsules are filled by introducing the powdered material into the longer end or body of the capsule and then slipping on the cap. Hard gelatin capsules are made from gelatin and other materials used either to enable capsule formation or to improve their performance (see Table 30-2).<sup>21</sup> Hard gelatin capsules contain 12–16% water, but the water content can vary, depending on the storage conditions. When the humidity is low, the capsules can become brittle; if stored at high humidities, the capsules can become flaccid, sticky, and lose their shape. Storage in high-temperature areas can also affect the quality of hard gelatin capsules. Gelatin capsules do not protect the fill materials from atmospheric water vapor, as moisture can readily diffuse through the gelatin wall.

Companies having equipment for preparing empty hard gelatin capsules include Lilly, Parke-Davis, Scherer, and Smith-Kline. The latter's production is mainly for its own use; the others are suppliers to the industry. With this equipment, stainless steel pins, set in plates, are dipped into the gelatin solution, which must be maintained at a uniform temperature and an exact degree of fluidity. If the gelatin solution varies in viscosity, it will correspondingly decrease or increase the thickness of the capsule wall. This is important, since a slight variation is sufficient to make either a loose or a tight joint. When the pins have been withdrawn from the gelatin solution, they are rotated, while being dried in kilns through which a strong blast of filtered air with controlled humidity is forced. Each capsule is removed from the pins, trimmed to uniform length, and joined, the entire process being mechanical.

Table 30-2. Gelatin Capsule Additives

Additives	Function and Examples
Coloring Agent	Aesthetic, Identification, Psychological effect and Light protection (e.g., E122, E127, E171)
Process Aids	Surfactants: help in gelatin to take the shape of the moulds Silicon Fluid: assistant in enteric coating
Performance Aids	Flavoring agent: improve patient acceptability
Preservative	Gelatin is good medium for bacterial and fungal growth (e.g., Sulfur dioxide)
Gelatin Extenders	To reduce the quantity of gelatin needed per capsule (e.g., hydroxylalkylstarch)
Protective Coating	To improve the capsule stability (i.e., moisture resistance and prevent capsule sticking)

Capsules are supplied in a variety of sizes. The hard, empty capsules (Fig. 30-36) are numbered from 000, the largest size that can be swallowed, to 5, which is the smallest. Larger sizes are available for use in veterinary medicine. The approximate capacity for capsules from 000 to 5 ranges from 600 to 30 mg, depending on the densities of the powdered drug materials. FDA issued a draft guidance for the industry in January 2011 about the maximum capsule bead size, which is 2.0 mm. This is based on approved product information and human studies that demonstrate food is chewed to approximately 2 mm in median particle size before swallowing.<sup>22</sup>

Commercially filled capsules have the conventional oblong shape illustrated above, with the exception of capsule products from Lilly and SmithKline. For Lilly products, capsules are tapered at the base of the body to give the capsule a bullet-like shape; products encapsulated in this shape of capsule are called Pulvules. The SmithKline capsules differ in ends of both the cap and body are angular.

After hard gelatin capsules are filled and the cap applied, there are a number of methods used to ensure the capsules will not come apart, if subjected to vibration or rough handling, as in high-speed counting and packaging equipment. The capsules can be spot-welded by means of a heated metal pin pressed against the cap, fusing it to the body, or they may be banded with molten gelatin applied around the joint. Colored gelatin bands around capsules have been used for many years as a trademark by Parke-Davis for their line of capsule products, Kapseals. Another approach is the Snap-Fit and Coni-Snap capsules that use a pair of matched locking rings in the cap and body portions of the capsule. Prior to filling, these capsules are slightly longer than regular capsules of the same size. When the locking rings are engaged after filling, their length is equivalent to that of the conventional capsule. Following several tampering incidents, pharmaceutical companies now use a number of locking and sealing technologies in addition to tamper-resistant packaging.

For extemporaneous compounding, the pharmacist must determine the size of the capsule needed for a given prescription. The correct capsule size can be determined from the volume of the material to be held by a single capsule. For powdered materials, the body of the capsule is filled with the desired weight of powder and the cap replaced. Weight checks of the compounded capsules should be done to verify the correct amount of powder has been filled in each capsule.

In addition to the transparent, colorless, hard gelatin capsule, capsules are also available in various transparent colors, such as pink, green, reddish brown, blue, yellow, and black. If they are used, it is important to note the color, as well as the capsule size, on the prescription, so that a refilled prescription will duplicate the original. Colored capsules have been used chiefly by manufacturers to give a specialty product a distinctive appearance. Titanium dioxide is added to the gelatin to form white capsules or to make an opaque, colored capsule. Commercial prescription products must be given further identification by markings with special numbers to permit exact identification by the pharmacist or physician.

### Extemporaneous Filling Methods

When filling capsules on prescription, the usual procedure is to mix the ingredients by trituration, reducing them to a fine and uniform powder. The principles and methods for the uniform distribution of an active medicinal agent in a powder mixture are discussed in Chapter 23. Granular powders do not pack readily in capsules, and crystalline materials, especially those that consist of a mass of filament-like crystals, such as the quinine salts, are not fitted easily into capsules, unless powdered. Eutectic mixtures that tend to liquefy may be dispensed in capsules, if a suitable absorbent, such as magnesium carbonate, is used. Potent drugs given in small doses are mixed with an inert diluent, such as lactose, before filling into capsules. When incompatible materials are prescribed together, it is sometimes

possible to place one in a smaller capsule and then enclose it with the second drug in a larger capsule.

The powder is placed on paper and flattened with a spatula, so the layer of powder is not greater than about 1/3 the length of the capsule being filled. This helps keep both the hands and capsules clean. The cap is removed from the selected capsule and held in the left hand; the body is pressed repeatedly into the powder until filled. The cap is replaced, and the capsule is weighed. In filling the capsule, the spatula is helpful in pushing the last quantity of the material into the capsule. If each capsule has not been weighed, there is likely an excess or a shortage of material, when the specified number of capsules have been packed.

Today, many manual and automatic capsule filling machines are available for increasing the speed of the capsule filling operation. Figure 30-37 illustrates a capsule-filling machine that is supplied by Torpac Inc. (ProFiller® 100). Many community pharmacists find this a useful apparatus, and some pharmaceutical manufacturers use it for small-scale production of specialty items. It is a 100-hole, hand-held capsule filling system available in all capsule sizes from 000 to 5, including el sizes. Production rates of 2000–3200 capsules per hour, within 1–2% of target capsule weight, are possible. Entire capsules (cap and body) are placed in the machine; the lower plate holds the capsule bodies in place and makes it possible to remove the caps. The powder is filled in the bodies; the accuracy of the fill depends on the selection of capsule size and the amount of pressure applied during filling. The capsule caps are then rejoined with the bodies. For large batches, the hand-operated machine (ProFiller® 3800) can be used, as illustrated in Figure 30-38. It is a bench-top filler with a bench-top Orienter (loader) that

Figure 30-37. Hand operated capsule machine. (Courtesy of Torpac Inc.)

Figure 30-38 Hand operated capsule machine, Model 3008-bs. (Courtesy of Torpac Inc.)

fills 300 capsules per try with an output of up to 7200 to 9000 capsules/hr.

### Machine Filling Methods

Large-scale capsule filling equipment operates on the same principle as the manual machines described above, namely the filling of the body of the capsule. Compared with tablets, powders for filling into hard gelatin capsules require a minimum of formulation efforts. The active ingredient is mixed with a sufficient volume of a diluent to fill the body with the desired amount of drug. Since powder flow is of great importance in the rapid and accurate filling of the capsule bodies, glidants, such as silica derivatives or the stearates, are also used frequently. As is true with tablets, additives present in the capsule formulation can influence drug release. Tablets and capsules of a combination product containing triamterene and hydrochlorothiazide in a 2:1 ratio were compared clinically. The tablet caused approximately twice as much excretion of hydrochlorothiazide and three times as much triamterene as the capsule.<sup>23</sup> The manner of operation of the machine can influence the volume of powder filled into the base of the capsule; therefore, the weights of the capsules must be checked routinely as they are filled (see Table 30-3).

Hard capsules are usually filled with active ingredient in dry powder form, yet other preparation may also be filled in capsules, including tablets, pellets, and even certain types of liquids. If liquids are filled in hard gelatin capsule, a banding step is generally necessary to prevent leakage of the fill. The filling of capsules is carried out in four steps: 1) separating the cap from the capsule body, 2) filling the body, 3) rejoining the capsule cap and body, and 4) discharge of the filled capsules. Filling the hard capsules with powders varies greatly from one manufacturer to another. The following are the four methods for filling the powder into hard capsules:

**The Plate Method**—The plate method is consider the basic and traditional filling method and is probably the oldest system used to fill hard gelatin capsules. It depends on overlaying the powder or granules over the capsule body in the dosing disc and then a using tamping device for dose punching and filling. The excess material is removed before replacing the caps. H Höfliger has developed a method, dependent on using free flowing material combined with a tamping punch (Fig. 30-39). In this method, the powder is compressed and tamped against the

Figure 30-39. Filling capsule by tamping method. (Courtesy of Harro Höfliger Verpackungsmaschinen GmbH.)

base plate of the dosage disc, which is designed to give a certain fill-weight in the capsule.

Although the filling weight can be adjusted slightly, by changing the tamping force, the dosing amount is more or less defined by the thickness of the dosing discs. Height adjustable dosing discs are on the market, but tests have shown that, due to the nature of the design, only easy to fill powders can be processed on this type of device. Furthermore, the constancy of the powder bed height influences the fill weight. Without extra measures, the tamp filling principle is not suitable for dosages below 30 mg. Powders that tend to segregate are problematic when dosing discs are above a certain diameter.

In comparison to the vacuum drum filler, there is more residual powder in the powder bowl at the end of a production run. Thus, this filling method, as well as the dosator nozzle principle, is usually not first choice, if the powder is expensive and batch sizes are small. Irrespective of these limitations, the tamp filling method is a very robust and easy to maintain system.

**Intermittent Compression Filling**—This method is used by Zanasi and other companies. In this method the powder is fed into the dosage hopper, and then the dosage tube enters the powder bed. This leads to form a unit mass inside the tube, which is lifted by the dosator and ejected into the capsule body

Table 30-3. Capsule Fill Chart

CAPSULE FILL WEIGHTS (MG) BASED ON SIZE AND DENSITY										
POWDER DENSITY (g/ml)	CAPSULE VOLUME (ML)									
	0.95	0.78	0.68	0.54	0.5	0.37	0.3	0.25	0.21	0.13
	CAPSULE SIZE									
	00	0e1	0	1e1	1	2	3	4e1	4	5
0.3	285	234	204	162	150	111	90	75	63	39
0.4	380	312	272	216	200	148	120	100	84	52
0.5	475	390	340	270	250	185	150	125	105	65
0.6	570	468	408	324	300	222	180	150	126	78
0.7	665	546	476	378	350	259	210	175	147	91
0.8	760	624	544	432	400	296	240	200	168	104
0.9	855	702	612	486	450	333	270	225	189	117
1	950	780	680	540	500	370	300	250	210	130
1.1	1045	858	748	594	550	407	330	275	231	143
1.2	1140	936	816	648	600	444	360	300	252	156
1.3	1235	1014	884	702	650	481	390	325	273	168
1.4	1330	1092	952	756	700	518	420	350	294	182
1.5	1425	1170	1020	810	750	555	450	375	315	159

(Fig. 30-40). One of the important factors that should be considered in this method is producing sufficient compression force to form an united mass and perfectly transferring it to the capsule body.

The dosator procedure is suitable for powder dosing quantities of  $\geq 20$ mg; however, it has only limited usage with very cohesive powders, with a high level of fine particles. Dosator pins can be manufactured with coated front surfaces or from materials to which the respective powders are less likely to adhere (e.g., certain polymers, which are certified by the FDA as product-contact materials.)

**Continuous Compression Filling**—This method was first developed by mG2 company. It is similar to the intermittent method in principle, yet it differs in application of high filling speeds. In this method, the dosator dips into the powder, and then fills the capsule body. The movement is rapid and continuous.

**Vacuum Filling**—This method was developed first by Perry Industries Inc. In this filling process the dosator draws the powder by suction, not like the previous process (i.e., punch). Some compression takes place by suction, allowing the material to stay in the dosator by vacuum pressure. The dosator then delivers the powder into the capsule body, after releasing the vacuum and applying positive pressure. One important technique of vacuum filling is called vacuum-drum dosing.

The principle construction of such a dosing system is represented in Figure 30-41. In the center is the rotating dosing drum, which consists of a core with a connection to the vacuum/pressure system and an outer casing with one or more rows of holes, which form the dosing chambers. Each dosing cham-

**Figure 30-40.** Intermittent compression filling of capsules. (Courtesy of Harro Hofliiger Verpackungsmaschinen GmbH.)

**Figure 30-41.** Filling capsule by Vacuum-Drum Method. (Courtesy of Harro Hofliiger Verpackungsmaschinen GmbH.)

ber is positioned over a cross drilled hole in the core that is connected with the air system. The openings turned toward the core of the chamber are closed by a suitable filter membrane. The filter material forms the separation of the chamber to the vacuum/pressure system and prevents the powder particles from being drawn off during dosing.

The filling cycle starts when the dosing cavities are positioned beneath the powder bed and vacuum is applied. The powder is forced into the cavities in the stationary or slowly rotating drum. By maintaining the vacuum, the drum is rotated for  $180^\circ$  above the target, the vacuum is turned off, and the powder slug is ejected by means of a short pulse of compressed air. Finally, the drum is rotated to the exhaust channel to remove residual powder adhering to the filter membrane or the walls of the dosing cavity.

There are many new capsule filling machines that work with one or more of the mentioned processes of capsule filling. Figure 30-42 shows a Modular capsule filling machine (Modu-CLS), produced by H Höfliiger. Figure 30-43 shows another new capsule filling machine, produced by PharmaLand (PCF 1200 Model).

All capsules, whether filled by hand or by machine, will require cleaning. Small quantities of capsules may be wiped individually with cloth. Larger quantities are generally processed through a capsule deduster/polisher.

### Uniformity of Dosage Units

Uniformity of dosage units is defined as the degree of uniformity in the amount of the drug substance among dosage units, USP 34<sup>24</sup>. The uniformity of dosage units of capsules can be demonstrated by either of two methods: Content Uniformity or Weight Variation (Table 30-4).

Disintegration tests are not usually required for capsules, unless they have been treated to resist solution in gastric fluid (enteric-coated). In this case, they must meet the requirements for disintegration of enteric-coated tablets. For certain capsule dosage forms, a dissolution requirement is part of the monograph. Procedures used are similar to those employed in the case of compressed tablets.

### SOFT ELASTIC CAPSULES

Soft elastic capsules, also known as soft gelatin capsules or softgels, differ from hard gelatin capsules in several ways. First, the capsule shells are typically made and filled simultaneously. Commercially filled soft gelatin capsules are available in a wide variety of shapes (e.g. round, oblong, tubular). The gelatin is plasticized by the addition of glycerin, sorbitol, or other suitable material, which gives the shell its characteristic flexibility. Preservatives are often included in the capsule shell formulation to prevent microbial or fungal growth.

Soft gelatin capsules are generally filled with liquids, where the drug is dissolved or dispersed in a solvent. The oral bio-availability of poorly water soluble drugs can be enhanced when the drug is dissolved in the fill liquid. Selection of the fill liquid (solvent) depends on the physicochemical properties of the drug, presence of other additives, and weight or volume of the content. Product stability is dependent on the properties of the capsule shell, storage conditions, and fill content<sup>25</sup>. For example, water vapor migration from the atmosphere can migrate through the capsule shell into the fill liquid and potentially cause precipitation of the drug.

### Manufacturing Methods

**Plate Process**—In this method, a set of molds is used. A warm sheet of prepared gelatin is laid over the lower plate, and the liquid is poured on it. A second sheet of gelatin is carefully put in place, followed by the top plate of the mold. The set is placed under a press where pressure is applied to form the capsules. Filled capsules are then washed off with a volatile solvent to remove any traces of oil from the exterior. The sheets of gelatin may have the same or different colors.

**Rotary-Die Process**—In 1933, the rotary-die process for soft gelatin capsules was perfected by Robert P Scherer.<sup>26</sup> The rotary-die machine is a self-contained unit capable of continuously and automatically producing finished capsules from a supply of gelatin mass and filling material, which may be any liquid, semiliquid, or paste that will not dissolve gelatin. Two continuous gelatin ribbons, which the machine forms, are brought into convergence between a pair of revolving dies and an injec-

tion wedge. Accurate filling under pressure and sealing of the capsule wall occur as dual and coincident operations; each is delicately timed against the other. Sealing also severs the completed capsule from the net. The principle of operation is shown in Figure 30-44 (see also Fig. 30-45).

By this process, the content of each capsule is measured individually by a single stroke of a pump, so accurately constructed that a plunger travel of 0.025 in will deliver 1 <minim> (apoth). The Scherer machine contains banks of pumps arranged so that many capsules are formed and filled simultaneously. All pumps are engineered to extremely small mechanical tolerances and to an extremely high degree of precision and similarity. All operations are controlled on a weight basis, by actual periodic checks with a group of analytical balances. Individual net-fill weights of capsules, resulting from large-scale production, vary no more than 3% from theory, depending on the materials used.

The rotary-die process makes it possible to encapsulate viscous materials, such as ointments and pastes. In this manner, solids can be milled with a vehicle and filled into capsules. When it is desirable to have a high degree of accuracy and a hermetically sealed product, this form of enclosure is ideally suited.

The modern and well-equipped capsule plant is completely air-conditioned with a high-quality water source, a practical necessity for capsule production. Its facilities and operations include the availability of carbon dioxide at every exposed point of operation for the protection of oxidizable substances before encapsulation. Special ingredients have also been used in the capsule shell to exclude light wavelengths destructive to certain drugs.

**Norton Capsule Machine**—This machine produces capsules completely automatically, by leading two films of gelatin between a set of vertical dies. These dies, as they close, open, and close, are in effect a continual vertical plate, forming row after row of pockets across the gelatin film. These are filled with medication and, as they progress through the dies, are sealed, shaped, and cut out of the film as capsules, which drop into a cooled solvent bath.

**Accogel Capsule Machine**—Another means of soft gelatin encapsulation uses the Accogel machine, a process developed at Lederle. The Accogel, or Stern machine, uses a system of rotary dies but is unique, in that it is the only machine that can successfully fill dry powder into a soft gelatin capsule. The machine is available to the entire pharmaceutical industry by a lease arrangement and is used in many countries of the world. It is extremely versatile, not only producing capsules with dry powder, but also encapsulating liquids and combinations of liquids and powders. By means of an attachment, slugs or compressed tablets may be enclosed in a gelatin film. The capsules can be made in a variety of colors, shapes, and sizes.

**Seamless Process (Bubble Method)**—The seamless technique produces soft gelatin capsules without requirement of dies. In this process, a molten gelatin stream runs through an outer nozzle of a concentric tube at a constant rate. The medicated liquid formulation is dispensed through the inner orifice by means of a pump. The emerging stream is broken up into an intermittent but steady flow of uniform sized by a pulsating mechanism, leading to the formation of droplets enveloped in molten gelatin. The formed capsules are quickly removed from the nozzle, slowly congealed, and automatically ejected from the system.

**Table 30-4. Application of Content Uniformity (CU) and Weight Variation (WV) Tests for Capsule Dosage Forms**

Dosage type	Subtype	Dose and ratio drug substance	
		≥25 mg	<25 mg
Hard gelatin capsule	Powder or others	WV	CU
Soft gelatin capsule	Suspension, emulsion or gel	CU	CU
	Solutions	WV	WV

**Figure 30-44.** Schematic drawing of a rotary-die soft gelatin capsule filler. (Courtesy of R.P. Scherer: Detroit, MI.)

**Microencapsulation**— Microencapsulation is a process or technique by which thin coatings can be applied reproducibly to small particles of solids, droplets of liquids, or dispersions, thus, forming microcapsules. It can be differentiated readily from other coating methods in the size of the particles involved; these range from several tenths to about 5000 micrometers in size. As a technology, microencapsulation is placed in the section on capsules only because of the relationship in terminology to mechanical encapsulation previously described. The topic is also discussed in Chapter 32.

A number of microencapsulation processes have been disclosed in the literature, some based on chemical processes involving a chemical or phase change and others are mechanical in nature, requiring specialized equipment.<sup>27,28</sup> A number of coating materials have been used successfully to microencapsulate materials; examples of these include gelatin, polyvinyl alcohol, ethylcellulose, cellulose acetate phthalate, and styrene maleic anhydride. Film thickness can be varied considerably, depending on the surface area of the material coated and other

**Figure 30-45.** Rotary-die soft gelatin capsule filler. (Courtesy of Pharmagel Engineering SPA: Milan, Italy.)

physical characteristics of the system. The microcapsules may consist of a single particle or clusters of particles. After isolation from the liquid manufacturing vehicle and drying, the material appears as a free-flowing powder. The powder is suitable for formulation as compressed tablets, hard gelatin capsules, suspensions, and other dosage forms. Microencapsulation has applications for masking the taste of bitter drugs, but can also be used as a means of formulating prolonged-action dosage forms, protecting chemicals against moisture or oxidation, and modifying a material's physical characteristics for ease of handling in formulation and manufacture.

**Figure 30-46** Basic steps of microencapsulation by solvent evaporation.

The technique of microencapsulation by solvent evaporation is widely applied in pharmaceutical industries to obtain the controlled release of drug (Fig. 30-46). The basic steps of microencapsulation by solvent evaporation include: 1) dissolving of the hydrophobic drug in an organic solvent containing the polymer; 2) emulsification of this organic phase in an aqueous phase; 3) extraction of the solvent from the organic phase, by the aqueous phase, accompanied by solvent evaporation, transforming droplets of dispersed phase into solid particles; and 4) recovery and drying of microencapsulation particles to eliminate the residual solvent. For insoluble or poorly water-soluble drugs, the oil-in-water (o/w) method is frequently used.

RECENT TRENDS IN PHARMACEUTICAL COATING TECHNOLOGY 620

### INTRODUCTION

Any introduction to tablet coating must be prefaced by an important question—*Why coat tablets?*<sup>2</sup>—since coatings are often applied to dosage forms that are already functionally complete. That said, a broad range of pharmaceutical oral solid dosage forms are coated, for a plethora of reasons that include

1. Protecting the drug from its surrounding environment (particularly air, moisture, and light) in order to improve stability.
2. Masking unpleasant taste and odor.
3. Making it easier for the patient to swallow the product.
4. Improving product identity, from the manufacturing plant, through intermediaries, and to the both healthcare workers and patients.
5. Facilitating handling, particularly in high-speed packaging/filling lines, and automated counters in pharmacies, where the coating minimizes cross-contamination due to dust elimination.
6. Improving product appearance, particularly where there are noticeable visible differences in tablet core ingredients from batch to batch.
7. Reducing the risk of interaction between incompatible components. This would be achieved by using coated forms of one or more of the offending ingredients (particularly active compounds).
8. Improving product robustness because coated products generally are more resistant to mishandling (abrasion, attrition, etc).
9. Modifying drug release, as in repeat-action, delayed release (enteric coated) and sustained-release products.

### EVOLUTION OF THE COATING PROCESS

Coating of medicinal products is a concept steeped in history. Rhazes (850–932 AD) used the mucilage of psyllium seeds to coat pills that had an offending taste. Subsequently, Avicenna<sup>1</sup> was reported to have used gold and silver for pill coating. Since those early times, a wide range of materials has been used in *tablet coating*. White<sup>2</sup> mentioned the use of finely divided talc in what was at one time popularly known as *pearl coating*, while Kremers and Urdang<sup>3</sup> described the introduction of the gelatin coating of pills by Garot in 1838.

An interesting reference<sup>4</sup> reports the use of waxes to coat poison tablets. These waxes, being insoluble in all parts of the gastrointestinal tract, were intended to prevent accidental poisoning (the contents could be “activated” by breaking the tablet open prior to administration).

While earlier coated products were produced by individuals working in pharmacies, particularly when extemporaneous

compounding was the common practice, that responsibility now has been assumed by the pharmaceutical industry. Early attempts to apply coatings to pills yielded variable results and usually required the handling of individual pills. Such pills would have been mounted on a needle or held with a pair of forceps and literally dipped into the coating fluid, a procedure that would have to be repeated more than once to ensure that the pill was coated completely. Subsequently, the pills were held at the end of a suction tube, dipped, and then the process repeated for the other side of the pill. Not surprisingly, these techniques often failed to produce a uniformly coated product.<sup>5</sup>

Initially, the first sugar-coated pills seen in the United States were imported from France about 1842<sup>5</sup>; while Warner, a Philadelphia pharmacist, became among the first indigenous manufacturers in 1856.<sup>6</sup>

Pharmaceutical pan-coating processes were initially based on those used in the candy industry, where techniques were highly evolved, even in the Middle Ages. Candy coating processes typically used coating pans made of copper because drying was accomplished by applying an external heat source directly to the outside of the coating pan. Current pharmaceutical coating processes use coating pans, of a broad range of designs, made from stainless steel, where drying of the product being coated is achieved by means of a supply of heated air, and moisture and dust-laden air is removed from the vicinity of the pan by means of an air-extraction system.

Conventional pharmaceutical pan-coating processes, employed essentially for sugar coating, remained unchanged for the first half of the twentieth century. However, since then there have been significant advances made in coating-process technology, mainly as a result of a steady evolution in pan design and associated ancillary equipment, primarily control systems.

Until the early 1950s, pharmaceutical coating was dominated by the sugar coating of tablets. However, at that time, a new form of technology (called film coating) was developed. Recognizing the potential limitations of the sugar-coating process, the pioneers of film coating created significant improvements by employing coating formulations based on polymers dissolved in highly volatile organic solvents, with the result that coating processes that took days to carry out could now be completed in only a few hours.

While the use of organic solvents circumvented the problems associated with the poor drying capabilities of conventional equipment available at the time, this approach had its disadvantages; these organic solvents were highly flammable, potentially toxic, and presented significant handling and environmental problems.

Fortunately advances in equipment design, including the introduction of fluid-bed coating processes and those using side-vented pans coating pans, have resulted in the gradual emergence of coating processes where drying efficiencies have been maximized. The result has been the emergence of aqueous

coating processes as the preferred means, with a few exceptions, of coating pharmaceutical products

While advances in equipment design have resulted in film coating becoming the dominant process for coating pharmaceutical oral solid dosage forms, these improvements (in equipment design) have also benefited the sugar-coating process, creating fully automated processes that can produce a batch in less than one day.

## PHARMACEUTICAL COATING PROCESSES

There are essentially four major techniques for applying coatings to pharmaceutical solid dosage forms: (1) sugar coating, (2) film coating, (3) microencapsulation, and (4) compression coating.

Although it could be argued that the use of mucilage of psyllium seed, gelatin, and so on, as already discussed, was an early form of film coating, *sugar coating* is regarded as the oldest method for applying pharmaceutical coatings. This process involves the application of aqueous solutions of sugar (typically sucrose, although sugar alcohols such as sorbitol may also be used). Formerly, sugar coating involved a significant number of individual applications of various coating formulations (resulting in tablet weight increases of 50–100%) and employing techniques that needed highly-skilled process operators. The result was that a batch of tablets could easily take up to 5 days to coat (although recent advances, as mentioned earlier, have now allowed this time to be reduced to less than one day).

*Film coating*, which involves the deposition of a thin polymeric film (comprising polymers, plasticizers, coloring agents and, sometimes, flavoring agents) onto the dosage form from solutions that were originally organic-solvent-based, but which now rely much more on water as the prime solvent. While the majority of film-coating formulations are intended for immediate-release applications (that is, they are not intended to affect drug release from the final dosage form), film coatings can also be used for modifying drug release from the final dosage form as well. Polymer systems used to modify drug release are not soluble in water and thus these systems are commonly formulated as aqueous-based suspensions.

*Microencapsulation* is a modified form of film coating, differing only in the size of the particles to be coated and the methods by which this is accomplished. This process is based on either mechanical methods such as pan coating, air-suspension techniques, multi-orifice centrifugal techniques, and modified spray-drying techniques, or physicochemical ones involving coacervation-phase separation, in which the material to be coated is suspended in a solution of the polymer. Phase separation is facilitated by the addition of a nonsolvent, incompatible polymer or inorganic salts or by altering the temperature of the system.

*Compression coating* involves the use of modified tableting machines that allow the compaction of a dry coating around a tablet core produced on the same machine. Essentially, a tablet core is produced on one side of the machine, is then transferred into a larger die partially filled with coating powder, additional coating powder is added on top of the core tablet, and the powdered coating material is finally compacted into a layer surrounding the core tablet. The main advantage of this type of coating process is that it eliminates the use of any solvent, whether aqueous or organic in nature. However, compression coating is mechanically complex and has not been commonly adopted as a method for coating tablets, although in recent times, modifications of this process have been found useful as a means of applying special coatings for novel drug-delivery applications.

## SUGAR COATING OF COMPRESSED TABLETS

While the term *sugar* is somewhat generic and lends itself to describing a range of carbohydrate materials, sugar coating processes commonly use sucrose because it is one of the few materials that produces smooth, high-quality coatings that are essentially dry and tack-free at the end of the process. While the

popularity of sugar coating has certainly declined, this process is still used by many companies that have invested in the complete modernization of the process. In spite of certain inherent disadvantages of sugar coating, products that have been expertly sugar coated still remain among the most elegant available.

Since sugar coating is a multistep process, where esthetics of the final coated product is an important attribute, it has typically been highly dependent on the use of skilled process operators. Sugar coating is commonly a manual process, where coating materials (either in liquid or powder form) are applied by hand to the surface of the rotating bed of tablets. While sugar coating has historically been a lengthy and tedious process to undertake, processing times have been effectively reduced in recent years through process modification, typically involving thin sugar-coating procedures, and process automation (in which case, coating application is accomplished using automated dosing techniques).

The sugar-coating process is commonly divided into six main steps: (1) sealing, (2) subcoating, (3) smoothing, (4) color coating, (5) polishing, and (6) printing.

### Sealing

This step involves the application of a specialized polymer coating directly to the tablet core for the purpose of separating tablet ingredients (primarily the drug) from water (which is a major constituent of subsequent processing steps) in order to achieve good product stability. A secondary function is to strengthen the tablet core. Sealing coats usually consist of alcoholic solutions (approximately 10–30% solids) of resins such as shellac, zein, cellulose acetate phthalate, or polyvinyl acetate phthalate.

Historically, shellac has been a popular choice of material for the sealing step; however this natural polymer can undergo further polymerization on storage, causing the seal coat to become completely insoluble to the point where bioavailability of the active pharmaceutical ingredient (API) may be compromised. This problem may be resolved by incorporating a small amount of polyvinylpyrrolidone (PVP) into the shellac-based seal coat formulation.

The quantities of material required to be applied as a sealing coat will depend primarily on tablet and batch size. Another variable is tablet porosity because highly porous tablets will tend to soak up the first application of solution, thus preventing it from spreading uniformly across the surface of every tablet in the batch. In this case, one or more further applications of resin solution may be necessary to ensure that the tablet cores are sealed effectively.

Because most sealing coats develop a degree of tack (stickiness) at some time during the drying process, it is usual to apply a dusting powder to prevent tablets from sticking together or to the pan. A common dusting powder is asbestos-free talc. Excessive use of talc may cause problems, firstly, by imparting a high degree of slip to the tablets, thus preventing them from rolling properly in the pan, and secondly by creating a surface that, at the beginning of the subsequent subcoating stage, is very difficult to wet. Such poor wetting often results in uneven subcoat buildup, particularly on the tablet edges. If there is a tendency for either of these problems to occur, one solution is to replace part or all of the talc with some other material such as terra alba, which will form a slightly rougher surface. Use of talc now is being frowned upon because of its potential health problems.

If it is necessary to prepare a delayed-release (enteric-coated) product, this can be achieved by making additional applications of the seal-coat solution. Under these circumstances, however, it is more preferable to use seal-coating formulations based on synthetic polymers such as polyvinyl acetate phthalate or cellulose acetate phthalate, rather than shellac because these have more suitable delayed-release characteristics.

### Subcoating

Subcoating is a step in the sugar-coating process that can have a marked effect on ultimate tablet quality. Possibly 50% of the final coating weight gain is achieved during the subcoating stage.

Historically, subcoating has been accomplished by applying a “glue” (in the form of an aqueous solution of a suitable gum, such as gum acacia, or even elatin) to the sealed tablet cores: once this solution has been distributed uniformly throughout the tablet mass, it is followed by a liberal dusting of powder, which serves to reduce tack and facilitate tablet buildup. This procedure of application of gum solution, spreading, dusting, and drying is continued until the requisite buildup has been achieved. Thus, the final subcoating is a sandwich of alternate layers of gum and powder. Some examples of binder solutions are shown in Table 31-1 and those of dusting powder formulations in Table 31-2.

While this approach has proved to be very effective, particularly where there is difficulty in covering edges, a *lumpy* subcoat can be the result, especially if care is not taken during application of the alternate layers. Additionally, if the amount of dusting powder applied is not matched to the binding capacity of the gum solution, not only will the ultimate coating be brittle, but also dust will collect in the back of the coating pan, and by becoming reattached to the tablet surface during subsequent applications of the gum solution, contribute to excessive roughness. An alternative approach, particularly when using an automated dosing system, involves the application of a suspension subcoat formulation (essentially a coating formulation where the powdered materials responsible for coating buildup are dispersed into the gum-based solution). An example of a suspension subcoating formulation is shown in Table 31-3. Employing suspension subcoating formulations not only allows the solids loading to be matched more closely to the binding capacity of the base solution, but often enables the less-experienced operator to achieve satisfactory results.

### Smoothing

Depending on the success achieved during subcoating, especially in terms of achieving a smooth surface, it may be necessary to smooth out the tablet surface further prior to application of the color coating. Smoothing usually can be accomplished

by the application of a simple syrup solution (approximately 60–70% sugar solids).

Often, the smoothing syrups contain a low percentage of titanium dioxide (1–5%) as an opacifier. This can be particularly useful when the subsequent color-coating formulation uses water-soluble dyes as colorants because a white, opaque smoothing coat creates a more reflective surface, resulting in a brighter, cleaner final color.

### Color Coating

This stage is often the most critical in sugar coating because it has the greatest impact on the final visual effect, and involves the multiple application of syrup solutions (60–70% sugar solids) containing appropriate coloring materials. The types of coloring materials used can be divided into two categories: water-soluble dyes or water-insoluble pigments. The nature of the colorant selected often defines the type of color-coating procedure to be employed.

When used by a skilled artisan, water-soluble dyes produce the most elegant sugar-coated tablets because it is possible to obtain a cleaner, brighter final color. However because water-soluble dyes are migratory colorants (that is to say, moisture that is removed from the coating on drying will cause migration of the colorant, resulting in a nonuniform appearance), great care must be exercised in their use, particularly when dark color shades are required. Such care can be achieved by applying small quantities of colored syrup that are just sufficient to wet the surface of every tablet in the batch, and then allowing the tablets to dry slowly. It is essential that each application be allowed to dry thoroughly before subsequent applications are made, otherwise moisture may become trapped in the coating and may cause the tablets to *sweat* on standing.

When using water-soluble dyes, the final color obtained may be the result of up to 60 individual applications of colored syrup. This factor, combined with the need to dry each application slowly and thoroughly, results in very long processing times (e.g., assuming 50 applications are made, which can take between 15 and 30 min each, the coloring process can take up to 25 hours to complete). The more recent introduction of preformulated dye-based coloring systems has obviated many of these problems.

Tablet color coating with water-insoluble pigments offers some significant advantages. First, because pigments are insoluble in water, color migration during the drying step is essentially eliminated. In addition, if the pigment is opaque or is combined with an opacifier such as titanium dioxide, the desired color can be developed much more rapidly, thus resulting in a thinner color coat. Since each colored syrup application now can be dried more rapidly, and fewer applications are required, significant reductions can be achieved in both processing times and costs.

Although water-insoluble pigment-based color coatings are by no means foolproof, they will permit more abuse than a dye color-coating process and are easier to use by less-skilled coating operators. Pharmaceutically acceptable pigments can be classified either as inorganic pigments (e.g., titanium dioxide, iron oxides) or certified lakes. Certified lakes are produced from water-soluble dyes using a process known as *laking*, whereby each dye molecule is bonded to the surface of a suitable insoluble substrate (such as alumina hydrate, a material chemically very similar to the aluminum hydroxide used in many antacid formulations).

Certified lakes, particularly when used in conjunction with an opacifier such as titanium dioxide, provide an excellent means of coloring sugar coatings and permit a wide range of shades to be achieved. However, the incorporation of pigments into the syrup solution is not as easy as with water-soluble dyes because it is necessary to ensure that the pigment is wetted completely and dispersed uniformly. Thus, the use of pigment color concentrates, which are commercially available, is usually beneficial.

**Table 31-1. Binder Solution Formulations for Subcoating**

	A, % W/W	B, % W/W
Gelatin	3.3	6.0
Gum acacia (powdered)	8.7	8.0

Sucrose (powdered)	28.0	38.0
Gum acacia (powdered)	2.0	—

**Table 31-3. Typical Suspension Subcoating Formulation**

	% W/W
Distilled water	25.0
Sucrose	40.0
Calcium carbonate	20.0
Talc (asbestos-free)	12.0
Gum acacia (powdered)	2.0
Titanium dioxide	1.0

## Polishing

Sugar-coated tablets are, by nature, very dull in appearance, and thus need to be polished to achieve a glossy finish. Polishing is accomplished by applying mixtures of waxes (beeswax, carnauba wax, candelilla wax, or hard paraffin wax) to the tablets in a polishing pan. Such wax mixtures may be applied as powders (usually in a finely milled form) or as solutions/dispersions in various organic solvents.

## Printing

To identify sugar-coated tablets (in addition to shape, size, and color) often it is necessary to print them, either before or after polishing, using pharmaceutical branding inks, by means of the process of *offset rotogravure*.

## Sugar-Coating Problems

Various problems may be encountered during the sugar coating of tablets. Any process in which tablets are kept tumbling constantly can cause problems if the tablets are not strong enough to withstand the applied stress. Tablets that are too soft or have a tendency to laminate may break up and the fragments adhere to the surface of otherwise good tablets; thus a few bad tablets in the batch can end up spoiling the whole batch.

Traditional sugar-coating pans exhibit inherently poor mixing characteristics. The consequence of this is that if care is not exercised during the application of the various coating formulations, the distribution of coating materials throughout the batch can be nonuniform, creating finished tablets of varying sizes.

Excessive use of dusting powders may result in a coatings being formed in which the quantity of fillers exceeds the binding capacity of the coating formulation, creating soft coatings or those with an increased tendency to crack.

Irregularities in appearance are not uncommon and occur either as the result of color migration during drying when water-soluble dyes are used, or of *washing back* when overdosing of colored syrups causes the previously dried coating layers to be re-dissolved. Rough tablet surfaces will produce a *marbled* appearance during polishing because wax buildup occurs in the small depressions in the tablet surface.

## FILM COATING OF SOLID DOSAGE FORMS

Film coating is a process involving the deposition of a thin, uniform coating onto the surface of the substrate. Unlike sugar coating, which is typically only applicable to the coating of tablets, film coating has greater flexibility in allowing a broad range of products (e.g., tablets, powders, granules, nonpareils, capsules) to be coated. Film coatings are typically applied continuously to a moving mass of product, usually by means of a spray atomization technique, although manual application procedures have been used.

Historically, film coating was introduced in the early 1950s to combat the shortcomings of the then predominant sugar-coating process. Film coating has proved successful as a result of the many advantages offered, including

1. Minimal weight increase (typically 2–3% of tablet core weight)
2. Significant reduction in processing times
3. Increased process efficiency and output
4. Increased flexibility in formulations
5. Improved resistance to chipping of the coating.

In the early years of film coating, the major process advantages resulted from the greater volatility of the organic solvents used. However, the use of organic solvents is not without its disadvantages, including:

1. Flammability hazards
2. Toxicity hazards

3. Concerns over environmental pollution
4. Cost (relating to minimizing items 1 to 3 and to the cost of the solvents themselves).

However, subsequent to its initial introduction, film coating has benefited from significant advances in process technology and equipment design, with the result that less volatile, and safer, solvents such as water can be easily accommodated by the process.

## Film Coating Raw Materials

The major components in any film-coating formulation consist essentially of a polymer, plasticizer, colorant, and solvent (or vehicle).

Ideal properties for the polymer include solubility in a wide range of solvent systems to promote flexibility in formulation, an ability to produce coatings that have suitable mechanical properties, and appropriate solubility in gastrointestinal fluids so that key objectives with respect to bioavailability can be achieved.

Cellulose-based polymers are commonly used in film coating, particularly hydroxypropyl methylcellulose. Suitable substitutes are hydroxypropyl cellulose, which may produce slightly tackier coatings, and methylcellulose. Alternatives to the cellulose polymers are acrylic copolymers (such as methacrylate and methyl methacrylate copolymers) and vinyl polymers (such as polyvinyl alcohol, polyvinylpyrrolidone-vinyl acetate copolymer, and polyvinyl alcohol-PEG copolymer).

For immediate-release (IR) film-coating applications, where there is no intent to modify drug-release characteristics, polymers are soluble in water and typically used as solutions in either water (preferred) or organic solvents.

Many of the commonly used polymers are available in a range of molecular-weight grades, a factor that also must be considered in the selection process. Molecular weight may have an important influence on various properties of the coating system, such as solution viscosity and mechanical strength and flexibility of the resultant film.

The incorporation of a plasticizer into the formulation improves the flexibility of the coating, reduces the risk of the film cracking, and potentially improves adhesion of the film to the substrate. To ensure that these benefits are achieved, the plasticizer must show a high degree of compatibility with the polymer and be retained permanently in the film, if the properties of the coating are to remain consistent on storage. Examples of typical plasticizers include glycerin, propylene glycol, polyethylene glycols, triacetin, acetylated monoglycerides, citrate esters (e.g., triethyl citrate), or phthalate esters (e.g., diethyl phthalate).

Colorants are usually added to improve product appearance, aid in product identification, and improve coated product stability. As in the case of sugar coating, colorants can be classified as either water-soluble dyes or insoluble pigments.

The use of water-soluble dyes is precluded with organic solvent-based film coating because of the lack of solubility in the solvent system. Thus, the use of pigments, particularly aluminum lakes and inorganic pigments (such as titanium dioxide and iron oxides), provides the most useful means of coloring film-coating systems. Although it may seem obvious to use water-soluble dyes in aqueous formulations, the use of insoluble pigments is preferred because:

1. They can reduce the permeability of the coating to moisture, thus potentially improving product stability.
2. They serve as bulking agents to increase the overall solids content in the coating dispersion without dramatically increasing viscosity.
3. They tend to be more light stable.
4. They are generally opaque, and thus can help to improve the stability of photolabile APIs, such as nifedipine.

The major solvents used in film coating typically belong to one of these classes: alcohols (such as methanol, ethanol, and

isopropyl alcohol), ketones (such as acetone), esters (such as ethyl acetate), chlorinated hydrocarbons (such as dichloromethane), and water. Solvents perform an important function in the film-coating process because they facilitate the application of the coating to the surface of the substrate. Good interaction between solvent and polymer is necessary to ensure that optimal film properties are obtained when the polymer solution dries and a solid film coating is formed. The initial interaction between solvent and polymer will yield maximum polymer chain extension, producing films having the greatest cohesive strength and, thus, the best mechanical properties.

Although it is very difficult to give typical examples of film-coating formulations because these will depend on the properties of the materials used, such formulations usually are based on 5–25% (w/w) coating solids in the requisite vehicle (with the higher concentration range preferred for aqueous formulations), of which 60–70% is polymer, 6–7% is plasticizer, and 20–30% is pigment.

Over the last 30 years, the general trend with respect to film-coating formulations for IR applications is for pharmaceutical companies to buy ready-made coatings (these are usually dry powders, comprising polymers, plasticizers, and colorants that are reconstituted at the point of use by dispersion in water). With a major focus on cost reduction in film coating, many of these coating systems can be used at higher concentrations in water (typically 18–25% w/w solids, compared to the 10–15% w/w solids experienced with regular coating formulations), enabling significant reductions in processing time to be achieved, as suggested by Porter.<sup>7</sup>

## MODIFIED-RELEASE FILM COATINGS

Film coatings can be applied to pharmaceutical products to modify drug release. The USP describes two types of modified-release dosage forms, namely those that are *delayed release* and those that are *extended release*. Delayed-release products often are designed to prevent drug release in the upper part of the gastrointestinal (GI) tract. Film coatings used to prepare this type of dosage form are commonly called *enteric coatings*, while film coatings that are required to extend drug release over a long period of time (from 6 to 24 hours) are commonly called *sustained- or controlled-release* film coatings.

### Enteric Coatings

Enteric coatings generally remain intact in the stomach but will dissolve and release the contents of the dosage form once it reaches the small intestine. The purpose of an enteric coating is to delay the release of drugs that are inactivated by the stomach contents, (e.g., pancreatin, erythromycin, and substituted benzimidazole compounds, such as proton pump inhibitors) or may cause nausea or bleeding by irritating the gastric mucosa (e.g., aspirin, and many nonsteroidal anti-inflammatory drug substances). In addition, such coatings can be used to give a simple repeat-action; in this case, a tablet core containing part of the dose is enteric coated, and then additional API is applied to the surface of the enteric coated tablet, with the result that the outer-most layer of API will be released immediately on ingestion, while the remainder of the dose will only be released once the enteric coating has dissolved.

The functionality of enteric coatings stems from the way the polymers react to differences in composition of the respective gastric and intestinal environments, especially with regard to pH and enzyme content. Although there have been repeated attempts to produce coatings that are susceptible to enzymatic breakdown, this approach is not popular because such breakdown of the coating can be relatively slow. Thus, most currently used enteric coatings are weak acids that remain undissociated and thus insoluble in the low pH environment of the stomach but readily ionize and dissolve when the pH rises to above 5. The most effective enteric polymers are polyacids having a  $pK_a$  of about 5. Coatings that respond to enzymatic breakdown are

now being considered as protective coatings suitable for the colonic delivery of polypeptide drugs.

Historically, the earliest enteric coatings used formalin-treated gelatin, but this approach was unreliable because the polymerization of gelatin could not be controlled accurately and often resulted in failure to release the drug, even in the lower intestinal tract. Another early candidate was shellac, but again the main disadvantage resulted from further polymerization that occurred on storage, often resulting in failure to release the active contents. Pharmaceutical formulators now prefer to use synthetic polymers to prepare more effective enteric coatings.

One of the oldest synthetic polymers used for enteric coating is cellulose acetate phthalate (CAP). However, a pH greater than 6 usually is required to allow the coating to dissolve, and thus a significant delay in drug release may ensue. It also is relatively permeable to moisture and gastric fluid compared to other enteric polymers, and it is very susceptible to hydrolytic decomposition (where phthalic and acetic acids are split off from the polymer chains), resulting in a change in polymer properties, and thus enteric coating performance.

Other useful enteric-coating polymers include polyvinyl acetate phthalate (PVAP, which is less permeable to moisture and gastric fluid, more stable to hydrolysis, and able to ionize at a lower pH); hydroxypropyl methylcellulose phthalate (HPMCP, which has properties similar to PVAP); acrylic copolymers, such as methacrylic acid-methacrylic acid ester copolymers (some of which have a high dissociation constant); cellulose acetate trimellitate (CAT, which has properties similar to CAP); carboxymethyl ethylcellulose (CMEC); and hydroxypropyl methylcellulose acetate succinate (HPMCAS). Today, acrylic copolymers are often preferred (in terms of performance and global acceptability) for designing enteric coating formulations.

Since enteric coating polymers are, by nature, insoluble in water (except at a pH >5), their use in aqueous coating systems is predicated by the use of either liquid polymer dispersions (sometimes called latices or pseudolatices) or dry powder coating systems that can readily be dispersed in water prior to use.

### Sustained-Release Coatings

The concept of sustained-release formulations was developed to eliminate the need for multiple dosage regimens, particularly for those drugs requiring reasonably constant blood levels over a long period of time. In addition, it also has been adopted for those drugs that need to be administered in high doses, but where too rapid a release is likely to cause undesirable side effects (e.g., the ulceration that occurs when potassium chloride is released rapidly into the milieu of the gastrointestinal tract).

Formulation methods used to obtain the desired drug release rate from sustained-action dosage forms include

1. Increasing the particle size of the drug.
2. Embedding the drug in a matrix.
3. Coating the drug or dosage form containing the drug.
4. Forming complexes of the drug with materials such as ion-exchange resins.

Only those methods that involve some form of coating fall within the scope of this chapter. A discussion of other controlled release drug delivery systems can be found in Chapter 32 (Oral Modified Release Drug Delivery Systems). The mechanisms of drug release from film-coated products are also provided.

Materials that have been found suitable for producing sustained-release coatings include:

1. Mixtures of waxes (beeswax, carnauba wax, etc.) with glyceryl monostearate, stearic acid, palmitic acid, glyceryl monopalmitate, and cetyl alcohol. These provide coatings that dissolve slowly or are broken down by other means in the GI tract.
2. Shellac and zein. These polymers remain intact until the pH of gastrointestinal contents becomes less acidic.

- Ethylcellulose, which provides a membrane around the dosage form and remains intact throughout the gastrointestinal tract. However, it does permit water to permeate the film, dissolve the drug, and diffuse out with the dissolved drug.
- Acrylic resins, which behave similarly to ethylcellulose as a diffusion-controlled drug-release coating material.
- Cellulose acetate (diacetate and triacetate), which can function as semi-permeable membranes.
- Silicone elastomers.
- Polyvinyl acetate.

As with enteric coatings, many of the synthetic polymers suitable for sustained-release film-coating applications are available as aqueous polymer dispersions that can be used in aqueous coating processes.

Various methods have been used to prepare sustained-release products using film-coating techniques. Examples include the application of suitable film coatings to:

- Dried granules (either irregular or spheronized)<sup>8</sup>
- Drug-loaded beads (or nonpareils)
- Drug crystals
- Drug/ion-exchange-resin complexes
- Tablets, including mini tablets<sup>9</sup>

In the first four examples, the final coated particles can be either filled into two-piece hard-gelatin capsules or compacted into tablets. Additionally, coated drug/ion-exchange-resin complexes may be dispersed in viscous liquids to create liquid suspensions.

An interesting application of the film-coated, sustained-release tablet is the osmotic pump concept as described by Wong *et al.*<sup>10</sup> In this device, a tablet core (formulated to contain osmotically active ingredients) is film coated with a semi-permeable membrane. This membrane is subsequently *pierced* with a laser to create a delivery orifice. Once such a device is ingested, the infusion of water generates an osmotic pressure within the coated tablet that *pumps* the drug out through the orifice.

With sustained-release products, one must remain aware constantly of the fact that the final dosage forms typically contain drug loadings that are sufficiently high to cause problems if the entire dose is released quickly. This phenomenon, commonly called *dose-dumping*, can be avoided only if:

- The film coating is mechanically sound and will resist rupture on ingestion of the dosage form.
- Sufficient coating is applied uniformly across the surface of the material that is to be coated.
- The dosage form is not chewed or crushed prior to ingestion.

## FILM-COATING PROBLEMS

As with sugar coating, problems may occur during, or subsequent to, the film-coating process. Porter<sup>11</sup> has provided a comprehensive review of common problems experienced with film-coated products.

The tablets being coated may not be sufficiently robust or may have a tendency to *laminates* while being coated. Since film coats are relatively thin, their ability to hide defects is significantly less than that of sugar coating. Hence, tablets that have poor resistance to abrasion (i.e., they exhibit high friability characteristics) can be problematic because imperfections may readily be apparent after coating. It is very important to identify tablets with suspect properties, whether mechanical or performance related (e.g., poor dissolution), prior to a coating process because subsequent recovery or reworking of tablets may be extremely difficult after a coating has been applied.

Various process-related problems can occur during the application of a film coating. One example is *picking*, which is

a consequence of the fluid delivery rate exceeding the drying capacity of the process, causing tablets to stick together and subsequently break apart. Another example, *orange peel* or *roughness*, is usually the result of premature drying of atomized droplets of solution, or it may be a consequence of spraying too viscous a coating solution such that effective atomization is difficult.

*Mottling*, or lack of color uniformity, can result from uneven distribution of color in the coating, a problem often related to the use of soluble dyes in aqueous film coating, when color migration can occur, either by evolution of residual solvent in the film or by migration of plasticizer in which the colorant may be soluble. The use of pigments in the film-coating process minimizes the incidence of this latter objection considerably. However, uneven color also can result from inadequate dispersion of the pigments in the coating solution.

Finally, some major problems occur as the result of internal stresses that develop within the film as it dries. One example is *cracking*, which occurs when these stresses exceed the tensile strength of the film. This problem may be compounded by the existence of post compaction strain relaxation (a phenomenon that can occur with certain types of tablet formulations, such as those containing ibuprofen, after ejection from the die during the tableting process), which causes tablets to expand. Another example is *logo-bridging* (i.e., bridging of monograms present in the surface of the tablet core), which occurs when the internal stresses are able to overcome the adhesive bonds formed between the coating and the tablet surface, causing the film to pull away so that legibility of the monogram is lost. An understanding of the properties of the various ingredients used in the film-coating formulation and how these ingredients interact with one another can allow the formulator to avoid many of these internal-stress-related problems.

Porter and Terzian<sup>12</sup> have described a systematic approach that may be used to solve common film-coating problems.

## COATING PROCEDURES AND EQUIPMENT

### COATING PANS

Sugar coating historically has involved the lading of the various coating fluids onto a cascading bed of tablets in a conventional coating pan (Fig 31-1) fitted with a means of supplying drying air to the tablets and an exhaust to remove moisture and dust-laden air from the pan.

Typically, after the requisite volume of liquid has been applied, a period of time is allowed for the tablets to mix and the liquid to become fully dispersed throughout the batch. To facilitate the uniform transfer of liquid, the tablets often are *stirred* by hand, or in larger pans, by means of a rake, to overcome mixing problems often associated with *dead spots*, an inherent problem seen with conventional pans. Finally, tablets are dried by blowing air onto the surface of the tablet bed. Thus, sugar coating is a sequential process consisting of consecutive cycles of liquid application, mixing, and drying.

During the early history of film coating, the equipment used was adapted essentially from that already employed for sugar coating. Although lading of coating liquids during the film-coating process has been practiced, usually the liquid is applied using a spray technique. Spray equipment used is essentially of two types:

- Airless (or hydraulic) spray, where the coating liquid is pumped under pressure to a spray nozzle with a small orifice and atomization of the liquid occurs as it expands rapidly on emerging from the nozzle. This is analogous to the effect achieved when one places one's finger over the end of a garden hose.
- Air spray, where liquid is pumped, under little or no pressure, to the nozzle and is subsequently atomized by means of a blast of compressed air that makes contact

**Figure 31-1.** Typical equipment setup for conventional sugar coating.

with the stream of liquid as it passes from the nozzle aperture.

Airless-spray techniques typically are used in large-scale film-coating operations employing organic solvents, while air-spray techniques are more effective in both small-scale laboratory set-up or all aqueous film-coating operations.

Spray application enables finely atomized droplets of the coating solution to be delivered across the surface of the moving tablet mass in a manner that achieves uniform coverage while preventing adjacent tablets from sticking together as the coating solution is rapidly dried. While all the events that take place during the spray application process occur continuously and concurrently, the overall picture can be more simply represented as shown in Figure 31-2.

The spray process can be operated either intermittently or continuously. In the early years of film coating, the lack of adequate drying conditions inside the coating apparatus, together with the preference for using airless coating techniques (with their inherently higher delivery rates) with organic solvent-based formulations often required the use of intermittent spray procedures. This technique allowed excess solvent to be removed during the nonspray part of the cycle and thus reduced the risk of *picking* and the tendency for tablets to stick together. However, in later years, improvements in drying capabilities have resulted in the preferred use of continuous spray procedures, as this permits uniform coatings to be applied in a shorter process.

**Figure 31-2.** Schematic representation of the film-coating process.

As mentioned earlier, pan equipment initially was completely conventional in design and, with the exception of the addition of spray-application equipment, was similar to that used in sugar coating. Fortunately, film-coating formulations were based on relatively volatile organic solvents, which enabled acceptable processing times to be achieved in spite of the relative deficiencies of the air-handling systems. However, such equipment did not produce a completely enclosed system, a fact that made effective solvent containment extremely difficult to achieve. Although conventional pans possessed acceptable properties with regard to mixing of the tablet mass in the sugar-coating process (particularly as this could be augmented by manual stirring of the tablets during processing), they were less suited to meet the more rigorous demands of the film-coating process, even when some simple baffle system was installed.

The introduction of aqueous film coating in the latter part of the twentieth century presented a more serious challenge to the continued use of conventional processing equipment. Limitations in both drying and mixing capabilities potentially resulted in significantly increased processing times while substantially compromising product quality and long-term stability. Fortunately, these problems have been eliminated as coating-pan design has evolved and coating process technologies have improved.

Although conventional, solid-wall coating pans had their limitations, the design shown in Figure 31-3, commonly called the Pellegrini pan and being a somewhat angular pan rotating on a horizontal axis, provided significant improvements for the sugar-coating process and was more easily adaptable to film coating because the presence of an integral baffle system ensures that more uniform mixing is achieved. Additionally, because process drying air and extraction are introduced through the rear opening, the front can potentially be closed off to produce a more-or-less enclosed coating system. Pellegrini pans are available with capacities ranging from the 10-kg laboratory scale-up to 1000 kg for high-output production.

In solid-wall coating pan designs, including that shown in Figure 31-3, drying air is blown only onto the surface of the tablet bed, thus inherently limiting drying capacity. To offset this limitation, several attempts have been made to improve air exchange, particularly within the tablet bed. One such approach, shown schematically in Figure 31-4, allows one of the air plenums (inlet or exhaust) to be immersed into the tablet bed, thus improving drying capacity.

Two such types of equipment, both based on the Pellegrini style of coating pan, are supplied by IMA (called the GS Coater) and Nicomac.

A major advance in pan coating technology occurred with the introduction of the side-vented pan concept, an innovation developed by Eli Lilly. This concept, originally called the Accela-cota, became the basis for a wide range of *side-vented* coating

**Figure 31-3.** Schematic diagram of a Pellegrini coating pan.

**Figure 31-4.** Schematics of upgraded conventional coating pans. A: Direct airflow. B: Reverse airflow.

**Figure 31-5.** Schematics of side-vented coating pans. A: Direct airflow. B: Reverse airflow.

pan designs, a schematic of which is shown in Figure 31-5. The salient features of side-vented coating pans are:

1. An angular pan (fitted with an integral baffle system) that rotates on a horizontal axis.
2. A coating system that is completely enclosed.
3. A perforated pan that allows drying air to be pulled through a cascading bed of tablets while the coating liquid is applied to the tablet surface using a spray-atomization technique.

Side-vented coating pans exhibit dramatically improved drying characteristics, a feature that facilitated the successful adoption of aqueous film-coating technology. Manufacturers of side-vented coating pans include Thomas Engineering, Oystar-Manesty, O'Hara, Glatt, Dumoulin, Vector Freund, Driam, IMA, and Nicomac, to name but a few. A comprehensive overview of coating equipment that can be used for pharmaceutical applications has been provided in a recent publication.<sup>13</sup>

Ongoing trends with side-vented coating pans have produced:

1. Designs that permit multidirectional air flow.
2. Fully automated, computerized coating processes (especially for production-scale coating purposes).
3. Effective clean-in-place (CIP) or wash-in-place (WIP) cleaning systems that facilitate compliance with good manufacturing processes (GMPs).
4. Laboratory-scale coating equipment provided with interchangeable coating pans representing batch capacities in the range of 3–40 kg (depending on product density).
5. Coating pans designed to permit continuous processing (where the product is constantly introduced into one end and flows, fully coated, out the other).

Although improvements in coating-pan design have predominately occurred to improve the aqueous film-coating process, they have also benefited other processes, including sugar coating.

### FLUIDIZED-BED COATING EQUIPMENT

Fluid-bed processing technology has long been used in the pharmaceutical industry, initially for drying, and subsequently for granulation. While several attempts have been made to apply this technology to the film-coating process, a significant advance came with the introduction of the Wurster concept (a schematic of which is shown in Figure 31-6) in the 1950s.

At a time when organic-solvent-based coating formulations were still primarily used, the Wurster process was extremely popular for coating a variety of pharmaceutical dosage forms, especially tablets. Although fluid-bed processing inarguably exhibits the most effective drying characteristics of any film-coating process, the introduction of aqueous coating formulations initially created waning interest in using the Wurster process for coating tablets. A major factor in this trend undoubtedly was related to the increased potential (compared with use of coating pans) for tablet breakage in the fluid-bed process. During the last 30 years, however, resurgent interest in the Wurster process has occurred as a result of the growing demand for applying film coatings to pellets, granules, and powders (so-

**Figure 31-6.** Schematic diagrams for three basic processes used for fluid-bed film coating.

called *multiparticulates*) when producing modified-release coated dosage forms.

The suitability of the fluid-bed process for film coating multiparticulates also has generated interest in processes other than the Wurster for this application. In particular, modifications of the spray granulation process (often termed the *top-spray coating process*) and a rotary process (often called the *tangential spray process*) have both been used for the film coating of multiparticulates. Schematics for all these processes also are shown in Figure 31-6.

The major manufacturers of fluid-bed processing equipment (Glatt Air Techniques, Vector Corporation, and GEA) all have adopted a principle in which a basic processing unit is designed to accept modular inserts for each of the three fluid-bed coating processes shown in Figure 31-6. Selection of a particular type of insert often is determined by the nature and intended functionality of the coating applied; for example

1. Granulator Top-Spray Process—preferred when a taste-masking coating is being applied; additionally suitable for the application of hot-melt coatings.
2. Wurster, Bottom-Spray Process—preferred for the application of modified-release coatings to a wide variety of multiparticulates; also suitable for drug layering when the drug dose is in the low-to-medium range.
3. Rotor, Tangential-Spray Process—suitable for the application of modified-release film coatings to a wide range of multiparticulate products; ideal for drug layering when the dose is medium to high; also useful as a spherulizing process for producing spheroidal pellets from powders.

### POTENTIAL FOR TOTALLY AUTOMATED COATING SYSTEMS

Over the course of time, the pharmaceutical industry has witnessed a general transition away from manually operated sugar-coating processes, requiring total operator involvement, to film-coating processes, where operator intervention is infrequent. Increasing familiarity with, and understanding of, tablet coating as a unit process, and a desire to ensure compliance with GMPs, ultimately have increased the desire to achieve reproducible and consistent conformity to design specifications for every batch of product made; this is especially the case if the requirements of more recent FDA initiatives, such as Quality by Design (QbD), are to be met. Meeting these requirements is clearly compromised if the idiosyncrasies of individual process operators are allowed to have a less-than-positive impact on final product quality (in its broadest sense).

Employing the tenets of QbD, by designing fully optimized processes, creating an effective design space, and implementing effective Process Analytical Technologies (PAT) all have a positive impact on process control. Process automation, especially when responding to appropriate feed-back and feed-forward directives from a well designed process that is being monitored by suitable PAT capabilities, contributes effectively to the whole concept of QbD.

Since a sugar-coating process always has been highly operator dependent, such dependence can be minimized through automation. However, the natural sequencing of events that are the basis of the sugar-coating process adds a level of complexity when considering the implementation of automation. Nonetheless, implementation of PAT, such as the effective use of nIR sensors, simplifies these challenges when it comes to automation.

### QUALITY CONTROL OF COATED TABLETS

The most important aspects of coated tablets that must be assessed from a quality-control standpoint are appearance characteristics and drug availability. From the appearance standpoint, coated tablets must be shown to conform, where applicable, to some color standard, otherwise the dispenser and the consumer may assume that differences have occurred

from previous lots, signifying a changed or substandard product. In addition, because of the physical abuse that tablets, both in their uncoated and coated forms, receive during the coating process, it is essential to check for defects such as chipped edges and picking, and ensure that they do not exceed predetermined limits.

Often, to identify the products, coated tablets may be imprinted (particularly with sugar-coated tablets) or bear a monogram (commonly seen with tablets that are film-coated). The clarity and quality of such identifying features must be assessed. The failure of a batch of coated tablets to comply with such preset standards may result in 100% inspection being required or the need for the batch to be reworked.

Batch-to-batch reproducibility for drug availability is of paramount importance; consequently each batch of product should be submitted to some meaningful test such as a dissolution test. Depending on the characteristics of the tablet core to be coated, tablet coatings can modify the drug release profile, even when not intended (unlike the case of enteric- or controlled-release products). Since this behavior may vary with each batch coated (being dependent, for example, on differences in processing conditions or variability in raw materials used), it is essential that this parameter be assessed, particularly in products that are typically borderline (refer to Chapter 30 Oral Solid Dosage Forms).

A review of various techniques that may be used to assess the quality of coated products, especially film-coated tablets, has been provided by Porter and Felton.<sup>14</sup>

### STABILITY TESTING OF COATED PRODUCTS

The stability-testing program for coated products will vary depending on the dosage form and its composition. Many stability-testing programs are based on studies that have disclosed the conditions a product may encounter prior to end use. Such conditions usually are referred to as normal and include ranges in temperature, humidity, light, and handling conditions. The conditions to be employed in modern stability-testing programs often conform to the guidelines established by the International Committee on Harmonization (ICH). A more detailed discussion on the stability of pharmaceutical products may be found in Chapter 4.

Limits of acceptability are established for each product for qualities such as color, appearance, availability of drug for absorption, and drug content. The time over which the product retains specified properties, when tested at normal conditions, may be defined as the *shelf life*. The container for the product may be designed to improve the shelf life. For example, if the color in the coating is light-sensitive, the product may be packaged in an amber bottle and/or protected from light by using a paper carton. When the coating is friable, resilient material such as cotton may be incorporated in both the top and bottom of the container, and if the product is affected adversely by moisture, a moisture-resistant closure may be used and/or a desiccant may be placed in the package. The shelf life of the product is determined in the commercial package tested under normal conditions.

The stability of the product also may be tested under exaggerated conditions. This usually is done for the purpose of accelerating changes so that an extrapolation can be made early, concerning the shelf life of the product. Although useful, highly exaggerated conditions of storage can supply misleading data for coated dosage forms. Any change in drug release from the dosage form is measured *in vitro*, but an *in vivo* measurement should be used to confirm that drug availability remains within specified limits over its stated shelf life. This confirmation may be obtained by testing the product initially for *in vivo* availability and then repeating at intervals during storage at normal conditions for its estimated shelf life (or longer).

Interpretation of stability data for coated, modified-release products should be undertaken with extreme care because the diffusion characteristics of polymeric films can change

significantly under exaggerated temperature and/or humidity conditions. This change may be confounding when trying to predict their diffusion characteristics under more moderate conditions and thus can prove misleading when predicting shelf life.

When elevated-temperature stability studies are conducted on products coated with aqueous polymeric dispersions (latices or pseudo-latices), the data obtained might be more indicative of morphological changes that have occurred in the film. Such changes may result from partial destruction of the film when coated material adheres together in the container and subsequently is broken apart; additionally, these changes might result from further coalescence of the coating (which can occur when the coating is not coalesced completely during the coating process).

Stability tests usually are conducted on a product at the time of development, during the pilot phase and on representative lots of the commercial product. Stability testing must continue for the commercial product as long as it remains on the market because subtle changes in a manufacturing process and/or a raw material can have an impact on the shelf life of a product.

### RECENT TRENDS IN PHARMACEUTICAL COATING TECHNOLOGY

There is an inherent conservatism expressed by pharmaceutical manufacturers towards accepting major changes in raw materials (i.e., non-active ingredients) and processing technologies. Thus, change tends to be evolutionary rather than revolutionary. Still, some interesting events have occurred over the last decade.

Of particular note is the growing interest in *Process Analytical Technology* (PAT). This has resulted in bringing many analytical procedures out of the laboratory and closer to the manufacturing process with which they may be associated. The desire here is to introduce, ideally as an in-line control function, specific analytical techniques that can be used to enhance the quality of the final coated products. One example is the use of near infra-red techniques that can be used to analyze coated product in such a way that, for example, product moisture contents, drug contents, amounts of coating applied, and even, to some extent, drug release rates can be predicted before that product is discharged from the coating process. The use of terahertz in-line analytical techniques has recently been proposed<sup>15</sup> as a means of determining coating process endpoint.

A major regulatory initiative that is having a significant impact on pharmaceutical manufacturing processes in general is the quest to implement *Quality by Design* (QbD). Certainly, film-coating processes are not exempt from this initiative, but at the same time pose a significant challenge, primarily because in the past scant attention has been paid to critical issues relating to film-coating formulations and processes that ultimately affect product quality. Today, PAT initiatives are considered an integral part of the focus on QbD.

A major change having a significant impact on the way coating of pharmaceutical products is viewed encompasses the growing interest in continuous film coating processes. Initially, continuous coating processes were primarily considered as a useful tool for the manufacture of large-volume consumer healthcare products; in recent years, focus has begun to switch to more mainstream pharmaceutical products, and, in particular, their relevance to in-line continuous pharmaceutical products (where raw materials are fed in at one end, and finished packaged products emerge at the other end). Certainly, such in-line continuous processes facilitate the implementation of PAT and QbD initiatives, but also lead, at least potentially, to significant cost reductions in the manufacturing process.

Generally, continuous coating processes are based on the concept of a stretched side-vented coating pan, where uncoated product is introduced at one end, passes by a whole bank of

Figure 31-7. Schematic diagram of continuous film-coating process.

spray guns, and emerges from the other end fully coated (see Figure 31-7). The advantages of this type of process include:

1. Increasing output (typical outputs are in the range of 500 to 1000 kg h<sup>-1</sup>), compared to common batch processes which might coat a 250 kg batch in one to two hours, while a 500 kg batch might be coated in 3–4 hours.
2. Reducing residence time in a process where product is typically exposed to stressful conditions (attrition, high humidities and temperatures) from several hours to about 15 minutes.
3. Improving uniformity of distribution of coating materials.

As stated earlier, continuous coating processes have typically been reserved for coating large-volume products where desired applied coating levels are in the range of 3–4% (based on the tablet core weight). With the growing interest in complete in-line manufacturing processes, where the throughput rate of the coating process needs to be matched to the output of a single tablet press, lower volume output continuous coating processes (with outputs in the range of 25 to 50 kg h<sup>-1</sup> up to 100 to 150 kg h<sup>-1</sup>) are now available. The subject of continuous film-coating processes has been reviewed in detail by Porter<sup>16</sup> and Cunningham *et al.*<sup>17</sup>

Currently, most coating processes involve the spray application of liquid coating systems where solidification of the coating is achieved through solvent removal (i.e., drying), and distribution of coating materials is facilitated through constant motion of the material being coated. Recently, a method of electrostatically applying powder coatings, essentially using currently available pharmaceutical coating pans, has been described by Zhu *et al.*<sup>18</sup> This process involves the sequential application of a liquid plasticizer to the tablets being coated, followed by a powder application of the remaining coating materials, and then completing the formation of the coating using a heat-curing step. This technique has been utilized with a range of existing pharmaceutical coating materials, and has application for both immediate-release and modified-release coating applications. Other dry powder coating techniques that do not rely on electrostatic charges have also been investigated.

SUMMARY 631

### INTRODUCTION

In recent years, the scope of drug delivery technologies has expanded significantly, irrespective of the route of administration, as a result of an advanced understanding of disease, science, and safety associated with pharmaceuticals. The overall purpose of drug delivery systems, however, has remained constant: to provide a therapeutically effective amount of drug to the appropriate site in the body for a desired duration of action. The site at which a drug is delivered (drug targeting) and the rate at which the drug is released (profile) have to be carefully considered during dosage form design and product development. Site-specific drug delivery has been one of the key focus areas for pharmaceutical formulation scientists for many decades. The main purpose of site-specific drug delivery systems is to improve the efficacy and safety of drugs. Pharmaceutical scientists have also focused on the development of formulations that deliver drugs at a desired release rate, the duration of which may span from very fast (a few seconds) to very slow and controlled (days, weeks, and months). Combining site-specific aspects of drug delivery with controlled release rates is highly desirable for patient treatment.

With better understanding of gastrointestinal (GI) tract anatomy, physiological barriers to drug absorption, and the need for different release profiles for different disease conditions, more efficient and advanced drug delivery systems have been developed. In recent years, the purposes of such modified-release drug delivery technologies have evolved to the optimization of drug performance and to the enhancement of patient tolerance (reduction in side-effects). These technologies have not only had a significant impact on the success of developing and commercializing new chemical entities, but the reformulation of marketed drug products for better patient acceptance has allowed pharmaceutical companies to extend the patent life of their products. As a result of the market success and thus opportunities for enhanced drug delivery systems, considerable efforts have been expended on developing appropriate polymeric carriers and sophisticated processing and manufacturing machineries. A tremendous amount of research has been directed toward the development of robust modified-release (MR) oral dosage forms. These efforts have followed the science-based and risk-managed process of drug product development, supported by quality-by-design (QbD) principles. This chapter describes various modified-release technologies used for drug delivery to the oral cavity (oral route of administration) as well as formulation approaches and manufacturing considerations.

### RATIONALE AND DEFINITIONS OF ORAL MODIFIED-RELEASE TECHNOLOGIES

The oral route for delivering medications has been the preferred route for most drugs due to patient acceptance, ease of administration, accurate dosing, cost-effective manufacturing methods, and generally the improved shelf-life of the product.

For conventional oral dosage forms, the drug (active pharmaceutical ingredient [API]) is rapidly released after administration and subsequently absorbed into the body from the GI tract. The concentration of drug in the blood peaks shortly after administration as the drug absorption process dominates, then decreases over time as metabolism and/or excretion processes dominate. Conventional immediate-release (IR) dosage forms, however, do not maintain the plasma levels of the drug within the therapeutic range for an extended period of time and thus a short duration of action may be observed. For many drugs and therapeutic indications, multiple dosing of IR formulations provides satisfactory clinical performance with an appropriate balance of efficacy and safety. For example, multidose therapy may be tolerated for short-term treatment, but is not desirable for treating chronic conditions. To reduce dosing frequency and eliminate the fluctuations in blood concentration associated with conventional delivery, extended-release (ER) systems have been and continue to be developed, where the drug is slowly released over an extended timeframe. Delayed-release (DR) technologies exhibit a lag time in drug release (no drug released immediately) to target the drug to a specific site in the body. Both ER and DR systems are broadly referred to as modified-release (MR) dosage forms. The common goal for the development of any MR formulation is to enhance the drug's therapeutic benefits, minimize side-effects, and improve the overall management of the disease. These technologies may be combined with conventional IR delivery or combined with other MR technologies.

### DELAYED-RELEASE SYSTEMS

Delayed-release systems are designed to target drug release to a specific site in the body. The delay in drug release is usually achieved by coating an oral solid dosage form with an enteric polymeric film. These polymers, commonly referred to as polyacids, possess acidic functional groups (such as carboxyl groups) and exhibit pH-dependent solubility. The enteric film remains intact in the low pH of the stomach and starts to dissolve at the higher pH of the small intestine when sufficient ionization of these acidic functional groups occurs. According to the US Food and Drug Administration (FDA), a delayed-release dosage form is defined as one "that releases a drug (or drugs) at a time other than promptly after administration. Enteric-coated articles are delayed-release dosage forms."

The general purposes of enteric coatings are:

- to protect the drug in the dosage form from the harmful effects of the gastric environment (i.e., acidic or enzymatic degradation);
- to minimize the irritating effects of certain drugs (e.g., nonsteroidal anti-inflammatory drugs) on the gastric mucosa; and/or
- to deliver the drug to the intestine for local effects.

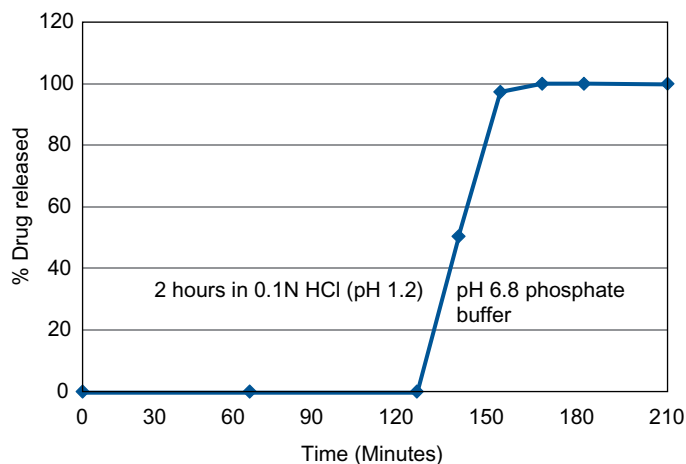

**Table 32-1. Common Enteric Polymers and Their Respective pH Thresholds**

General class	Enteric polymer	pH trigger <sup>a</sup>
Cellulosics	Cellulose acetate phthalate (CAP)	6.0
	Cellulose acetate trimellitate (CAT)	4.8
	Hydroxypropyl methylcellulose acetate succinate (HPMCAS)	5.5–6.8
	Hydroxypropyl methylcellulose phthalate (HPMCP)	5.0–5.5
Vinyls	Polyvinyl acetate phthalate (PVAP)	5.0
Acrylics	Poly (methacrylic acid: ethylacrylate) (1 : 1)	5.5
	Poly (methacrylic acid: methylmethacrylate) (1 : 1)	6.0
	Poly (methacrylic acid: methylmethacrylate) (1 : 2)	7.0
Natural polymers	Shellac	7.2
	Rosin	6.0

<sup>a</sup>As indicated by their manufacturers.

Commonly used polymers in enteric coating applications are classified based on their chemical backbone (i.e., celluloses, vinyls, and acrylics) (Table 32-1). Natural polymers such as shellac and rosin have also been used.<sup>1</sup> Some of the enteric polymers are esters that are susceptible to hydrolysis when exposed to elevated humidity. The polymer materials are commercially available as aqueous dispersions or as powders that are dissolved or dispersed in an appropriate solvent prior to application. More details about the application of polymeric films to solid dosage forms can be found in Chapter 30. In addition to the polymer, excipients, such as plasticizers, pigments, and anti-adherents, may be added for processing or functionality. Several fully formulated systems containing any necessary excipients are also commercially available.<sup>2,3</sup> Note that when formulating an acid-labile drug in an enteric dosage form, an intermediate sealcoat may be necessary to separate the API from the acidic enteric material.

Enteric-coated tablets are tested for their resistance to disintegration in 0.1 N HCl (pH 1.2) media, to simulate their performance in the stomach, a low pH condition when fasted. The enteric-coated system may also be evaluated at a slightly elevated pH (e.g., USP acetate buffer pH 4.5) to simulate fed state (food effects) and/or the administration of multiple doses of proton pump inhibitors.<sup>4</sup> In addition, the amount of acid taken up by the coated dosage form using gravimetric evaluation after exposure to the acidic media may be determined. Drug dissolution from the enteric-coated dosage forms is evaluated in acidic pH initially (typically 1–2 h, as recommended by the drug product monograph for a specific API) and then in an appropriate phosphate buffer. A typical drug-release profile of an enteric-coated tablet is shown in Figure 32-1. Ideally, no drug is released during exposure to the acidic environment and rapid release is observed when the pH of the test media is increased. It is possible to apply an enteric coat to an ER dosage form. In that case, the enteric coating will cause a delay in drug release (as described above) and, after the enteric layer dissolves, the drug will slowly release from the product over an extended time period. Extended-release products are described in detail below.

**Figure 32-1.** Typical release profile for an enteric-coated dosage form.

## EXTENDED-RELEASE SYSTEMS

Extended-release systems for oral drug delivery maintain therapeutic blood levels of a drug for a prolonged period. Terms such as extended-release, sustained-release, and slow-release have been used interchangeably in the literature. The term “controlled-release” is a more specific term and may be defined as delivery of a drug at a predetermined rate for a defined time period. Commercially available ER products are often designated by suffixes such as “CR” (controlled-release), “LA” (long-acting), and “ER,” “XL,” and “XR” (extended-release). Figure 32-2 provides an example of a typical drug release profile of an ER product. These systems reduce fluctuations in drug concentration in the blood. Since these products are administered less frequently, patient adherence to the dosing regimen may be improved. Despite the higher unit cost of the delivery system in comparison to conventional IR dosage forms, there is an economic savings benefit for ER formulations. Economic savings may also result from a decrease in hospitalizations and less lost work time, as chronic disease conditions are better managed.

When developing an ER dosage form, physiological and biopharmaceutical factors (e.g., GI tract transit time and pattern, rate and window of absorption, localized metabolism in the GI tract, and potential food effect) and the physicochemical properties of the drug (e.g., chemical nature and physical form of the

**Figure 32-2.** Typical release profile for an extended-release (ER) dosage form in comparison to an immediate-release (IR) product.

drug, dose, solubility, and stability of the drug in the GI tract) must be considered, as these may influence the design of the delivery system and the desired release performance of the product. The following sections discuss these parameters as well as safety aspects of ER products. The remainder of the chapter focuses on specific delivery technologies that are used today to achieve extended drug release from solid oral dosage forms.

### BIOPHARMACEUTICAL CONSIDERATIONS FOR EXTENDED-RELEASE DRUG PRODUCT FORMULATION AND DEVELOPMENT

The anatomy and physiology of the GI tract are complex. There are differences in the lengths, pH, transit time, and surface area available for absorption. Table 32-2 provides a summary of average anatomical and physiological features found in healthy humans, irrespective of gender or race. The values may differ from person to person, along with the age of the person and also GI health status (e.g., gastric acidity, diarrhea, and colitis). Oral ER formulations generally remain intact and are subjected to these considerably different conditions while traveling through the GI tract.

Knowledge of the GI anatomy and physiology is important when designing suitable ER dosage forms. A drug must first be released from the dosage form, then dissolve in the GI media before being absorbed through GI membranes. Thus, a drug must be soluble in the given GI media for absorption to occur. Most drugs, however, are weak acids and bases and their solubility is affected by the different pH in the GI tract. GI conditions, transit time, and the presence and types of food ingredients can also significantly influence drug absorption.

Some drugs may be preferentially absorbed in a specific region of the GI tract, referred to as an “absorption window.” Knowledge of such narrow regional absorption is critical for designing suitable ER delivery systems.<sup>5</sup> For this specialized delivery, one formulation strategy would be to create an ER gastroretentive system, where the dosage form is retained and the drug is released in the stomach so the drug is in solution when passing the absorption window.<sup>6–8</sup>

The most absorptive region of the GI tract is the small intestine. However, the general transit time of oral dosage forms through the small intestine is relatively short. Various studies using noninvasive modalities have assessed the effect of food and the dosage form shape and size on transit time of nondisintegrating tablets through segments of the human GI tract. In addition to the presence of food, other inherent GI motility ailments may further alter the transit time of the solid dosage form in GI tract. Table 32-3 shows a range of transit times reported for ER tablets, caplets, and pellets.<sup>9,10</sup>

Dietary food consists of different components such as proteins, carbohydrates, fats, fibers, minerals, and other nutrients. The presence of food alters the volume of liquid, pH and viscosity of the GI content, as well as GI transit times. Hence the performance of an ER formulation may differ when administered with food.<sup>11,12</sup> Food intake can influence the rate of drug release from the dosage form, the rate of drug absorption, the amount of drug absorbed, or all of these parameters simultaneously.<sup>13</sup>

Various physiological mechanisms prevent the absorption of foreign material from the GI tract. Intestinal metabolic enzymes found in abundance in the intestinal epithelium walls may metabolize the drug before absorption can occur. The activity of such enzymes varies in the small intestine, with levels rising slightly from the duodenum to the jejunum and declining in the ileum and colon. The presence, concentration, and distribution of these enzymes are highly variable from person to person and also vary with gender, age, and race. There is also an efflux mechanism involving P-glycoproteins. Many drugs have been shown to possess poor bioavailability due to intestinal enzymes and the efflux pump systems.<sup>14</sup> Components of food can inhibit GI metabolism and efflux of certain drugs, resulting in an increase in absorption and bioavailability. For example, grapefruit juice has been shown to enhance bioavailability of a number of

drugs by inhibiting both the efflux transporter P-glycoprotein and intestinal metabolism.<sup>15,16</sup> In fact, grapefruit juice has been reported to cause as high as 300 percent increase in the concentration of cyclosporin, midazolam, terfenadine, and felodipine, orally administered medications.<sup>17</sup>

### SAFETY CONSIDERATIONS AND RISK MANAGEMENT

Oral ER formulations carry higher drug payloads compared to IR formulations. A formulation that fails to sustain drug release and abruptly releases the drug in an IR fashion (called “dose-dumping”) is potentially dangerous.<sup>18,19</sup> Careful consideration, therefore, must be given to the safety and risk management of these ER formulations. One of the key reasons reported for dose-dumping is related to the food effect, which is compounded by a formulation which is not robust. For example, very low levels of rate-controlling material may make a formulation more sensitive to both food components and the higher mechanical stress imposed by the GI tract.<sup>20</sup>

Most ER formulations are intended to be used/administered whole. Any damage to the integrity of the dosage form may also result in dose-dumping. Warning labels should be included on the packaging of such ER formulations. The concept of dose-dumping is also applicable for DR products. Note that there are several ER patient-friendly formulations, such as sprinkle capsules or multiparticulate systems, which have been formulated to be subdivided prior to administration without compromising the drug release mechanism.<sup>21</sup>

Another consideration for possible dose-dumping relates to concomitant use of alcohol with ER formulations. Alcohol is known to be a good solvent for many release-controlling materials, and the alcohol content in beverages may dissolve or weaken the rate-controlling system, potentially resulting in dose-dumping in the stomach.<sup>22</sup> During drug product development, the potential alcohol effect on the performance of the formulation should be evaluated.<sup>23–25</sup>

### DRUG PROPERTIES RELEVANT TO ER PRODUCT FORMULATION AND DEVELOPMENT

Drug dose and solubility are the most important physicochemical properties to consider when developing an ER product. Extended-release systems designed to reduce dosing frequency inherently carry greater amounts of the drug than their corresponding IR formulations. A combination of safety data, elimination half-life, the therapeutic window, and typical drug levels in conventional formulations provide some indications of the total amount of drug required for an ER preparation. For large-dose drugs, the size of the dose may present significant challenges when formulating oral ER dosage forms. This is further complicated if the high-dose drug is also highly soluble in water.

As mentioned previously, drugs must be in solution in order to be absorbed from the GI tract. The aqueous solubility of a drug affects its dissolution rate, which in turn establishes its concentration in the solution and, hence, the driving force for passive diffusion across the absorptive membranes in the GI tract. The Noyes-Whitney equation, shown below under sink conditions, demonstrates the importance of drug solubility in the rate of mass transfer of solute particles into the continuous phase:

$$\frac{dM}{dt} = \frac{DAC_s}{h}$$

where  $dM/dt$  is the rate of mass transfer or rate of dissolution,  $D$  is the diffusion coefficient,  $A$  is the total surface area of the device,  $C_s$  is the aqueous saturated solubility of the drug, and  $h$  is the height of the boundary (diffusion) layer.

In general, drugs with extreme aqueous solubilities pose challenges for ER formulation development. For example, any system relying on diffusion of the drug through a polymer barrier membrane (reservoir system) may not be suitable for poorly soluble drugs. In contrast, it may be difficult to sufficiently slow the dissolution of a drug with very high aqueous solubility. Thus,

**Table 32-2. Summary of Physiological Considerations of Human Gastrointestinal Tract**

GI Region	Length (cm)	Diameter (cm)	pH	Micro-organism (counts/g content)	Proposed mechanisms of absorption										SA (m <sup>2</sup> )	Transit time for food (h)	Villi present	Constituents (enzymes,others)
					P	C	A	F	I	E

NR, Not reported; P, passive diffusion; C, convective transport; A, active transport; F, facilitated transport (carrier mediated); I, ion pair transport; E, endocytosis; Y, yes; N, no; SA, surface area available for absorption.

**Table 32-3. Reported Ranges of Transit Times of Different Dosage Forms Through Human Gastrointestinal Tract**

Dosage form	Transit time in stomach (h)		Transit time in small intestine (h)	
	Fasted	Fed	Fasted	Fed
Extended-release tablets (11 mm round)	0.1–1.1	2.0–4.8	3.9–5.6	2.2–7.7
Extended-release caplets (17 × 4 mm)	0.3–2.0	1.0–9.0	1.1–6.0	1.2–5.8
Extended-release pellets (0.3–1.8 mm diameter, administered in gelatin capsules)	0.1–4.5	0.1–4.5	1.8–7.5	1.2–5.8

the aqueous solubility of a drug is a critical property that influences the technology selected to achieve the extended release.

### DRUG RELEASE RATE CONSIDERATIONS

Ideally, an ER system should deliver drug to the desired site at a rate according to the needs of the body (i.e., a self-regulated system based on a feedback control). Although some researchers are investigating possible approaches to develop such an ideal dosage form (e.g., self-regulating insulin delivery pump), this is still a difficult goal to achieve, especially for oral drug administration. The key question for the formulation scientist is what should be the rate of drug release to maintain therapeutic blood levels. Ideally, the rate of absorption of the drug should be equal to the overall rate of elimination. This means that drug release must be independent of the amount of drug in the dosage form and should remain constant over time. This type of release is referred to as zero-order kinetics. Although it may not be necessary to maintain a constant level of drug in the blood for all therapeutic cases, zero-order release has been idealized as the ultimate goal for an ER delivery system. The majority of ER systems follow first-order kinetics, where drug release is dependent on the amount remaining in the dosage form at any given time. Drug release is thus faster initially and slows over time as drug is depleted from the delivery system. As mentioned previously, ER systems may be combined with IR delivery to attain high initial blood concentrations that are then maintained over an extended time period. Delayed-release technologies may also be combined with ER systems, resulting in an initial delay in release followed by prolonged drug release.

There are vast amounts of literature covering the mathematical description of drug release kinetics for ER systems.<sup>26,27</sup> While a detailed discussion of mathematical modeling of drug release kinetics is beyond the scope of this chapter, the most common mathematical equations used to describe different release profiles are shown in Table 32-4, where  $Q$  is the cumulative amount of drug released at time  $t$ ,  $K$  is a rate constant, and  $n$  is the diffusional exponent. The Peppas–Sahlin model (Table 32-4) describes systems that have intermediate values of  $n$ , where at least two processes contribute to the overall release mechanism. According to the model,  $K_d$  is the diffusional rate constant,  $K_r$  is the relaxational rate constant, and  $m$  is a purely Fickian diffusion exponent for a device of any geometrical shape exhibiting extended release. The value of  $n$  has been routinely used to characterize drug release mechanisms, using the calculated ranges shown in Table 32-5.

**Table 32-4. Summary of Some Equations Describing Drug Release Kinetics from the Extended-Release Systems**

Kinetics	Equation
Zero order	$Q = k t + a$
Higuchi model (1963)	$Q = k (t)^{0.5}$
Korsmeyer–Peppas model (1983)	$Q = k (t)^n$
Peppas–Sahlin model (1989)	$Q = K_d t^n + K_r t^{2n}$

**Table 32-5. Diffusional Exponent ( $n$ ) and The Theoretical Mechanism of Drug Release From Swellable Systems having Spherical Geometry**

Diffusional exponent ( $n$ )	Drug release mechanism
$0.43 < n < 0.50$	Fickian diffusion (first order)
$0.50 < n < 0.89$	Anomalous release (pseudo-first order)
$0.89 < n < 1.00$	Case II transport (zero order)
$n > 1.00$	Super case II transport (unknown release)

### ORAL EXTENDED-RELEASE TECHNOLOGIES

Most currently available ER formulations incorporate one or more of the following general technological approaches:

- **Matrix systems:** Monolithic (*mono* is single and *lith* is a block of material) matrices are the most common version. These systems comprise one or more release-controlling materials with one or more drugs uniformly dispersed in the matrix. Two types of such systems are employed, depending on the nature of the rate-controlling material.
  - **Hydrophilic matrix systems:** Drug particles are dispersed in a hydrophilic polymeric matrix; drug release occurs by dissolution of the drug, diffusion through the gel layer (formed upon exposure to GI fluids), and/or erosion of the matrix.
  - **Insoluble matrix systems:** Drug is dispersed in a matrix of water-insoluble polymers or waxes; drug release occurs as the GI fluids permeate the matrix and dissolve the drug.
- **Reservoir systems:** A drug-containing unit (core) is enclosed by a polymeric barrier coat. Two key reservoir systems have been commonly used:
  - In **simple diffusion systems**, a drug-containing core is surrounded by a water-insoluble polymer coating. Drug release is achieved by diffusion of drug through the coating.
  - **Osmotic systems** contain osmotic agents in the coated drug core. Drug release occurs through an orifice in the coating layer due to an osmotic pressure gradient generated as the GI fluids permeate into the core.

Details about each of these systems is provided below.

#### Matrix-Based Extended-Release Systems

**Wax matrices** are prepared by adding drug to molten fat or wax, cooling to congeal the material, then granulating and compressing into tablets. Fatty acids, alcohols, and waxes which are solid at room temperature and do not melt at body temperature are used for this type of delivery system. Examples of materials used for the preparation of wax matrices include carnauba wax, fatty alcohol, glycerol palmitostearate, stearyl alcohol, beeswax, aluminum monostearate, and glycerol monostearate.

These materials may be used alone or in combination with a hydrophilic polymers. Drug release occurs as GI fluids permeate into the pores of the matrix, causing drug dissolution, and the dissolved drug then diffuses out of the system. The presence and levels of wetting and channeling agents, such as soluble sugars or hydrophilic low-viscosity grade polymers, in the matrix are used to further modulate drug release. Lipidic matrix systems have also been developed, where drug release occurs through a combination of erosion of the lipid matrix and diffusion through pores in the matrix.

These waxy materials are derived from natural products and are complex mixtures of multiple components.<sup>28</sup> Hence, variability of source or changes in the isolation and purification processes may alter their composition in subtle ways that may influence drug release profiles. In addition, fatty acids and waxes exhibit complex solid state behavior, including polymorphism, leading to phase transition behavior on cooling and storage. These physical changes can also affect drug release rates. If waxes coat the drug particle during processing, drug release may not be complete.

*Ion-exchange resins* are water-insoluble crosslinked polymeric resins that complex oppositely charged drugs. These systems are formed by prolonged exposure of the drug to the resins. Drug-containing resins are milled to the desired particle size and can be subsequently filled into capsules, tableted, or suspended in liquids. Drug release from these systems occurs, as the name implies, by an ion-exchange mechanism. For example, a cationic drug in an anionic resin is replaced by protons, sodium, or other electrolyte in the GI fluids. The GI fluids must penetrate into the resin and the dissolved drug has to diffuse out of the matrix. As would be expected, drug release from these systems is dependent on pH and electrolyte concentration. These systems can be coated with rate-controlling membranes to further control drug release.

*Inert matrices* are prepared by wet granulation of a drug with water-insoluble polymers such as ethylcellulose, methylacrylate, methylmethacrylate, polyvinyl chloride, or polyvinyl acetate.<sup>29,30</sup> Drug release from these matrices is by simple dissolution of the drug and diffusion through fluid-filled pores. Water ingresses into the matrix, and the solid drug on and adjacent to the surface dissolves into the media, creating pores and channels in the tablet core that allow additional drug to dissolve, and the process continues.

Higuchi's mathematical equation defines drug release from inert matrices as:

$$Q = \left[ \left( D \frac{C_s}{\tau} \right) (2A - \epsilon C_s) t \right]^{1/2}$$

where  $Q$  is the amount of drug released per unit surface area after time  $t$ ,  $D$  is the diffusion coefficient of the drug in the dissolution medium,  $\epsilon$  is the porosity of the matrix,  $\tau$  is the tortuosity of the matrix,  $C_s$  is the saturated solubility of the drug in the dissolution medium, and  $A$  is the total amount of drug present per unit volume in the matrix. Drug release rates from inert matrices may be altered by changing either the porosity or the tortuosity of the matrix. A high tortuosity means that the effective average diffusion path is large and thus drug release is slower. The porosity term takes into account the space available for drug dissolution, and an increase in porosity results in faster drug release. Water-soluble excipients can be added as pore formers, and these agents alter the tortuosity of the matrix. Inclusion of some water-insoluble excipients may reduce the wettability of the matrix, resulting in a reduction in the penetration of the dissolution media and subsequent slower drug release. Higher compaction forces during tableting in general lead to lower porosity and hence slower drug release.

As mentioned, ethylcellulose is one of the polymers used to prepare inert matrices. It is a water-insoluble cellulose ether polymer available in different molecular weight grades which

exhibit varying viscosities in organic solutions as well as available in different particle size grades. Ethylcellulose is available commercially as a dry powder (e.g., Ethocel) and as an aqueous dispersion (e.g., Surelease). Small particle size grades of ethylcellulose are required to generate a high tortuosity (large diffusion path) in the tablet. However, small particle sizes in the dry state coupled with high concentrations of the polymer will likely lead to a formulation with poor flow properties and static charges so wet granulation methods may be required. Polymethacrylates and polyvinyl acetate have also been used to study inert matrices with ER characteristics. Drug release from these inert matrix formulations is dependent on drug solubility, polymer level, mechanical properties of the tablets, and the type and amount of other excipients used.

*Hydrophilic matrices* are prepared by direct compression or by wet granulation of a blend of one or more drugs with suitable release-retardant hydrophilic polymers plus other excipients necessary for processing. These matrices are a simple and cost-effective approach for the manufacture of ER systems.<sup>31</sup> A wide range of natural and semisynthetic polymers have been studied to produce hydrophilic matrices, as shown in Table 32-6. These materials can be used alone or in combination to fabricate hydrophilic matrices.

The most widely utilized hydrophilic matrix formers are the high molecular weight (high viscosity grade) nonionic cellulose ethers, and more specifically, hydroxypropyl methylcellulose (HPMC, also referred to as hypromellose). The popularity of HPMC can be attributed to its flexibility to obtain desired drug release profiles, cost-effectiveness, and broad safety and regulatory acceptance. These systems can be readily prepared with conventional tableting equipment. To fully explore the formulation, manufacturing, and drug release mechanism from hydrophilic matrices, examples of HPMC matrices will be used throughout this section of the chapter.

On exposure to water or gastrointestinal fluids, hydrophilic polymers in the matrix system rapidly hydrate to form a viscous gel layer. The polymer undergoes transition from a "glassy" solid to a "rubbery" gelatinous state. Failure to generate a uniform and coherent gel may result in a more rapid drug release. It is the physicochemical characteristics of the gel layer which control water uptake and drug release from the matrix. Gel growth occurs as water permeates in the matrix to hydrate the solid polymer particles immediately beneath the gel, increasing the thickness of the gel layer. Simultaneously, the outer surface of the matrix becomes hydrated, polymer chains fully relax and disentangle from each other and erode from the matrix surface into the surrounding media. Water continues to penetrate

**Table 32-6. Common Polymers Studied in Hydrophilic Matrix Formulations**

Cellulosic	Hypromellose (hydroxypropylmethylcellulose (HPMC)) Hydroxypropylcellulose (HPC) Hydroxyethylcellulose (HEC) Sodium carboxymethylcellulose (Na-CMC)
Noncellulosic: gums/polysaccharides	Sodium alginate Xanthan gum Carrageenan Ceratonia (locust bean gum) Chitosan Guar gum
Noncellulosic: others	Poly(ethylene oxide) Homopolymers and copolymers of acrylic acid (e.g., carbomers)

**Table 32-7. Formulation and Manufacturing Considerations in the Design of Hydrophilic Matrices**

Formulation components	Key considerations
Drug	Solubility, dose, pKa, stability, and particle size
High viscosity grade of polymer	Particle size, type, and level
Filler excipients	Level/type (water soluble/insoluble)
Lubricants and glidants	Level/type (stearates, nonstearates, and fatty acids)
Others	Release rate modifiers, stabilizers, solubilizer, surfactant, and buffering agents
Manufacturing aspects	
Direct compression	Flow and compressibility of the formulation
Dry granulation	Double compression and reworkability
Wet granulation	Solvent (aqueous or hydro-alcoholic), binders, high or low shear, fluid bed methods
Hot melt extrusion	Type, level, and melting point of polymer and drug

toward the core of the tablet at a controlled rate, until all of the tablet hydrates and ultimately erodes completely.

Although a rapid burst release of drug from the external surface area may occur, drug release is controlled either by diffusion through the gel layer or by gradual erosion of the gel. Diffusion is the dominant mechanism controlling the release of water-soluble drugs while water-insoluble drugs are released predominantly by the erosion of the gel layer. Practically, drug release generally occurs by a combination of dissolution, diffusion, and erosion, and follows first-order kinetics. Consistent and reliable release requires that polymer hydration and gel layer formation is rapid to obviate potential matrix disintegration and premature drug release. For this reason, hydrophilic polymers for matrix applications are usually supplied in small and defined particle size ranges (e.g., METHOCEL™ CR grades). HPMC and polyethylene oxide (POLYOX™) are well known for their rapid hydration and gel formation and thus highly suitable as rate-controlling polymers in hydrophilic matrices.<sup>32</sup> Polyethylene oxide resins have been shown to be among the fastest hydrating water-soluble polymers, quickly forming a gel layer to regulate drug release.<sup>33</sup> Table 32-7 shows some of the general formulation and manufacturing considerations for hydrophilic matrices.

In order to reduce the initial burst effect, scientists have investigated combinations of faster hydrating polymers to rapidly form the gel layer. The application of an insoluble but permeable film coat on the surface of the matrix is another approach to reducing the initial drug burst. Water ingress through the insoluble membrane and drug dissolution are subsequently slowed, generating a lag time in the release profile. Following sufficient water ingress, the hydrophilic polymer(s) hydrates

and, due to swelling of the matrix, causes rupture of the insoluble membrane.

Modulation of drug release in hydrophilic matrices is achieved by various approaches that regulate gel strength and structure. For example, faster drug release can be obtained when lower polymer concentration, lower viscosity grades of the polymer, and/or highly water-soluble excipients are used in the matrix formulation. All these factors reduce gel strength which in turn increases both the diffusion rate (faster water ingress and faster drug diffusion out of the device) and the rate of polymer disentanglement (erosion). According to the percolation theory, which describes a cluster percolating as a group of adjacent particles of the same component from one side to the other side of a system, polymer concentration must be above a threshold level (the critical point). When formulating above this critical point, a coherent gel layer controlling the drug release rate is formed.<sup>34</sup> When the polymer concentration is close to the critical point, the matrix system may be too sensitive to small variations in formulation or manufacturing processes. Based on the percolation theory, the critical concentration for different types of HPMC to obtain robust ER formulations is above 18 percent v/v of polymer.<sup>35</sup> Different viscosity grades of polymer are used to modulate faster or slower drug release. For example, a sufficient concentration (above the critical point) of a low-viscosity grade of HPMC (METHOCEL™ K100LV or K4M) is generally used for drugs with poor water solubility. However, for drugs with very high water solubility, a stronger gel layer is required and hence higher viscosity grades of HPMC (METHOCEL™ K15M or K100M) are used.

Another factor affecting drug release from hydrophilic matrices is the excipient(s) used in the formulation. More specifically, excipient solubility and concentration in the formulation have been reported to significantly affect drug release.<sup>36</sup> The manufacturing process is also important and may affect release characteristics from the dosage form. Use of polymer blends is yet another approach to refine drug release. For example, HPMC matrices containing other hydrophilic polymers such as polyethylene oxide, carbomer, sodium carboxymethylcellulose (Na CMC), or sodium alginates have been shown to alter drug release.<sup>37</sup> These materials create strong hydrogen bonding between the carboxyl and hydroxyl groups of HPMC and the other polymers, leading to stronger gel layers and slower drug release.

Since release from a hydrophilic matrix is directly related to the surface area of the tablet, geometric approaches to modify drug release have been investigated, predominantly for achieving zero-order release profiles. The Geomatrix technology is an example of such an approach. The system consists of a multi-layered tablet, the interior being a simple HPMC matrix containing the drug that is sandwiched between two outer layers that control the exposed surface area during GI transit. These outer layers contain HPMC and other ingredients, but no drug (Figure 32-3). The outer layers hydrate and, as they dissolve, a larger surface area of the core layer is exposed to the dissolution media, ideally leading to a constant, zero-order release profile ([www.skyepharma.com](http://www.skyepharma.com)).

### Reservoir Systems

As mentioned earlier, a simple reservoir ER system is a unit that contains a drug-containing core surrounded by a polymeric film coating. The film coating controls the rate of water uptake into the system and the drug, once dissolved, diffuses out

**Figure 32-3.** Schematic of the Geomatrix technology for zero-order drug release.

**Figure 32-4.** Influence of the amount of coating (Surelease) applied on the release of chlorpheniramine maleate (CPM) pellets.

through the membrane. The reader is referred to Chapter 30 for details about the coating process. Drug release across the insoluble membrane from a reservoir-type system is described by Fick's first law of diffusion:

$$\frac{dM}{dt} = \frac{ADK\Delta C}{l}$$

where  $dM/dt$  is the dissolution rate,  $A$  is the surface area,  $D$  is the diffusion coefficient,  $K$  is the partition coefficient,  $\Delta C$  is the concentration gradient, and  $l$  is the diffusion path length (film thickness). For a given drug and formulated system,  $A$ ,  $D$ ,  $K$ , and  $\Delta C$  remain nearly constant; thus drug release is inversely proportional to the diffusion path length or the coating thickness. Film thickness is not generally determined during manufacturing, although it may be investigated during product development stages. Regardless, film thickness is proportional to the amount of polymer applied, often reported as a percentage weight gain. Figure 32-4 shows that increasing the amount of applied polymer slows drug release. Note that many other variables influence drug release from reservoir systems. For example, the permeability of the coating may be altered by the inclusion of hydrophilic polymers or water-soluble materials. These agents dissolve upon ingestion to create pores in the coating. Commonly used polymers for reservoir systems include ethylcellulose ethers (such as ETHOCEL™), acrylic polymers (such as Eudragit RL 30D and Eudragit RS 30D), and polyvinyl acetate (Kollicoat SR 30D).

Reservoir systems may be formulated in different forms such as tablets, mini-tabs, or spheres/pellets (typically 350–1000  $\mu\text{m}$ ). Mini-tabs are small tablets with a diameter of about 2–5 mm. These units can be coated with rate-controlling polymers and filled into hard capsule shells. Mini-tabs can be manufactured by direct compression processes, similar to conventional tablets, with specialized tablet tooling. These systems combine the

advantages of multiparticulate dosage forms (described in the next paragraph) with the more established manufacturing techniques of tableting.<sup>38</sup>

A great deal of interest has recently been focused on microparticulate reservoir systems. These microparticles can be filled into capsules or compressed with other excipients to produce tablets. These systems can potentially be formulated to contain multiple drugs and/or multiple release profiles by blending different populations of microparticles. After ingestion, the individual coated particles, each containing a portion of the total dose, disperse and move through the GI tract. One of the primary advantages of these systems is their more consistent transit through the GI tract in comparison to larger particles (i.e., tablets). Gastric emptying variations as well as inter- and intra-patient variability are generally reduced. In addition, the risk of dose-dumping is minimized, since it is unlikely that the rate-controlling membrane of all subunits would be compromised, assuming a robust formulation.

There are two general processes used to manufacture reservoir-type multiparticulates, differing predominantly in the structure of the core, as shown in Figure 32-5. A wet granulation or hot melt extrusion process can be used to create drug-containing cores which are then coated with the rate-controlling membrane. Alternatively, drug can be applied to starter seeds or inert carrier material (e.g., Suglets), where a liquid binder is used to adhere drug to the core. Subsequently, the rate-controlling membrane is applied. The selection of the manufacturing process is dependent on the expertise and equipment available within the company.

It is highly desirable to have spheres of uniform and narrow size distributions, smooth surfaces, and low friability in order to achieve reproducible drug release profiles.<sup>39</sup> Changes to the particle size and size distribution will influence surface area available for drug release. Figure 32-6 shows how a decrease in particle size from 14–18 mesh (1000–1410  $\mu\text{m}$ ) to 30–35 mesh (500–590  $\mu\text{m}$ ) significantly increased the release of a model drug when similar amounts of the rate-controlling membrane (ethylcellulose) were applied.<sup>39</sup> These results were attributed to a decreased film thickness of the coating, arising from an increase in total surface area of the smaller pellets. While this specific example used drug-layered pellets, the principles also apply to coated pellets prepared by wet granulation or other approaches. A narrow particle size distribution of the microparticles will minimize batch-to-batch variation in the thickness of the rate-controlling membrane and thus in drug release. It is also important that microparticles, irrespective of the manufacturing process, are physically strong enough to withstand the rigors of coating. Friable particles may break or fracture during processing, leading to product loss and, most importantly, change in surface area.

### Osmotic Pump Systems

Another option of the coated reservoir system is the osmotic pump. Osmotic agents (osmogens) are included in the tablet core, and a delivery orifice is drilled through the coating membrane. As water diffuses through the coating, the osmotic pressure increases, and it is this osmotic pressure gradient that is

**Figure 32-5.** Schematics of two reservoir-type microparticulates (A) wet granulation (extrusion) and spheronized drug-containing pellet coated with a rate-controlling membrane; (B) drug-layered pellet coated with a rate-controlling membrane.

**Figure 32-6.** The influence of starter-seed size distribution on chlorpheniramine maleate (CPM) release from ethylcellulose barrier membrane coated (10 percent weight gain of surelease) multiparticulate systems

**Figure 32-7.** Drug release profiles of bilayer osmotic tablets uncoated and coated with varying amounts of a semipermeable cellulose acetate membrane.

the driving force to push drug out of the system through the delivery orifice. The primary advantage of the osmotic system is that only osmotic pressure is required to be effective, and thus drug release from the system is independent of the environment. That is, drug release is not influenced by the pH changes that occur as the product moves through the GI tract. These systems are also less sensitive to food effects.

The most common polymer used for barrier coating of osmotic systems is cellulose acetate. This material has been shown to be mechanically strong enough to withstand core swelling and the hydrostatic pressure created inside the system. Ethylcellulose, another water-insoluble polymer, has also been investigated as a barrier membrane coating for osmotic pumps to a lesser extent.<sup>40</sup>

A key parameter for controlling drug release from the osmotic pump systems is the permeability of the barrier membrane to GI fluids. Figure 32-7 shows how drug release is affected by increasing weight gain (thickness) of a semipermeable membrane. In addition to changing the permeability of the membrane, drug release can also be influenced by surface area of the tablet, as this variable also affects the ingress of the GI fluids.

The first osmotic pump developed was the “elementary osmotic pump.” After an initial lag time, sufficient fluid would permeate through the membrane to generate the osmotic pressure gradient. Drug release would occur at a constant rate, but only until the osmotic pressure gradient diminished. In addition, drug release from these systems was not complete.

A newer version of the osmotic pump was developed to overcome these issues. The “push–pull osmotic pump” consists of a

**Figure 32-8.** Cross-section of a push–pull osmotic pump (PPOP) tablet. 1. Pull layer (drug layer). 2. push layer, 3. semipermeable membrane, 4. drug delivery orifice.

bilayer tablet core, one layer containing the drug and low-viscosity POLYOX™ (e.g., POLYOX N80), called pull-layer, and the other layer containing a swellable polymer (e.g., POLYOX coagulant and osmogen, called the push-layer). A cross-section of a push–pull osmotic pump is shown in Figure 32-8. The swellable layer maintains the osmotic pressure gradient as the drug (and osmogen) is depleted from the system. The critical formulation variables for the push–pull osmotic include polymer hydration rate and swelling kinetics as well as osmogen levels. Note that both dissolved and dispersed drug can be released from this system. As with the elementary pump, drug release is independent of pH, ionic strength, and other physiological factors. These attributes reduce patient variability. Moreover, since osmotic pressure is maintained over time due to the swelling layer, not only does drug release follow zero-order kinetics, drug release is more complete than with elementary pumps. Push–pull osmotic pump systems have been used to successfully deliver some challenging drugs, making them a huge commercial success in the market.<sup>41</sup>

## SUMMARY

Advancements in the science and technology of oral modified-release drug delivery systems have resulted in the commercial availability of a number of products. More importantly, these improved delivery systems are impacting the health of patients worldwide. The development and commercialization of modified-release products is no longer considered just a life-cycle management strategy for the manufacturer. Formulation scientists will continue to investigate and develop novel drug delivery platforms to improve the overall effectiveness of drug therapies.

### INTRODUCTION

Inhalation therapy has been used for many years, and there has been a resurgence of interest in delivery of drugs by this route of administration. The number of new drug entities delivered by the inhalation route has increased over the past five to ten years. This type of therapy also has been applied to delivery of drugs through the nasal mucosa, as well as through the oral cavity for buccal absorption. Originally, this type of therapy was used primarily to administer drugs directly to the respiratory system (treatment of asthma); inhalation therapy is now being used for drugs to be delivered to the bloodstream and finally to the desired site of action. Proteins (insulin), steroids, cardiac agents, immunizing agents, etc., are being developed for delivery in this manner.

Drugs administered via the respiratory system (inhalation therapy) can be delivered either orally or nasally. Further, these products can be developed as a

- nebulizer/atomizer
- dry powder inhaler
- nasal inhaler
- metered-dose aerosol inhaler.

Drugs delivered via a nebulizer/atomizer are generally formulated as sterile aqueous solutions (or suspensions) and are inhaled by the patient through an atomizer, nebulizer, or other similar devices. These products are not included in this chapter.

Dry powders have been used for inhalation therapy for over 75 years. The active ingredients were packaged in capsules, representing a single dose of drug. The capsule was punctured, and a small amount of powder fell into a chamber while the patient inhaled. The procedure was repeated until all of the powder was inhaled. While these dry powders were somewhat popular during the early 1940s to 1950s, they fell into disuse with the introduction of the aerosol metered dose inhaler, which became available around 1955. This first generation MDI was formulated with chlorofluorocarbons (CFC), was compact and portable, and contained epinephrine hydrochloride or albuterol as the active ingredient. These MDIs quickly became the dosage form of choice for inhalation therapy, especially for the treatment of asthmatics. With the phase-out of CFCs starting in 1996, dry powders containing about 25–30 to 60 doses of active ingredient were developed and became commercially available from 2000 to 2003. Several dry powder inhalers currently available include salmeterol, fluticasone, and budesonide. Mometasone dry powder inhaler is available in Europe. These dry powder inhalers do not contain a propellant. These consist of active, very potent drugs that are dispensed from a specially designed package. An accurate amount of drug as a dry powder is released

from a small unit dose package while the patient inhales deeply. The dry powder will then travel to the lungs along with the inspired air. Carrier molecules, such as lactose, are often used to reduce agglomeration of the small drug particles as well as facilitate fluidization during the inhalation process. The technology of dry powders is not a part of this chapter.

The nasal metering drug delivery system produces an aqueous spray, consisting of active ingredient and excipients. The drugs used can act locally within the nasal mucosa or systemically by passing through the nasal mucosa and enter the general circulation system. This occurs via numerous capillary vessels present in the mucosa. These nasal sprays can also be formulated similarly to MDIs, using propellants and a nasal actuator. The pressurized type of nasal inhaler is included in this chapter.

The development of the metered-dose inhaler (MDI) in the mid-1950s made possible a convenient dosage form for the delivery of medication to the respiratory system. Atomizers and nebulizers were cumbersome to use and in many instances did not offer convenience of use, so that administration of drugs by atomizers/nebulizers was generally left to hospital or at-home use. While many improvements were made to these nebulizers and atomizers, they lacked the convenience of use especially as to their portability and use outside of a hospital and/or home setting.

Metered-dose inhalers consist of a pressurized container filled with active ingredient, excipients and propellant, and a metered-dose valve. The pressurized container is placed within an oral adapter (mouthpiece), and when the unit is dispensed, an exact amount of drug is expelled in the proper particle size distribution to achieve maximum deposition of drug into the lungs. The aerosol dosage form (MDI) has become the dosage form of choice for delivery of drugs to the lungs. Metered-dose inhalers are formulated as solutions or suspensions of active drug in a mixture of solvents, dispersing agents, and liquefied gas propellants.

Topical aerosol products are becoming more popular because they are easy to administer and have a better feel than ointments and creams. Topical pharmaceutical aerosols can be formulated as a spray, foam, and semisolid. They can be used to deliver therapeutic agents topically (to the skin surface), rectally, and vaginally. They consist of a liquid, emulsion, or semisolid concentrate and liquefied gas or compressed gas propellant. Each of these systems is discussed in later parts of this chapter.

Many therapeutically active ingredients have been administered or applied to the body by means of the aerosol dosage form. This dosage form has been used orally to dispense a variety of agents, such as budesonide, salmeterol xinafoate, fluticasone propionate, fenoterol, epinephrine hydrochloride, albuterol, albuterol sulfate, metaproterenol sulfate, cromolyn sodium, flunisolide hemihydrate, ipratropium bromide, beclomethasone dipropionate, and triamcinolone acetate.

These MDIs were formulated using a CFC propellant. However, these CFC propellants are being phased out.

Oral aerosols have been used mainly for the symptomatic treatment of asthma, as well as for the treatment of several other ailments. These aerosols have been readily accepted by both physician and patient.

### ADVANTAGES

One of the main reasons for the rapid and widespread acceptance of the MDI dosage form for the administration of therapeutically active agents is that it affords many distinct advantages to the user. These advantages have been described by various investigators and, for MDIs, include the following:

- Rapid onset of action.
- Circumvention of the first-pass effect and avoidance of degradation in the GI tract.
- Lower dosage that will minimize adverse reactions, especially in the case of steroid therapy, in which most of the steroid reaches the respiratory tract and less is swallowed.
- Dose titration to individual needs and ideal for prn medication.
- Alternative route when therapeutic agent may interact chemically or physically with other medicinals needed concurrently.
- Viable alternative when the drug entity exhibits erratic pharmacokinetics upon oral or parenteral administration.
- Container and valve closure are tamperproof.

The pressure package is convenient and easy to use. Medication is dispensed in a ready-to-use form at the push of a button. There is generally no need for further handling of the medication. Since the medication is sealed in a tamperproof pressure container, there is no danger of contamination of the product with foreign materials, and at the same time, the contents can be protected from the deleterious effects of both air and moisture. Easily decomposed drugs, such as epinephrine, lend themselves to this type of package, for oxygen is excluded from the headspace.

Sterility is always an important consideration with certain pharmaceutical and medicinal preparations. While initial sterility is generally no problem to the manufacturer, there is concern for the maintenance of the sterility of the package during use, for example, with ophthalmic preparations. When necessary, the aerosol package can be prepared under aseptic conditions, and sterility can be maintained throughout the life of the product. For those products requiring regulation of dosage, a metering valve can be used. An accurately measured dose of therapeutically active drug can be administered quickly and, in the case of drugs for inhalation, buccal, or nasal application, in the proper particle-size range.

There are many advantages to the administration of medicinal agents by inhalation, buccally and nasally. Response to drugs administered by inhalation, buccally and nasally, is prompt, often very specific and with minimal side-effects, faster in onset of activity than drugs given orally and, with most drugs, approaching intravenous therapy in rapidity of action. Drugs that normally are decomposed in the GI tract can be administered safely by inhalation, buccally and nasally. The use of the self-pressurized aerosol package makes this type of therapy simple, convenient, and acceptable, compared with the use of atomizers and nebulizers, which are bulky and require cleaning.

### DEFINITIONS

The term aerosol is used to denote various systems ranging from those of a colloidal nature to systems consisting of pressurized packages. Aerosols have been defined as colloidal systems consisting of very finely subdivided liquid or solid particles, dispersed in and surrounded by a gas. Originally, the term aerosol referred to liquid or solid particles having a specific size range, but this concept has fallen into disuse.

The present-day definition refers to those products that depend upon the power of a liquefied or compressed gas to dispense the active ingredient(s) in a finely dispersed spray, foam, or semisolid. Pump systems that also dispense the active ingredient(s) in the form of a finely dispersed mist (although of greater particle size) often are classified as aerosols. These pump systems generally are used to dispense medication intranasally.

In 1978, the use of certain chlorofluorocarbons (CFCs) was curtailed by the FDA, EPA, and CPSC. These restrictions applied to the use of Propellants 11, 12, and 114 (CFCs) for use in all aerosol products. Exemptions were granted to MDIs and a few other essential uses. Because of these restrictions, new valve systems and dispensing systems, which allowed greater use of liquefied hydrocarbons and compressed gases, were developed for non MDIs. Individual drugs which have been successfully converted to HFA propellants have had the CFC products phased out. These regulatory requirements are discussed in greater detail in the propellant section of this chapter.

## MODE OF OPERATION

### LIQUEFIED-GAS SYSTEMS

Liquefied gases have been used widely as propellants for most aerosol products. These compounds are useful for this purpose, since they are gases at room temperature and atmospheric pressure. However, they can be liquefied easily by lowering the temperature (below the boiling point) or by increasing the pressure. The compounds chosen generally have boiling points below 70°F (21°C) and vapor pressures between 14 and 85 psia at 70°F (21°C). When a liquefied-gas propellant is placed into a sealed container, it immediately separates into a liquid and a vapor phase.

Since these materials are liquefied gases, some of the molecules will leave the liquid state and enter the vapor state. As molecules enter the vapor state, a pressure gradually develops. As the number of molecules in the vapor state increases, the pressure also will increase. An equilibrium soon is attained between the numbers of molecules changing from a liquid to a vapor and from a vapor to a liquid. The pressure at this point is referred to as the vapor pressure (expressed as psia) and is characteristic for each propellant at any given temperature. The term psig (pounds/square inch gauge) represents the uncorrected gauge pressure and is to be distinguished from psia (pounds per square inch absolute), which is corrected to include atmospheric pressure (0 psig, which equals 14.7 psia). This vapor pressure is exerted equally in all directions and is independent of the quantity of liquefied gas present.

The pressure exerted against the liquid phase is sufficient to push the latter up a dip tube and against the valve. In cases when there is no dip tube (MDIs), the container is used in the inverted position so that the liquid phase is in direct contact with the valve. When the valve is opened, the liquid phase is emitted and comes into contact with the warm air at atmospheric pressure. The liquid propellant immediately reverts to the vapor state, since its boiling point is substantially below room temperature. As the contents of the container are expelled, the volume within the container occupied by the vaporized propellant increases, causing a temporary fall in pressure. However, as soon as the pressure decreases, a sufficient number of molecules change from the liquid state to the vapor state and restore the original pressure. When a compressed gas is used as the propellant, the relationship is quite different, and there is a drop in pressure as the contents are used.

### TWO-PHASE SYSTEM

This is the simplest of all aerosol systems. It consists of a solution or a suspension of active ingredients in liquid propellant or a mixture of liquid propellant and solvent. Both a liquid and a vapor phase are present, and when the valve is depressed,

**Figure 33-1.** Cross section of a typical space or surface coating aerosol spray.

liquid propellant containing dissolved active ingredients and other solvents are released. Depending on the nature of the propellants used, the quantity of propellant present, and the valve mechanism, a fine mist or wet spray is produced because of the large expansion of the propellant at room temperature and atmospheric pressure. This system is used to formulate aerosols for inhalation or nasal application.

Fluorocarbon propellants, primarily trichloromonofluoromethane (P-11), dichlorodifluoromethane (P-12), and dichlorotetrafluoroethane (P-114), are used for MDIs, provided that they currently have been approved under an NDA or ANDA. All new products must use other fluorocarbon propellants that are environmentally acceptable, a hydrocarbon propellant, or a compressed gas. The section dealing with propellants indicates those that are useful for this purpose.

A space spray generally contains from 2 to 20 percent active ingredients and from 80 to 98 percent propellant. While the pressure of space sprays is in the range of 30 to 40 psig, the particles that are produced range from less than 1 to 50  $\mu\text{m}$ . These particles remain suspended in air for relatively long periods of time. Space insecticides, room deodorants, and vaporizer sprays are examples of this type of system. MDIs formulated with a non-CFC propellant will generally have an internal pressure of about 50 to 70 psig.

A surface-coating spray (a relatively wet or coarse spray) can be achieved by decreasing the amount of low-boiling propellants

and increasing the ratio of active ingredients and solvents. The product concentrate can vary from 20 to 75 percent, and the propellant from 25 to 80 percent. Particles are produced ranging in size from 50 to 200  $\mu\text{m}$ . Products such as hair sprays, residual insecticides, perfumes, colognes, paints, protective coatings, and topical sprays are formulated in this manner. The pressure of this system is generally lower than that in the space spray.

Figure 33-1 shows a cross-section of a typical space or surface-coating aerosol spray.

The liquefied gas propellants widely used for MDIs include those shown in Table 33-1. Combinations of these propellants are used to achieve the desired spray characteristics. In certain instances the nature of the product will determine the propellant combination. Dispersion or suspension sprays used for MDIs are similar to space sprays in that they are two-phase systems in which the active ingredients are either dissolved or suspended in the liquid propellant phase. Over the past several years, Propellants 12, 12/11, or 12/114 have been used for these inhalation aerosols and were exempted from the CFC ban. Propellant 134a and 227ea are used to formulate non-CFC MDIs approved by the FDA for use in the United States. Their properties are shown in Table 33-2. Propellant 152a can be used in topical aerosols along with hydrocarbons, dimethyl ether (DME), and compressed gases. The properties of these propellants are included in Tables 33-3 to 33-5.

### THREE-PHASE SYSTEM

This system is useful for topical pharmaceutical aerosols in that it allows a greater use of liquid components not miscible with the propellants. Water is not miscible with liquefied-gas propellants and, in many instances, presents a problem, since active ingredients are soluble in water. With the increased emphasis upon the decrease of volatile organic compounds (VOCs) in all products, these systems are finding increased use. These problems have been overcome to a large extent by use of the three-phase system. Depending on the nature of the formulation, one of the following two systems may be employed. Dimethyl ether is most useful for products containing large amounts of water.

#### Two-layer system

In this system the liquid propellant, the vaporized propellant, and the aqueous solution of active ingredients make up the three phases. Since the liquid propellant and water are not miscible, the liquid propellant will separate as an immiscible layer. When a hydro alcohol mixture is used, the propellant and hydro alcohol solution will mix and form a single layer. When this propellant is of the fluorocarbon type, being denser than water, it will fall to the bottom of the container. Hydrocarbons, on the other hand, are lighter than water and, when used in this manner, will float on top of the aqueous layer. A spray is produced by the mechanical action of an exceedingly small valve orifice through which the liquid and some vaporized propellant are

forced by the vapor pressure of the propellant. The vapor layer is replaced continuously by vaporization of the liquid layer of propellant. This action results in the maintenance of a constant vapor pressure in the headspace.

An important characteristic of this system is that the propellant layer can be adjusted by varying the components so its specific gravity is almost equal to, but does not exceed, that of the hydroalcoholic phase. The propellant floats on top of the hydroalcoholic phase and, when shaken, is dispersed easily. When the valve is depressed, sprays are produced of varying characteristics, depending on the nature of the formulation.

<sup>b</sup> At the critical point (233°F)

<sup>c</sup> Volume of gas at atmospheric pressure soluble in one volume of water.

This system is designed to dispense pressurized products efficiently and economically, using relatively small amounts of hydrocarbon, HFA, or HCFC propellants.

The vapor phase of the propellant and the product concentrate enter the mixing chamber in the actuator through separate ducts or channels. The vaporized propellant enters, moving at tremendous velocity, while the product is forced into the actuator by the pressure of the propellant. It is at this point that product and vapor are mixed with violent force, resulting in a uniform, finely dispersed spray. Depending on the configuration of the valve and actuator, either a dry or a wet spray can be obtained.

Water-based aerosols developed for use in this system have the advantage that the chilling effect associated with liquefied-gas systems is eliminated. Since only vaporized propellant is dispensed, less propellant is required in the container. With greater use of water as a solvent for active ingredients, a greater range of products can be developed. Because the use of volatile organic compounds (VOCs) is now being curtailed, water is being used, when possible, as an alternative to some solvents such as alcohol. The use of P-152a and/or DME as a propellant also helps to reduce the VOC content of some aerosols such as hairsprays. Table 33-3 and Table 33-4 illustrate the properties of these propellants.

### Foam system

Foam aerosols, which often are classified separately, consist of three-phase systems in which the liquid propellant, which normally does not exceed 10 to 15 percent by weight, is emulsified with the drug-containing liquid. When the valve is depressed, the emulsion is forced through the nozzle, and in the presence of warm air and at atmospheric pressure, the entrapped propellant reverts to a vapor and whips the emulsion into a foam. The use of a dip tube is optional with this type of system, and when present, the container is designed for upright use. For those containers where the dip tube is omitted, the container must be inverted prior to use.

Foam valves have been developed that are applicable to both types of packages. Foam products operate at a pressure of about 30 to 45 psig at 70°F (21°C) and generally contain about 4 to 7 percent propellant, depending upon the nature of the propellant. Hydrocarbon propellants are used at the lower percentage, since their density is much lower than that of their fluorocarbon counterparts. A typical foam-type aerosol can be seen in Figure 33-2. Shave creams, suntan foams, and several topical dermatological aerosols have been formulated as foam aerosols. Generally, a blend of propane/isobutane or propane/isobutane/butane or isobutane alone is used for foam aerosols.

Some foams use P-152a as the propellant, since this propellant will produce a somewhat more stable foam and is less flammable than hydrocarbons. As a replacement for the CFCs, the

Figure 33-2. Foam type aerosol.

HFA propellant 134a is being currently used for foam formulations, making the product non-flammable. Depending on the formulation, some aerosols use nitrous oxide, carbon dioxide, or a mixture of both as the propellant. Contraceptive foam aerosols are formulated with a hydrocarbon, generally A-31, as the propellant.

### COMPRESSED-GAS AEROSOLS

Aerosols using compressed gases as the propellant are finding increased use. These propellants, especially nitrogen, carbon dioxide, and nitrous oxide, are acceptable for use with pharmaceuticals. Compressed gases are used to dispense the product as a solid stream, wet spray, or foam. These aerosol products use an inert gas such as nitrogen, carbon dioxide, or nitrous oxide as the propellant. The gas is compressed in the container, and it is the expansion of the compressed gas that provides the push or the force necessary to expel the contents from the container. As the contents of the container are expelled, the volume of the gas will increase, causing a drop in pressure, according to Boyle's law. This enables one to calculate the drop in pressure as the contents of a compressed-gas aerosol are used. Table 33-5 indicates some of the more important properties of these compressed gases. Depending upon the nature of the formulation and the type of compressed gas used, the product may be dispensed as a semisolid, foam, or spray.

### Semisolid dispensing

The concentrate generally is semisolid in nature, and since the gas is insoluble and immiscible with the concentrate, the product is dispensed in its original form. This system is applicable to the dispensing of dental creams, hairdressings, ointments, creams, cosmetic creams, foods, and other products. Compressed-gas aerosols operate at a substantially higher initial pressure of 90 to 100 psig at 70°F (21°C). This pressure is necessary to ensure adequate pressure for the dispensing of most of the contents from the container. The amount of product retained in the unit after exhaustion of the pressure varies with the viscosity of the product and loss of pressure, due to seepage of gas during storage. Since the concentrate generally is semisolid in nature and the dispensing characteristics depend largely on the viscosity of the product and the pressure within the container, the viscosity of the product concentrate must be adjusted accordingly.

### Foam dispensing

Soluble compressed gases, such as nitrous oxide and carbon dioxide, can be used to produce a foam when used with emulsion

products. This system is typical for whipped creams and toppings and several pharmaceutical and veterinary products. When this system is used, the gas dissolved in the concentrate will be evolved and cause a whipping of the emulsion into a foam. To facilitate the formation of a foam, this system is shaken prior to use to disperse some of the gas throughout the product concentrate.

### Spray dispensing

This system is similar to a space or surface spray except that a compressed gas is used as the propellant. Since these gases do not possess the dispersing power of the liquefied gases, a mechanical breakup actuator is used. The product is dispensed as a wet spray and is applicable to solutions of medicinal agents in aqueous solvents.

Another application for this type of system is found in the contact lens saline solutions. These consist of a normal saline solution packaged in an aluminum aerosol container and pressurized with nitrogen. Since these solutions may come in contact with the eye, they are sterilized using cobalt-60 gamma irradiation.

### BARRIER-TYPE SYSTEMS

The barrier-type aerosol system is gaining popularity in the pharmaceutical prescription and over-the-counter markets. Currently many of the sunscreen products are formulated in a barrier system into a spray, lotion or foam. These packaging systems are desirable because they are compact, portable, and ease to rub in. These systems separate the propellant from the product itself. The pressure on the outside of the barrier serves to push the contents from the container. The following types are available.

### Piston type

Since it is difficult to empty the contents of a semisolid from an aerosol container completely, a piston-type aerosol system has been developed. This uses a polyethylene piston fitted into an aluminum container. The product is placed into the upper portion of the container. The pressure from nitrogen (about 90 to 100 psig) or a liquefied gas pushes against the other side of the piston, and when the valve is opened, the product is dispensed. The piston scrapes against the sides of the container and dispenses most of the product concentrate. The piston-type aerosol system is shown in Figure 33-3. This system has been used successfully to package cheese spreads, cake decorating icings, and some ointments and creams. Since the products that use this system are semisolid and viscous, they are dispensed as a lazy stream rather than as a foam or spray. This system is limited to viscous materials since limp liquids, such as water or alcohol, will pass between the wall of the container and the piston. The piston type system has also been used to formulate post-foaming type gels.

### Plastic-bag and bag-in-bag type

This system consists of a collapsible plastic bag fitted into a standard, three-piece tinplate or aluminum container, as shown in Figure 33-4. The product is placed within the bag, and the propellant is added through the bottom of the container. Since the product is placed into a plastic bag, there is no contact between the product and the container wall except for any product that may escape by permeation through the plastic bag. A variation of this system is shown in Figure 33-5. The valve and a collapsed inner bag are inserted into a container. A compressed or liquefied gas is added at the same time as the valve/bag is inserted, and then the valve is crimped. The product is forced through the valve and into the bag. The bag expands and will compress the propellant resulting in an increase in pressure. As the valve is opened, the product will be dispensed. Ointments, creams, and gels can be packaged in this system.

Figure 33-3. Free piston aerosol system.

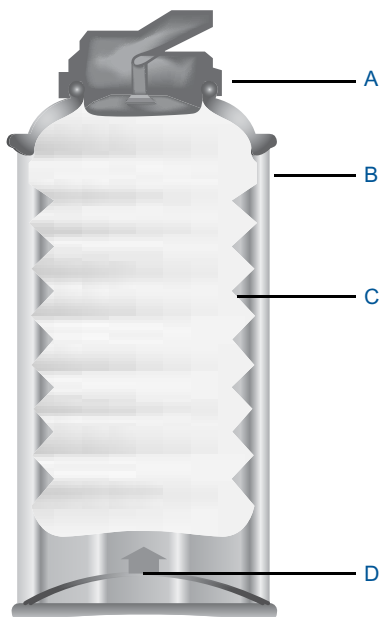

Figure 33-4. Plastic-bag aerosol system.

Limpid liquids, such as water, can be dispensed as either a stream or a fine mist, depending on the type of valve used, while semisolid substances are dispensed as a stream. To prevent the gas from pinching the bag and preventing the dispensing of product, the inner plastic bag is accordion-pleated. This system can be used for a variety of different pharmaceutical and nonpharmaceutical systems, including topical pharmaceutical products as a cream, ointment, or gel.

A modification of the barrier system dispenses the product as a gel that will then foam. By dissolving a low-boiling liquid such as isopentane or pentane in the product, a foam will result when the product is placed on the hands, and the warmth of

Figure 33-5. Bag-in-valve container system. (Courtesy of CCI container.)

the hands will cause vaporization of the solvent. This system, as well as the piston system, is used in post-foaming shave gels.

### Can-in-can systems

Figure 33-6 illustrates a system consisting of an aluminum can into which a second aluminum thin-walled can has been inserted. This inner can is glued to the outer can at the neck and forms a gas-tight seal. Then the neck of the can is fabricated. The propellant (liquid or compressed) is added through a small opening in the bottom of the can that is sealed with a rubber plug. A recent addition to this system includes replacement of the inner aluminum pouch with an inner plastic bag made of organic polymers. Sufficient space remains between this bag and the walls and the bottom of the outer container to accommodate sufficient propellant to evacuate the product completely. Systems illustrated by Figure 33-6 can be used with a continuous or metered-dose valve to dispense medicated solutions, gels, creams, and lotions.

Figure 33-6. Cross-section of the Lechner barrier pack. It consists of a rigid or flexible inner bag that can be evacuated more than 95 percent, depending upon the viscosity of the product. (Courtesy of Lechner GMBH.)

## PROPELLANTS

The propellant generally is regarded as the heart of the aerosol package. In addition to supplying the necessary force to expel the product, the propellant must also act as a solvent and diluent and has much to do with determining the characteristics of the product as it leaves the container. Various chemical compounds have been used as aerosol propellants.

Compounds useful as propellants can be classified as the following:

- Liquefied gases
- Chlorofluorocarbons (CFC)
- Hydrochlorofluorocarbons (HCFC)
- Hydrofluorocarbons (HFC) or Hydrofluoroalkanes (HFA)
- Hydrocarbons (HC)
- Hydrocarbon ethers
- Compressed gases.

### LIQUEFIED GASES

The liquefied-gas compounds have widespread use as propellants, since they are extremely effective in dispersing the active ingredients into a fine mist or foam, depending on the form desired. In addition, they are relatively inert and non-toxic. They have the added advantage that the pressure within the container remains constant. Two types of liquefied gases are used. The chlorofluorocarbons (CFCs) and hydrofluorocarbons (HFCs) find greater use since they are non-flammable in contrast to the flammable hydrocarbons. The hydrocarbons are advantageous since they are less expensive than any of the fluorocarbons and generally are environmentally acceptable.

### Chlorofluorocarbons (CFCs)

These compounds have been implicated in causing a depletion of the ozone layer and for responsibility for the greenhouse or for the global warming effect (increase in earth's temperature, rising sea levels, and altered rainfall patterns). Depletion of the ozone layer is also alleged to have resulted in an increase in the incidence of skin cancer. This is due to a greater penetration of the ozone layer by the skin-cancer-causing UV radiation from the sun (the ozone layer will prevent these rays from penetrating the earth's atmosphere). In 1974, the Environmental Protection Agency (EPA), Consumer Product Safety Commission (CPSC), and the FDA promulgated a ban on the use of chlorofluorocarbons, namely Propellants 11, 12, and 114, in most aerosol products. Certain pharmaceutical aerosols for inhalation use (MDIs) were exempted from this ban. According to the Montreal Agreement reached in 1988, beginning in 1989 the production of these propellants was restricted worldwide. Starting January 1, 1996, worldwide production of CFCs was reduced to only the amount needed for certain exempted uses that included MDIs for the treatment of asthma and chronic obstructive pulmonary disease (COPD). CFC propellants are used in all of the metered-dose inhalers in the United States. MDIs have been classified by the Environmental Protection Agency and Food and Drug Administration as "essential use" and as such are exempted from the ban on the use of CFCs. The EPA granted allocation of CFC 11, 12, and 114 to those manufacturers of MDI inhalers currently being sold so that these products can continue to be manufactured and available in the US marketplace. Currently EPA regulations prohibit the granting of a CFC allocation for any MDI classified as essential use and not approved by the FDA prior to December 31, 2000. Essentially this ruling prevents the development and sale of a generic version of these CFC containing MDIs. MDIs containing albuterol are the only MDI products available in generic form. All other CFC propelled MDIs can continue to be sold in the marketplace free from generic product competition.

Generic MDI products containing albuterol and those containing epinephrine have been developed since the late 1990s and are currently marketed by generic pharmaceutical companies. No other generic version of an MDI product is available in the United States.

In the latter part of the 1990s, FDA issued a ruling to encourage the development of ozone-friendly propellants (HFAs) so that essential use designation could be removed. This ruling allowed for the removal of essential use designation from existing MDIs containing CFCs if the following conditions are met:

- At least one non-CFC product with the same active drug is marked with the same route of administration, for the same indication, and with approximately the same level of convenience of use as the CFC product containing that active moiety (while these alternatives are not required to be MDIs, the presumption is that HFA MDIs would most easily fit criteria compared to, for example, dry powder inhalers).
- Supplies and production capacity for the non-CFC product(s) exist or will exist at levels sufficient to meet patient need.
- Adequate US post marketing use data are available for the non-CFC product(s).
- Patients who medically required the CFC product are adequately served by the non-ODS product(s) containing that active moiety and other available products.

The FDA Pulmonary-Allergy Drugs Advisory Committee met on June 10, 2004 to consider removing "Essential Use" designation for albuterol MDIs containing CFCs. The committee was in agreement that albuterol MDI met the first three criteria but was not in agreement as to the last criteria. Concern was raised as to the effect of removal of albuterol MDIs containing CFCs from the market place and what effect their replacement with an HFA albuterol would have upon the cost to the consumer. albuterol MDI is available in the US as a generic product while the HFA albuterol will not be available as a generic until 2015. This has caused concern to the committee members. The FDA has phased out albuterol CFC MDI as of December 31, 2005, after which date no albuterol CFC MDIs can be legally marketed in the United States. Epinephrine (Primatine Mist) containing CFC will be banned starting December 31, 2011.

While MDIs are currently being formulated with a HFC propellant in place of the CFC, only two drug entities have received FDA approval for marketing in the US. These include albuterol and beclomethosone propionate. In contrast to Europe and the rest of the world, almost every CFC metered-dose inhaler has been replaced with a HFC propellant. These replacements will be discussed in greater detail in another section of this chapter.

Since the early 1990s topical aerosol products have been reformulated using a hydrocarbon or a compressed gas propellant in place of the CFC. Compressed gasses, hydrocarbon, and HFC propellants are the suggested alternative propellant. Other than some of the specific properties of the CFCs and the HFCs, the principles of use in dosage form development remain essentially the same.

Liquefied gases provide a nearly constant pressure during packaging operations and have a large expansion ratio. Several of the fluorinated hydrocarbons have an expansion ratio of about 240, that is, 1 mL of liquefied gas will occupy a volume of approximately 240 mL if allowed to vaporize. Dimethyl ether has a value over 350. On the other hand, compressed gases expand only to the extent of 3 to 10 times the original volume.

The physicochemical properties of these compounds are of prime importance in the formulation and manufacture of aerosol products. The solvent power, stability, and lack of reactivity

of the propellants have made them extremely useful for this purpose.

## Nomenclature

To refer easily to the fluorinated hydrocarbons, a relatively simple system of nomenclature was developed some time ago by the refrigeration industry. A numerical designation is used to identify each propellant.

- All propellants are designated by three digits (000). When the first digit is zero, the propellant is designated by the last two digits, and zero is assumed to be the first digit (e.g., Propellant 011 is Propellant 11).
- The first digit is one fewer than the number of carbon atoms in the compound. When there are only two digits, (0) is understood to be the first digit and indicates a methane derivative. When this first digit is (1), the propellant is an ethane derivative; when (2), it is propane; and when (3), it is a butane derivative.
- The second digit is one more than the number of hydrogen atoms in the compound.
- The last digit represents the number of fluorine atoms.
- The number of chlorine atoms (for CFCs) in the compound is found by subtracting the sum of the fluorine and the hydrogen atoms from the total number of atoms that can be added to saturate the carbon chain.
- In the case of isomers, each has the same number, and the most symmetrical one is indicated by the number alone. As the isomers become more and more asymmetrical, the letter a, b, c, etc., follows the number.
- For cyclic compounds, a C is used before the number. The use of this system can be exemplified as follows: CFC 114–Dichlorotetrafluoroethane.
- Propellant 114 is an ethane derivative, has no hydrogens, and contains 4 fluorine atoms.
- Since 6 atoms are required to saturate the carbon chain, of necessity there must be 2 chlorine atoms. These can be arranged in two different ways; however, since there is no letter following the numerical designation, the symmetrical structure refers to Propellant 114.

For CFC 11–Trichloromonofluoromethane

- The designation is 0 for methane (first digit)
- 1 for number of fluorine atoms (third digit)
- 1 for one more than number of hydrogen atoms (second digit)
- 3 chlorine atoms required to saturate molecule.

For HFC-227–Heptafluoropropane

- The designation is 2 for propane (first digit)
- 7 for number of fluorine atoms (third digit)
- 2 for one more than number of hydrogen atoms (second digit)
- Since there is no letter following the third digit, the one H atom must be on the #2 carbon as this is the most symmetrical configuration.

For HFC-134a–Tetrafluoroethane

- The designation is 1 for ethane (first digit)
  - 4 for number of fluorine atoms (third digit)
  - 3 for one more than number of hydrogen atoms (second digit)
- There are two possibilities for the 2 hydrogen atoms (one on each carbon or two on one carbon). Since this designation has an “a” following the last digit, it is the asymmetrical compound.

## Physical properties

Table 33-1 shows some of the more useful physicochemical properties of CFC propellants. Propellants 11, 12, and 114 are included in the latest issue of the USP/NF and the *British Pharmacopoeia*. Specifications for these propellants, hydrocarbons, as well as the HFCs, HCFCs, and compressed gases, can be found in the *Handbook of Pharmaceutical Excipients*, Sixth Edition.

From a solubility standpoint, the CFC, HFC, and HCFC propellants, which are non-polar, are miscible with most non-polar solvents over a wide range of temperature. They also are capable of dissolving many substances. For the most part the propellants are not miscible with water, although the degree of miscibility depends on the individual propellants. A cosolvent such as ethanol, 2-propanol, or DME, must be used when water is present to produce a clear solution. However, when one considers that these propellants are used for metered-dose aerosols, the choice of cosolvent is extremely limited and, in many cases, to the use of ethyl alcohol. The alternative is to form an emulsion for topical aerosol pharmaceuticals.

One of the most important physicochemical properties of a propellant is its vapor pressure, which may be defined as the pressure exerted by a liquid in equilibrium with its vapor. When the vapor pressure exceeds atmospheric pressure, boiling and vaporization take place. However, if the vaporized molecules are prevented from leaving the container (by placing the propellant into a sealed container), they will fill the head space and eventually cause an increase in pressure. The pressure developed at equilibrium is the vapor pressure. The vapor pressure of a liquefied gas is independent of the quantity used but is influenced by temperature changes. Assuming ideal behavior for the liquefied gas, the effect of temperature on the vapor pressure can be calculated from

$$\log P = -\frac{\Delta H_{\text{vap}}}{2.303 RT}$$

where  $P$  is the vapor pressure,  $H$  is the heat of vaporization,  $R$  is the gas constant (generally  $1.987 \text{ cal deg}^{-1} \text{ mole}^{-1}$ ), and  $T$  is the absolute temperature.

Since

$$\ln P = -\frac{\Delta H_{\text{vap}}}{RT} + C$$

a plot of  $\log P$  versus  $1/T$  should yield a straight line, and from this the heat of vaporization may be calculated.

$$\Delta H_{\text{vap}} (\text{cal mole}^{-1}) = -(\text{slope})(2.303R)$$

These equations can be used to predict the behavior of pure propellants at elevated temperatures. When one considers that an aerosol preparation consists of a propellant and solvents or mixtures of these, the vapor pressure considerations are somewhat different. By mixing various propellants, such as Propellants 11 and 12 or Propellants 12 and 114, a range of vapor pressures is obtained. This is not possible when the HFCs are used, since the range in pressure between P-134a and P-227 is relatively small (about 26 psig, compared with about 70 psig between P-11 and P-12). The vapor pressure of a mixture of propellants may be calculated from Raoult's law, which states that the vapor pressure of a solution is dependent upon the vapor pressure of the individual components. For ideal solutions, the vapor pressure is equal to the sum of the mole fractions of each component present times the vapor pressure of the pure compound at the desired temperature.

Mathematically, this law may be expressed as

$$p_A = \frac{n_A}{n_A + n_B} p_A^\circ = N_A p_A^\circ$$

where  $p_A$  = partial vapor pressure of Component A,  $p_A^\circ$  = vapor pressure of pure Component A,  $n_A$  = mols of Component A,  $n_B$  = moles of Component B, and  $N_A$  = mol fraction of Component A.

$$p_B = \frac{n_B}{n_B + n_A} p_B^\circ = N_B p_B^\circ$$

The total vapor pressure of the system is obtained by

$$P_{\text{total}} = p_A + p_B$$

When the mole fraction of one component is large, the other component has a small mole fraction, and as such, it does not appreciably affect the vapor pressure. This system approaches ideal behavior.

When the components are of similar physical and chemical nature, the experimentally determined values and the calculated values are approximately the same. In the case of the fluorinated hydrocarbons, the deviation from ideal behavior is not great, and the results are approximately equal or within 5 percent. When other solvents are present, such as alcohols, the vapor pressures can be calculated in a similar manner.

### Chemical properties

The fluorinated hydrocarbons have been widely used as aerosol propellants because they generally are considered to be chemically inert. From the standpoint of formulation, the only chemical property that need be considered is hydrolysis, in regard to Propellant 11. While addition of fluorine to a carbon atom generally increases stability, a propellant such as trichloromono-fluoromethane may undergo hydrolysis with the formation of hydrochloric acid. Propellant 11 is not used with aqueous products, as hydrolysis will occur; Propellant 114 generally is used instead. For topical and cosmetic aerosols, hydrocarbons or hydrochlorofluorocarbons are used (Propellants 152b or DME). Propellants 134a and 227 have properties similar to those of P-12 except for their solubility characteristics.

### Hydrocarbons

Hydrocarbon propellants have replaced CFCs for topical pharmaceutical aerosols. Their low-order toxicity makes them suitable, while their flammability tends to limit their use. With the development of newer types of dispensing valves, the flammability hazard has been reduced considerably. The advantage of hydrocarbons is their greater range of solubility and a lower cost than CFCs. To date they represent a readily available replacement for CFCs as propellants, provided that the flammability hazard can be reduced.

The HFC propellant used for MDIs is also applicable to topical aerosol pharmaceuticals, with the added advantage of non-flammability.

In addition to having the proper vapor pressure, hydrocarbons have other properties that make them useful as propellants. Their density of less than 1 and their immiscibility with water make them useful in the formulation of three-phase (two-layer) aerosols. Being lighter than water, the hydrocarbon remains on top of the aqueous layer and serves to push the contents out of the container. Not being halogenated, hydrocarbons generally possess better solubility characteristics than the fluorinated hydrocarbons.

As with CFCs, a range of pressures can be obtained by mixing various hydrocarbons in varying proportions. As the composition of the hydrocarbons is likely to vary somewhat, depending on their source, blending of hydrocarbons must be based on the final pressure desired and not on the basis of a stated proportion of each component, whose pressure will depend on its purity. Table 33-6 lists some commonly used blends that are commercially available.

Finally, it should be indicated that the hydrocarbons are characterized further by their extreme chemical stability. They are not subject to hydrolysis, making them useful with water-based aerosols. They will react with the halogens but only under severe conditions.

### ALTERNATIVE PROPELLANTS (HCFCS AND HFCS)

Many pharmaceutical aerosols were developed originally using chlorofluorocarbons (CFCs) 11, 12, and 114. These propellants have found widespread use because of their inertness, non-flammability, and non-toxicity. Unfortunately, the CFCs have been implicated in depleting the ozone layer, and their use as aerosol propellants has practically been eliminated, except for exempted medical uses, which included MDIs.

Topical pharmaceutical aerosols have been successfully reformulated with Propellants 152a, DME, hydrocarbons, and compressed gases. Suitable valves are available that, together with modifications in formulation and propellant blends, produce topical aerosol pharmaceuticals that are satisfactory and acceptable.

Several new liquefied-gas materials have been developed to replace the CFCs as refrigerants and foaming agents and in other non-pharmaceutical uses. Propellant 134a and Propellant 227 have been developed as substitutes for Propellant 12 in MDIs and have survived many of the short- and long-term toxicity studies. To date, no suitable replacement has been found for Propellants 11 and 114. Propellant 114 is not essential for use with MDIs, but most of the present suspension formulations require a minimum amount of Propellant 11. Propellant 11 is used to form a slurry with the active ingredient and dispensing agent. This is impossible to accomplish with Propellants 134a and P-227 (unless these propellants are chilled well below their boiling point and handled as a cold fill). Propellant 11 also has

**Table 33-6. Commonly Used Hydrocarbon Blends**

Designation <sup>a</sup>	Pressure (psig at 70°F)	Composition (mol percent)		
		<i>n</i> -Butane	Propane	Isobutane
A-108	108 ± 4	Traces	99	1

<sup>a</sup> Designations used by Phillips Chemical Co, Bartlesville, OK. Other designations include: Aeron—Diversified CPC International, Inc., Channahon, IL

been used to dissolve the surfactants that have been used with CFC MDIs. The HFCs are extremely poor solvents and will not dissolve a sufficient amount of the currently used FDA-approved surfactants (oleic acid, sorbitan trioleate, and soya lecithin).

It also has been noted that some of the currently used valves are not compatible with these newer HFC propellants. The gaskets and sealing compounds used in metered-dose valves may present compatibility problems to the formulator; however, other gasket materials (EPDM) have been developed and found to be satisfactory. Several of the critical properties of these newer propellants are shown in Table 33-2. Additional details about their use in formulation of MDIs is included in a later part of this chapter.

## COMPRESSED GASES

The compressed gases such as nitrogen, nitrous oxide, and carbon dioxide have been used as aerosol propellants. Depending on the nature of the formulation and the valve design, the product can be dispensed as a fine mist, foam, or semisolid. However, unlike the liquefied gases, the compressed gases possess little, if any, expansion power and will produce a fairly wet spray and foams that are not as stable as liquefied-gas foams. This system has been used for the most part to dispense food products and, for non-foods, to dispense the product in its original form as a semisolid. Compressed gases have been used in products such as dental creams, hair preparations, ointments, and aqueous antiseptic and germicidal aerosols and are extremely useful in contact lens cleaner saline solution and barrier systems.

## CONTAINERS

### METAL

#### Tin-plated steel

To produce an aerosol container that was light and relatively inexpensive, tin-plated steel was used for aerosol containers. This resulted in the large-scale production of aerosol containers. For certain products the tin affords sufficient protection, so that no further treatment is necessary. For additional protection to either the drug product or container, a coating, usually organic in nature, may consist of an oleoresin, phenolic, vinyl, or epoxy coating. The liner (single or double coat) is added to the container prior to fabrication; that is, it is applied to the flat sheets of tin plate.

#### Aluminum

Many MDIs and pharmaceutical aerosols use an aluminum container. Aluminum containers (sometimes referred to as canisters) are produced by an impact extrusion process so that the container is seamless. These containers are extremely strong and will withstand relatively high pressures. A variety of different aluminum aerosol containers, ranging in size from 10 mL to 1260 mL, is available. While aluminum is less reactive than other metals used in can manufacture, added resistance can be obtained by coating the inside of the container with organic materials such as epoxy, vinyl, phenolic, or polyamide resins. Many of the MDIs will use an anodized or non-anodized internal surface, with or without an organic inner coating. Most of the aluminum containers for MDIs formulated with an HFC propellant are coated with an organic inner coating.

### Glass

For pharmaceuticals and medicinals, glass is preferred because of the absence of incompatibilities, as well as for its aesthetic value. The use of glass containers is limited to those products having a lower pressure and lower percentage of propellant. While glass is basically stronger than most metallic containers, a potential hazard is present if, and when, the container is dropped with subsequent breakage. Two types of glass aerosol containers are available. The uncoated glass container has the advantage of decreased cost and high clarity. The contents can

be viewed at all times. The plastic-coated glass containers are protected by a plastic coating that prevents the glass from shattering in the event of breakage. The plastic coated glass container is used for some topical and MDI aerosols.

## VALVES

Probably the most basic part of any aerosol or pressurized package is the valve mechanism through which the contents of the package are emitted. Together with the formulation, the valve determines the performance of a pressurized package. The interaction of these two components is such that one cannot readily be discussed without reference to the other.

The primary purpose of the valve is to regulate the flow of product from the container. It provides a means of discharging the desired amount when needed and prevents loss at other times. The valve also exerts a major effect on the character of the dispensed product. For example, a product formulated to produce a foam can be dispensed as a spray or as a wet stream by the use of different actuators or push buttons on the valve. The selection of proper propellants also governs whether a foam, spray, or wet stream will be produced.

### CONTINUOUS-SPRAY VALVES

Figure 33-7 illustrates the basic subcomponents used in aerosol valves. A fully assembled valve is shown in Figure 33-8.

A small hole about 0.013 to 0.020 in diameter sometimes is placed in the valve body, as seen in Figure 33-7. This allows the escape of a small quantity of vaporized propellant along with the product. This gives a greater degree of dispersion to the emitted spray, as well as cleaning the valve orifices following discharge. However, since a greater amount of propellant is used than with non-vapor tap systems, care must be exercised during formulation of the product to take this into account. One may also note a change in spray pattern from start to finish because of the change in propellant composition that takes place as the contents are used. Vapor-tap valves are used with powder aerosols, water-based aerosols, aerosols containing suspended materials, and other agents that would tend to clog the valve. They currently are used with hydrocarbon aerosols since the flame extension of the spray can be reduced substantially through use of a vapor-tap valve. This is accomplished by balancing the size of the vapor-tap opening and the valve orifice.

**Figure 33-7.** Continuous-spray aerosol valve, showing subcomponents used for sprays, foams, and semisolids.

**Figure 33-8.** Assembled continuous-spray valve.

### FOAM VALVES

Valves for foam or aerated products usually have only one expansion orifice, the one at the seat. Following this is a single expansion chamber that serves as a delivery nozzle or applicator. It is sufficiently large in volume to permit immediate expansion of the pressurized product to form the familiar ball of foam. As demonstrated earlier, the same formulation will be discharged as a solid stream when dispensed with a valve and actuator having small orifices and expansion chambers. Under these latter conditions, the ball of foam will begin to develop where the stream impinges on a surface. This rather interesting performance is used in some pressurized surgical soaps on the market. These products are preferred for use by surgeons and other operating room personnel since when applied the foam breaks down easily and is rubbed into large areas of the hands and arms. Another similar product contains ethyl alcohol and is made into a similar foam and used as a skin disinfectant or sprayed onto instruments, etc.

Because of their large openings, foam valves may lend themselves to use with viscous materials such as syrups, creams, and ointments. Foam valves also have been used to dispense rectal and vaginal foams. Metered valves are discussed later in this chapter.

### ACTUATORS

The actuator provides a rapid and convenient means for releasing the contents from a pressurized container. It provides the additional functional use in allowing the product to be dispensed in the desired form, that is, a fine mist, wet spray, foam, or solid stream. Mechanical breakup actuators are used for three-phase or compressed-gas aerosols. In addition, special actuators are available for use with pharmaceutical and medicinal aerosols that allow dispensing of products into the mouth, nose, throat, vagina, or eye.

### PACKAGING

Two methods have been used to package aerosol products. Unlike non-aerosol products, part of the manufacturing of necessity takes place during the filling operation. The propellant and product concentrate must be brought together in a way that ensures uniformity of product.

Depending on the nature of the product concentrate, the aerosol can be filled by a cold-filling or a pressure-filling process. There are advantages and disadvantages to both methods, and there are many factors that must be considered before deciding which process to use. Since aerosol packaging is a very specialized procedure, many of the pharmaceutical aerosols are manufactured and packaged at commercial contract filling facilities. A typical unit used to fill MDIs in the laboratory is shown in Figure 33-9, while Figure 33-10 illustrates a typical Pamasol aerosol packaging line for MDIs. Figure 33-11 shows

a Terco filling and packaging line for topical pharmaceutical aerosols.

## APPLICATIONS

Aerosol technology has been applied to the formulation of products containing therapeutically active ingredients. A pharmaceutical aerosol may be defined as an aerosol product containing therapeutically active ingredients dissolved, suspended, or emulsified in a propellant or a mixture of solvent and propellant and intended for oral or topical administration or for administration into the nose, eye, ear, rectum, or vagina.

MDIs are intended for administration as fine, solid particles or as liquid mists via the respiratory system or nasal passages.

**Table 33-7. Metered-Dose Inhalants (Solution and Suspensions): Prototype Formulation**

Solution (CFC, HFC) <sup>a</sup>
Active ingredient(s): solubilized antioxidants: ascorbic acid
Solvent blends: water, ethanol, glycols
Propellants: 12/11, 12/114 or 12 alone; 134a, 227, 134a/227
Suspensions (CFC)
Active ingredient(s): micronized and suspended
Dispersing agent(s): sorbitan trioleate, oleyl alcohol, oleic acid, lecithin, etc.
Propellants: 12/11, 12/114, 12 or 12/114/11 suspensions (HFC) <sup>a</sup>
Active ingredient(s): micronized and suspended solvent: ethanol
Dispersing agent(s): sorbitan trioleate, oleyl alcohol, oleic acid, lecithin, etc.
Propellants: 134a, 227, 134a/227
or
Active ingredient(s): micronized and suspended propellants: 134a, 227, 134a/227

<sup>a</sup> The reader is directed to the patent literature to ensure that the formulations are not covered by a patent.

They are used for their local action in the nasal areas, throat, and lungs, as well as for prompt systemic effect when absorbed from the lungs into the bloodstream (inhalation therapy). The particle size must be considerably below 10  $\mu\text{m}$  and, in most instances, should be between 3 and 6  $\mu\text{m}$  for maximum therapeutic response.

An alternative definition of this dosage form includes the following: Pharmaceutical aerosols are products that are packaged under pressure and contain therapeutically active ingredients that are released upon actuation of an appropriate valve system. They are intended for topical application to the skin as well as local application into the nose (nasal aerosols), mouth (lingual aerosols) or lungs (inhalation aerosols).

## AEROSOL FORMULATION

Topical pharmaceuticals may be formulated as aerosols using solutions, suspensions, emulsions, powders, and semisolid preparations, while MDIs are formulated as solutions or suspensions. Table 33-7 illustrates the basic formulation of aerosol products for use as metered-dose inhalants.

### Solution aerosols

Topical aerosols consist of a solution of active ingredients in pure propellant or a mixture of propellant and solvents. The solvent is used to dissolve the active ingredients and/or retard the evaporation of the propellant. Solution aerosols are relatively easy to formulate, provided the ingredients are soluble in the propellant. However, the propellants are non-polar in nature and in most cases are poor solvents for some of the commonly used medicinal ingredients. Through use of a solvent that is miscible with the propellant, one can achieve varying degrees of solubility of the active ingredient. For topicals (isopropyl alcohol, isopropyl myristate, polyethylene glycols, etc.), ethyl alcohol has found the greatest use, although some other solvents may be of limited value. For those substances that are insoluble in the propellant or propellant/solvent system, a dispersion or suspension can be produced. In this case the drug must be micronized so that the particles are less than 10 micrometers in average diameter.

The usual fluorocarbon propellants used in currently available MDIs are blended as indicated in Table 33-7 or used alone when appropriate. Propellant 11 is used often when solubility of the drug and solvents presents a problem, for it is a better solvent than either Propellant 12, 114, 134a, or 227. Additionally, Propellant 11 may be required to prepare a suitable slurry when preparing a dispersion aerosol. Generally the propellant represents upward of 60 weight-percent of the final formulation and, in most cases, may be as high as 99.9 percent. Propellant 12 may be used alone or in combination, as indicated. The proportion of each propellant is varied to obtain the desired pressure within the container and the proper particle-size distribution.

Topical pharmaceutical solutions are formulated using the hydrocarbon propellants, butane, isobutene, and propane. Although butane and isobutene can be used individually, the hydrocarbons are generally used as a blend, as shown in Table 33-6. Other non-MDIs are formulated as aqueous solutions (eye care, etc.) and utilize nitrogen as the propellant. These are packaged as a conventional aerosol or utilize a barrier system.

### Dispersions or po(powder aerosols)

These aerosols are similar to solution aerosols except that the active ingredients are suspended or dispersed throughout the propellant or propellant and solvent phase. This system is useful with antibiotics, steroids, and other poorly soluble compounds. Problems associated with the formulation of this system include agglomeration, caking, particle size growth, and valve clogging. Some of these problems have been overcome through use of lubricants such as isopropyl myristate, sorbitan trioleate, oleic acid, or other substances that provide slippage between particles of the compound as well as lubricating component parts of the valve. Surfactants also have been used to disperse the

particles. The use of dispersing agents such as sorbitan trioleate, oleic acid, or lecithin is useful in keeping the suspended particles from agglomerating. Thought also should be given to both the particle size and the moisture content of the powder. The moisture content should be kept between 100 and 300 ppm or less, depending upon the type of product, and the propellants and solvents must be dried by passing them through a drying agent. The particle size for metered-dose inhalants should remain in the micrometer range and should be between 2 and 8 micrometers or less, with a mass median diameter of between 3 and 6 micrometers.

## FORMULATION OF MDIS USING HFCS AS THE PROPELLANT

Several new environmentally acceptable propellants are available worldwide as replacements for CFCs in MDI inhalers. Among the alternatives is tetrafluoroethane (HFC 134a), which is available as Dymel 134a/P from DuPont Fluoroproducts; Solkane 134a pharma from Solvay; and Zephex 134a from Ineos Fluor.

Tetrafluoroethane (P-134a) is a hydrofluorocarbon (HFC) or hydrofluoroalkane (HFA) aerosol propellant (contains hydrogen, fluorine, and carbon) as contrasted to a CFC (contains chlorine, fluorine, and carbon). The lack of chlorine in the molecule and the presence of hydrogen reduce the ozone depletion activity to practically zero; therefore, tetrafluoroethane can be considered an alternative to CFCs in the formulation of metered-dose inhalers. It has replaced CFC-12 as a refrigerant since it has essentially the same vapor pressure. Its very low Kauributanol value and solubility parameter indicate that it is not a good solvent for the commonly used surfactants for MDIs. Sorbitan trioleate, sorbitan sesquioleate, oleic acid, and soya lecithin show limited solubility in tetrafluoroethane, and the amount of surfactant that actually dissolves may not be sufficient to keep a drug readily dispersed. Tetrafluoroethane has been used as a replacement for CFCs in MDIs containing albuterol. Two such products containing albuterol sulfate and one product containing beclomethasone dipropionate are currently available in the United States. Outside the US, this propellant has found greater use in Europe and the rest of the world, where many MDIs have been developed using tetrafluoroethane.

The use of tetrafluoroethane as a propellant for MDIs has been the subject of numerous patents throughout the world. These patents cover the formulation of MDIs, use of specific surfactants, cosolvents, etc. Many of these formulation patents are no longer valid in many countries of the world. The US patents have not been challenged to date.

US Patent No. 5605674 claims a self-propelling aerosol formulation which may be free from CFCs which comprises a medicament, 1,1,1,2-tetrafluoroethane, a surface active agent, and at least one compound having a higher polarity than 1,1,1,2-tetrafluoroethane.

The formulator is referred to the patent literature prior to formulating an MDI with tetrafluoroethane and/or heptafluoropropane (P-227) as the propellant. The use of an HFC as the propellant may also require a change in manufacturing procedure that necessitates a redesign of the filling and packaging machinery for an MDI.

One commercially available MDI is Proventil HFA (Schering), which contains albuterol sulfate suspended in ethanol, oleic acid, and tetrafluoroethane (P-134a). Each actuation delivers 108 µg of albuterol sulfate equivalent to 90 µg of albuterol from the mouthpiece. Similar versions of this product are available in the United Kingdom and the rest of the world. In 1998, 3M released Qvar for sale in the United Kingdom. This MDI contains beclomethasone in solution form. Since the respiratory fraction of the product is substantially higher than the current CFC product, according to the literature, a 200-microgram dose of Qvar achieved a total beclomethasone level comparable to a 400-microgram dose of the CFC-containing beclomethasone formulation. An NDA for Qvar

has since been approved by the FDA and Qvar MDI is now available commercially in the United States.

Another replacement for CFCs in metered-dose inhalers is heptafluoropropane (P-227), which is available as Dymel 227 ea/P from DuPont Fluoroproducts; Solkane 227 pharma from Solvay; and Zephex 227ea.

Heptafluoropropane is classified as a hydrofluorocarbon (HFC) aerosol propellant since the molecule consists only of carbon, fluorine, and hydrogen atoms. It does not contain any chlorine and consequently does not affect the ozone layer, nor does it have an effect upon global warming. It is therefore considered as an alternative propellant to CFCs for metered-dose inhalers. The vapor pressure is somewhat lower than that of tetrafluoroethane and dichlorodifluoromethane but considerably higher than the vapor pressure used to formulate most MDIs. Similar to tetrafluoroethane, heptafluoropropane is not a good solvent for medicinal agents used in the formulation of MDIs. Its use as a propellant is included in US Patent 5605674.

Although there are no MDIs formulated with this propellant currently available in the United States, the rest of the world, including Europe and Asia, have many MDIs that contain P-227. There are several MDIs formulated with P-227 currently under review by the FDA.

## Emulsions

An emulsion system is useful for a great variety of topical pharmaceutical products. Since these systems contain a relatively small amount of propellant (4 to 10 percent), there is little, if any, chilling effect. Active ingredients that may be irritating if inhaled can be used as a foam. Depending on the nature of the formulation and the manner in which the product is to be used, the foam is aqueous or nonaqueous and can be stable or quick-breaking.

Emulsions can be dispensed from an aerosol container as a spray, stable foam, or quick-breaking foam, depending on the type of valve used and the formulation. Two types of emulsions can be formulated for use in an aerosol. A W/O emulsion is one in which the water phase is dispersed throughout the oil phase; an O/W emulsion is one in which the water is the continuous phase.

If the product concentrate is dispersed throughout a propellant, the system behaves similarly to a W/O emulsion. However, since the propellant is in the external phase, the product is dispersed as a wet stream rather than as a foam. When the propellant is in the internal phase (O/W), a foam will be produced. The consistency and stability of the foam can be modified by choice of surfactants and solvents used.

Many water-based aerosols are of the W/O type, in which the propellant is in the external phase. Stable shave-cream foams, on the other hand, are produced by keeping the propellant in the internal phase.

The stable foam is similar to a shaving-cream formulation, into which therapeutically active ingredients are incorporated. The foam is dispensed and rubbed into the skin or affected area. By substituting glycols and glycol derivatives for the water in an emulsion, a nonaqueous foam is obtained. The foam stability can be varied by the choice of surfactant, solvent, and propellant. It has been suggested that these foams are applicable to ointment bases, rectal and vaginal medication, and burn preparations.

A quick-breaking foam allows convenient and efficient application of medication. In certain instances the product was dispensed as a foam that quickly collapsed. This was useful in covering large areas with no rubbing necessary to disperse the medication. These quick-breaking foams consist of alcohol, surfactant, water, and propellant.

## CONTAINER AND VALVE COMPONENTS

### Pharmaceutical containers

Aluminum is used as the material of construction for most metered-dose aerosols. While aluminum can be used without an

internal organic coating for certain aerosol formulations, many containers are available that have been anodized or may have an internal coating made from an epoxy, epoxy phenolic, or polyamide resin.

Aluminum containers are produced with a 20-mm opening so as to receive the standard metered 20 mm and non-metered valves. These canisters are used for MDIs and are fitted with a 20 mm metered-dose valve. albuterol made with a CFC will utilize a non-anodized aluminum canister while other MDIs use an anodized canister or one that has been coated internally with an organic liner. A variety of openings ranging from 13 to 20 mm are available for special and customized applications. Aluminum containers are manufactured from a slug of aluminum and are seamless; therefore, there is virtually no danger of leakage. Figure 33-12 shows a typical aluminum container used for MDIs.

**Pharmaceutical valves**

A typical metered-dose aerosol delivery system is illustrated in Figure 33-13. Metering valves fitted with a 20-mm ferrule are used with the above containers for all metered-dose inhalation, nasal aerosols, and oral products.

The metering valve delivers a measured amount of product, and the amount delivered is reproducible not only for each dose delivered from the same package but from package to package.

**Figure 33-12.** Typical aluminum aerosol container, cut-edge type used with an O ring.

**Figure 33-13.** Typical metered-dose aerosol delivery system.

Two basic types of metering valves are available, one for inverted use and the other for upright use. Generally, valves for upright use contain a thin capillary dip tube and are used with solution-type aerosols. On the other hand, suspension or dispersion aerosols use a valve for inverted use that does not contain a dip tube. Figures 33-14 and 33-15 illustrate both types of valves and are typical of those commercially available.

**Figures 33-14.** Metering valve, inverted. (Courtesy of Valois.)

**Figures 33-15.** Twenty-mm metered-dose valve showing the subcomponent parts and metering chamber. It is used in the upright position. (Courtesy of Bespake.)

An integral part of these valves is the metering chamber that directly is responsible for the delivery of the desired amount of therapeutic agent. The size of the chamber can be varied, so that from about 25 to 150 microliters of product can be delivered per actuation. Most of the products commercially available use dosages in the range of 25 to 75 microliters. The chamber is sealed via the metering and stem gasket. In the actuated position, the stem gasket will allow the contents of the metering chamber to be dispensed while the metering gasket will seal off any additional product from entering the chamber. In this manner the chamber always is filled and ready to deliver the desired amount of therapeutic agent.

These valves should retain their prime over fairly long periods of time. However, it is possible for the material in the chamber to return slowly to the main body of product in the event the container is stored upright (for those used in the inverted position). The degree to which this can occur varies with the construction of the valve and the length of time between actuations.

Both types of valves currently are used on commercially available oral inhalation aerosols. During the development stage, the compatibility of the valves should be determined with the exact formulation to be used, to determine the accuracy of the metered-dose in regard to doses delivered from the same container of product and from different containers. Additionally, one should ensure that there is no interaction between the various valve subcomponents and the formulation. If distortion or elongation of some of the plastic subcomponents occurs, this may result in leakage, inaccurate dosage, and/or decomposition of the active ingredients.

There also have been instances in which the therapeutic agent was adsorbed or absorbed onto the various plastic components, and a lower than normal dose of the active ingredient was dispensed. For these reasons, one must not only determine the total weight of product dispensed per dose but also the actual amount of active ingredient in each dose. Some test procedures use the results obtained by taking ten doses of material and determining the average amount present in one dose. When possible and when the analytical procedure permits detection of fairly small amounts of active ingredients present per dose, multiple single-dose assays should be performed. Using the average of ten doses may fail to reveal problems of variations in each of the individual doses dispensed.

### EVALUATION OF MDIS AND TOPICAL PHARMACEUTICALS

Various tests have been devised to ensure the integrity of the aerosol package. These aerosol products are said to be tamper-proof, since they cannot be opened and closed in the usual manner. Because these products are all under pressure, it is very difficult to add any foreign material to the product once the entire package is assembled. This also makes it rather difficult to obtain suitable samples for an analysis. Special sampling procedures and test methods have been developed and are used to determine the suitability of the product.

Topical pharmaceutical aerosols do not present any special problems other than the sampling procedure. The USP includes several tests under the specific monographs for the topical aerosols. These include delivery rate, leak testing, microbial limit test, and assay. While several of these products are dispensed as sprays, no special emphasis or consideration is given to the particle size of the droplets or particles emitted. The spray may be defined as a fine, dry, or wet spray. Of special interest for topical spray products is the concern that some of the smaller particles may be inhaled by the user.

MDIs require a greater amount of testing since the metered valve, oral adapter, and the formulation are collectively responsible for delivering the therapeutically active ingredient to the appropriate site in the respiratory passages. This assumes that the patient will administer the product properly, so that both the dose and depth of penetration of the medication can be ensured. Unfortunately, this is not always done. Both the physician and the pharmacist

have provided a most valuable service to the patient by taking the time to demonstrate the correct use of these inhalers.

Many of the tests required for the evaluation of MDIs are similar to those used for other dosage forms. These include description, identification, and assay of the active ingredient; microbial limits; moisture content; net weight, degradation products and impurities (if any); extractables; and any other tests deemed appropriate for the active ingredient.

Other tests specific for MDIs include the following:

#### Dose uniformity over the entire contents—(MDIS only)

This test is described in the USP/NF and determines the amount of active ingredient delivered through the mouthpiece (oral adapter) per a specified number of actuations (dose taken by patient).

#### Leakage rate

This test is also available in the USP/NF and is used to estimate the weight loss over a one-year period. Since there are several sealing gaskets present in a metered-dose valve, this test determines the integrity of the gaskets, as well as the proper crimping of the valve onto the container.

#### Total number of discharges per container

This is defined as the number of actuations per container and is not less than the label claim.

#### Spray pattern and/or plume geometry

This test evaluates the type of spray pattern emitted for the MDI and relates to the characteristics of the metering valve and oral adapter, as well as to the formulation.

It is beyond the scope of this chapter to discuss these tests in greater detail. The reader is referred to the USP/NF for specifics on each test. However, particle-size distribution is covered in greater detail because of its relationship to deposition of particles of drug in the respiratory system.

### PARTICLE-SIZE DISTRIBUTION

Particle-size distribution is probably one of the most important characteristics of an MDI. To be effective, the particles emitted from the spray must be below 10 micrometers and, in most cases, between 2 and 8 micrometers in diameter. Several methods are available for the determination of the particle-size distribution for MDIs. A common method includes a cascade impactor that depends upon the principle of carrying particles in a stream of air through a series of consecutively smaller jet openings. The heavier and larger-diameter particles are impacted on a slide under the larger opening, and as the openings

**Figure 33-16.** Cascade impactor (Impaq AS-6) used for particle-size distribution of MDIs (left-fitted with a 1000 mL sampling throat; right-fitted with USP throat).

**Figure 33-17.** Log probability plot of data from the cascade impactor (MMD, mass median diameter).

get smaller, the velocity of the stream increases, and the next larger particles are deposited on the next slides. Figure 33-16 illustrates a cascade impactor that can be used to indicate the particle-size distribution of MDIs.

Figure 33-17 and Table 33-8 give a typical analysis of a suspension MDI. Table 33-9 gives a full analysis of the particle size for a solution MDI. Other methods include the use of a microscope or instrumentation based on the use of laser technology. The reader is referred to the USP/NF for a more comprehensive review of this subject.

### Formulation factors

Included among formulation factors are the physicochemical characteristics of the active ingredients, the particle size and shape of the drug, the type and concentration of surface-active agent used, and, to some extent, the vapor pressure and the metered volume of propellants. In terms of physicochemical properties, the lipoidal solubility and pulmonary absorption rates of the active ingredient are of utmost importance. Another physicochemical factor governing the biopharmaceutics of a drug is its dissolution characteristics in pulmonary fluids. Drugs having a rapid dissolution rate in pulmonary fluids predictably produce much more intense and rapid onset of action, having a shorter duration than their less soluble derivatives. Therapeutic agents that exhibit very poor solubility in pulmonary fluids are to be avoided since they are likely to serve as irritants and precipitate bronchial spasms.

The selection of the appropriate surface-active agent (required in most pressurized inhalation suspension aerosols) is another important consideration, since the surfactant will influence droplet evaporation, particle size, and overall hydrophobicity of the particles reaching the respiratory passageways and pulmonary fluids. Solubility of these dispersing agents or surfactants is limited when formulating with an HFC propellant. Ethyl alcohol has been added to increase their solubility.

**Table 33-8. Cumulative Particle Size Distribution**

Slide no.	Particle size ( $\mu\text{m}$ )	Cumulative particle size distribution (percent)
Filter	Less than 0.5	0.55
6	0.5–1	5.35
5	1–2	18.98
4	2–4	61.59
3	4–8	90.2
2	8–16	96.67
1	16–32	100

**Table 33-9. Particle Size Distribution of Solution Type MDI**

Collection unit	Mass found		Cumulative particle size distribution
	$\mu\text{g}$	percent	percent
Valve stem	38.7	1.43	—
Mouthpiece	298.3	11.02	—
Collar	27.6	1.02	—
Induction Port	1057.8	39.07	—
Filter—(0.3 $\mu\text{m}$ )	70.2	5.46	5.46
Stage 6—(0.5 $\mu\text{m}$ )	66.3	5.16	10.61
Stage 5—(1.0 $\mu\text{m}$ )	151.4	11.77	22.39
Stage 4—(2.0 $\mu\text{m}$ )	303.8	23.64	46.02
Stage 3—(4.0 $\mu\text{m}$ )	408.8	31.8	77.83
Stage 2—(8.0 $\mu\text{m}$ )	204.4	15.9	93.73
Stage 1—(16.0 $\mu\text{m}$ )	80.6	6.27	100
Total A	2300.7		
Total B	1285.4		
Total C	2707.8		
Total R	1204.7		

Respirable dose ( $\mu\text{g}$ ) = 120.47

Respirable fraction = 52.36 percent

Mass median aerodynamic diameter (MMAD) ( $\mu\text{m}$ ) = 1.95

Geometric standard deviation (GSD) = 2.81

Mass balance = 99.73 percent

A = Total mass of drug found on the collar, induction port, filter, and stages 1–6.

B = Total mass of drug found on the filter and stages 1–6.

C = Total mass of drug found on the valve stem, mouthpiece, collar induction port, filter, and stage 1–6.

R = Total mass of drug found on stages 2–6 and filter.

The effects of propellant vapor pressure and the metered volume of propellants on drug deposition in the lungs recently have been studied using rather large, specialized, plastic adapters. Findings in this area have demonstrated that the amount of material deposited in the mouth, tube, and actuator (likely sites of material loss) increased as the vapor pressure was decreased and the metered volume increased.

### Component design

Component design, specifically that of the actuator and adapter, also has been shown to alter the particle size and the penetration and deposition of drugs into the lungs. Numerous studies have demonstrated that a complex set of interactions exist between the actuation type, valve dimensions, distance from actuator, and other component variables and that particle size (mass median diameters) could vary up to 40 percent by altering one or more of the aforementioned components.

One component that has undergone enormous modification in the last few years to improve drug delivery is the adapter or mouthpiece. Up to about the mid-1970s, almost all adapters were short and rather simplistic so as to minimize possible holdup of material in the adapter. The holdup in the short-stem adapters averages anywhere from 5 to 20 percent. Recently, however, numerous customized adapters having specific designs and dimensions have entered the marketplace.

Interest in the larger adapters (often referred to as tube spacers) can be attributed to any one or more of the following reasons. The larger adapter designs permit a complete evaporation of propellant, reducing initial droplet velocity and particle size. This reduction of particle size improves depth of drug penetration into the lungs, while a lower initial velocity decreases product impaction to the back of the esophagus (whiplash effect),

an effect common to short-stem adapters. The larger adapter designs also permit a decrease in pressure and increased volume flow that also has been reported to increase penetration of particles into the lungs. It should be pointed out that the larger tube spacers are not without problems. They are inconvenient because of their size, are expensive, and are somewhat difficult to clean. They also present the manufacturer with the problem of assessing product holdup in a rather complex device.

### Administration techniques

The metered-inhalation aerosol dosage form, although popular, generally is considered one of the most complicated to use drug-delivery systems currently marketed by the pharmaceutical industry. It is viewed by many as being only slightly simpler to use than an injectable, since inhalation products often require up to 10 to 15 maneuvers by the patient during use. Failure of the patient to perform any one of these maneuvers correctly may alter significantly the deposition of the drug into the appropriate portion of the lungs.

Differences in the directions for use of each inhalation product are a result of the product formulation and actuator design that the manufacturer deemed most appropriate for the particular product. In light of this, it is not surprising to find patients who require two or more aerosol inhalation products or who are constantly changing their medication (such as the asthmatic patient) occasionally experiencing difficulties in complying with the suggested method of application.

These problems present a unique opportunity for the pharmacist to counsel the patient on the correct use of these inhalers. Several manufacturers will provide placebo inhalers for this purpose. Others will provide videotapes that can be used by the pharmacist and other health professionals to teach the correct use of these inhalers. Brown bag and senior citizen programs, health seminars, and other similar programs can provide a suitable audience for group presentations. However, the most successful programs are conducted on a one-to-one basis in the privacy of the pharmacy.

Many attempts have been made to overcome these problems and increase the efficacy of this dosage form. A breath-activated inhaler has been developed by 3M Pharmaceuticals and is used as an integral part of their pirbuterol acetate inhalation aerosol. They found that in a study of 70 patients, the use of the breath-activated inhaler increased the efficient use of these inhalers from 50 to 91 percent. These patients were given both written and verbal instructions. Reading instructions alone increased the efficiency from 39 to 63 percent. Many other devices, including tube spacers, breath activated, and electronic devices have been under study for numerous years. To date none of these units have become commercially available other than one breath-activated (Maxair Autohaler – 3M) and one spacer (Azmecort In-halation Aerosol – Aventis Pharmaceuticals).

Tube spacers also increase the efficiency of drug delivery via MDIs. These spacers permit atomization of the delivered dose in a confined chamber or bag and eliminate the need for the precise synchronization of actuations and deep breathing with inspiration. Triamcinolone acetonide MDI is available as an MDI and is fitted with a tube spacer instead of the conventional short-stem actuators. Patients must check with their physician before using these spacers, since the particle-size distribution of the drug being dispersed through one of these spacers may be substantially different from those emitted from a short-stem actuator. Certainly, the deposition pattern will change, and the efficiency of the delivered dose reaching the proper pulmonary airways will be increased.

### NEWER DEVELOPMENTS

At present, there is much interest in developing MDIs for a variety of conditions, including asthma, emphysema, diabetes, AIDS, cancer, heart disease, and cystic fibrosis. Many of these

compounds have been developed using biotechnology processes, and their delivery to the respiratory system via an MDI is an extremely challenging undertaking. With the introduction of newer, alternative propellants, the challenge becomes even greater and presents a unique opportunity for the delivery of these compounds. There is very little interest by manufacturers of currently available MDIs formulated with a CFC to convert the existing therapeutic agents to a HFC product. As indicated previously, albuterol and beclomethasone propionate are the only two drug entities available in the United States with a HFC propellant. It is doubtful if any others will ever be converted to a HFC. Manufacturers are currently discovering newer therapeutic agents for development as an MDI, using the environmentally acceptable HFA propellant. Several “second generation steroids” are currently under development and are formulated with a HFA propellant.

The valve and container suppliers are cooperating with the industry to develop much-needed hardware to accommodate this change. At present, there is no specific, scheduled date when manufacturers can no longer use CFCs for their metered-dose inhalers. As long as CFCs remain available, the change-over will continue at the current slow pace.

APPENDIX A 666

The past 40 years have witnessed the emergence, development, and maturation of biotechnology in medicine and pharmaceuticals. Previously rare, or even unattainable, pharmaceuticals can now be produced in useful quantities by harnessing the power of molecular biology. Interestingly, the term *biotechnology* was first coined in 1919 by the Hungarian engineer Károly (Karl) Ereky to describe how products could be produced from raw materials with the aid of living organisms as agriculture began to join forces with industry following World War I.<sup>1</sup> Hence, biotechnology is not a new concept. Humans have been manipulating living organisms over the millennia to solve problems and improve the quality of life. But today, especially in the context of science and health, the term biotechnology is used interchangeably with “genetic engineering.” The concept of DNA manipulation is central to most modern references to biotechnology.

The practical realization of this technology has followed from our ability to now detect, decode, isolate, produce, and characterize the various proteins that coordinate the numerous functions essential to human life and health. Processes that precede or are causative in pathophysiology can not only be identified but also now manipulated in an attempt to restore normal function. This relatively new methodology involves the synergism of discoveries in recombinant DNA methodology, genetic engineering, immunology, genomics, proteomics, and bioinformatics, with advances in automation and data analysis to create a cogent, high-technology industry. Overall, biotechnology has led to the creation of new products for home and industry, improvement of agricultural yields, diagnosis of genetic disorders, and the enhancement of our medical arsenal against disease. The publications in February 2001 of the virtually complete sequence of the human genome<sup>2,3</sup> will certainly accelerate the application of these technologies. While the close of the past millennium has clearly witnessed the benefits resulting from the proliferation of biotechnology-derived products, new questions have arisen regarding issues of ethics and pharmacoeconomics. Nonetheless, it is clear that the benefits of biotechnology already have far outweighed the drawbacks.

### BACKGROUND

As biotechnology-derived pharmaceuticals have become commonplace in healthcare, pharmacy practitioners should have a detailed knowledge of the manufacture and use of these newer agents.<sup>4,5</sup> As a backdrop to understanding modern biotechnology, it will be instructive to review some of the basic biological milestones that precede it. Table 34-1 provides a compilation of milestones in biotechnology, especially for their connections with pharmaceutical sciences. It is clear that technology is proceeding at a rate that is already threatening to bypass our ability to manage the ethical dilemmas presented by these advances. Fortunately, visionaries such as Nobel laureate James Watson have used their positions to encourage the proper and ethical use of

genetic information and technology. As the initial director of the publically funded Human Genome Project, Watson announced 18 years ago a plan to set aside 3% of the project budget devoted to ethical, legal, and social implications (ELSI) research, a decision he recently deemed, “probably the smartest thing I did.”<sup>6</sup>

Nature has for some 3.5 billion years been conducting what we may call natural genetic experiments. These include mutation (random heredity alteration), crossing-over (breakage and exchange of corresponding segments of homologous chromosomes), and recombination at meiosis (fertilization). These processes all have contributed to the current diversity of life on this planet. In addition, it is well known that humans have been manipulating genetic characteristics of different species for over 10,000 years through inbreeding and cross-breeding experiments. To cite a few examples, one can point to the modern robust strains of wheat or corn, which are a far cry from their puny ancestors. Similarly, the varied breeds of dogs, cats, poultry, and cattle may be mentioned. These manipulative efforts continue, and in less than a lifetime, the development of larger and sweeter oranges, seedless watermelons, and flamboyant ornamental plants has occurred. Also familiar are such hybridizations as the tangelo (crossing the tangerine and the grapefruit) and the mule (crossing a donkey and a horse).

All cell structures and functions begin with proteins, and the code for building the proteins is found in deoxyribonucleic acid (DNA). This is why the discovery of the double-helix structure of DNA by Watson and Crick in 1953 fundamentally began the unraveling of the mystery of cell processes. (The 50th anniversary of publication of their model was celebrated in 2003, with some exceptional retrospective documentation published in print and on the Internet by Cold Spring Harbor Laboratory and the journals, *Science* and *Nature*). DNA, the genetic blueprint of an organism, is made up of building blocks known as nucleotides (molecules containing a sugar, nitrogen-containing purine or pyrimidine bases, and a phosphate group) that are connected in a very long ladder-like structure. When this rubber-like twisted-ladder structure is coiled tightly, it is referred to as a two-stranded, or double, helix.

There are four different nucleotides (containing the bases adenine, cytosine, guanine, and thymidine) with a total of about 3 billion nucleotide units in the human genome, tightly packed into chromosomes. These include the genetic code for a large number of genes, originally estimated at 100,000 in the human but downgraded to roughly 25,000 as a result of the Human Genome Project, a surprisingly low number compared with other species. Each of these genes controls the synthesis of a protein made up of a long strand of anywhere from 50 to 3000 amino acids. Nirenberg and Matthei, in 1961, and others later, elucidated how the nucleotide sequence of a gene regulates the particular sequence in which the 20 different amino acids will be united to produce a particular protein. A single codon is made up of units of three adjacent nucleotides; each codon specifies

**Table 34-1. Milestones in Biotechnology. The recent explosion of growth in the development and application of biotechnology may be traced to a number of successive, discrete, milestone discoveries and events.**

Discoveries and Events	Time, Scientists, and Companies
1. X-ray diffraction data and proposed double-helix model for the 3-dimensional structure of DNA	RE Franklin and MH Wilkins; JD Watson and FH Crick, 1953
2. Site-specific recognition and cleavage of DNA by restriction endonucleases	W Arber, 1962; M Meselson and R Yuan, 1968; HO Smith, 1970; D Nathans, 1971
3. Determination of the genetic code	M Nirenberg, S Ochoa, and P Leder, 1966; HG Khorana, 1966
4. Identification of DNA ligase	M Gellert, 1967
5. Identification of RNA-directed DNA polymerase (reverse transcriptase)	HM Temin and S Mizutani, 1970; D Baltimore, 1970
6. DNA cloning techniques	HW Boyer, S Cohen, and P Berg, 1971–1972

25. Simultaneous publication of human genome sequence by Human Genome Project and Celera Genomics	Human Genome Project and Celera Genomics, 2001
26. Approval of the first gene therapy drug worldwide, Adenovirus-based delivery of p53 tumor suppressor	Gendicine, in China, 2003
27. EMEA approval of the first biosimilar drug, Omnitrope (recombinant human growth hormone)	Sandoz, 2006
28. US district court in New York rejected the breast cancer gene patents	US district court in New York, 2010

one amino acid. The arrangement of codons in the DNA, following transcription into messenger RNA (mRNA), determines the sequence of amino acids that will form a particular protein. The detailed understanding of how these genes and their proteins govern basic cellular processes is the underpinning of molecular biology and biotechnology.

Because each of the major organs of the body (brain, liver, blood, tissue, etc.) has a specified set of tasks to perform, certain specific sets of genes in each organ (collection of specialized cells) must be activated and deactivated, that is, turned *on* and *off* as needed. Following the directions laid down by the genetic code of DNA and mediated by mRNA, each cell type continuously produces a unique and characteristic array of proteins. Each cell type maintains a complement of transcriptional

activating and repressing proteins whose actions balance to create the specific gene expression profile of a particular tissue. Moreover, epigenetic processes such as gene methylation and histone acetylation status also contribute to tissue-specific gene expression. Expressed proteins are then secreted into the extracellular milieu, while many are used within the cell itself. The number of possible biosynthetic permutations is very high if one considers that a typical protein can be made up of some 500 amino acids and, further, that every one of these sites may be occupied by any one of 20 different amino acids. It is likely that over the long periods of evolution of each organism, given the vast array of possible combinations of these amino acids, a multitude of unique proteins with all sorts of optimized functions have developed.

The concept that genetic information flows from DNA to RNA to proteins has become a fundamental milestone of modern biology. Thus, with the discovery of reverse transcriptase (from an RNA virus) by Temin and Baltimore, in 1970, which could convert its own genomic RNA into double-stranded RNA, a second milestone was reached. Molecular biology relies heavily on this enzyme to convert mRNA into DNA for gene cloning, library construction, and gene sequencing and detecting. Examples of cellular catalysts, or enzymes, include those that are involved in the digestion of food and others that produce the chemical building blocks of cell life, such as sugars and lipids, hormones for organism regulation, fuel for energy production, and important molecules such as DNA.

Proteins also make up the cell cytoskeleton providing an organized, three-dimensional structure. They permit directed transport and movement of molecules throughout the cell. They are embedded in the outer cell membrane and pump nutrients and ions across the membranes. They serve as receptor sites for hormones that finitely adjust the functions of the cell according to changing bodily needs. Another group of proteins regulates gene activities by binding to DNA and activating or repressing gene transcription. Still other proteins, and their smaller fragments (peptides), are secreted by cells as neurotransmitters or hormones like insulin. Some serve as carrier molecules, like hemoglobin, the body's oxygen carrier.

As is well recognized, these hormones and various related peptide molecules hold enormous power, and because they can act on numerous specific cell surface receptors, they can influence virtually all bodily functions from the nervous system to the immune system. It is obvious that their selectivity, potency, and often-desired evanescent effects on selective target cells make them enormously attractive candidates as a new generation of drugs in the *magic bullet* concept of Paul Ehrlich. Further, when administered parenterally, hormones have the potential to reach target receptors on the surface of cells, without the need to penetrate membranes. Not unlike the normal bodily processes, they can bind to cell surface receptors and activate the cell's particular function. An example of one such approach is seen with the anticancer drug interferon  $\alpha$ , which can stimulate some immune cells to attempt to overcome cancerous cell growth.

The body's specific defense response to invading organisms is due to the immune system. Normally, phagocytes called to a site of inflammation induced by pathogens mount a generalized attack response. Indiscriminately, they engulf cellular debris as well as anything recognized as foreign. Occasionally, however, this is not enough, and illness ensues. At this point, several more focused counterattacks proceed by the three types of white blood cells known as macrophages, T lymphocytes, and B lymphocytes. The key features of the immune system are specificity (the ability to focus on specific pathogens) and memory (the ability to recognize and respond rapidly to previously encountered infections). About 1% of the blood cells are white blood cells. The ones that are central to the immune responses are the following:

**B Cells**—Lymphocytes that produce antibodies (antibody-mediated immune response).

**Macrophages**—Phagocytic cells that alert helper T cells to the presence of pathogens.

**Helper T Cells**—*Master switches* of the immune system that stimulate the rapid division of both killer T cells and B cells.

**Suppressor T Cells**—Lymphocytes with regulatory functions; i.e., they slow down or prevent immune responses.

**Killer T Cells and Natural Killer (NK) Cells**—Lymphocytes that directly destroy body cells that already have been infected by pathogens (or cancer cells).

**Memory Cells**—A group of the T cell and B cell population that was produced during the primary encounter with a pathogen but was not used in the battle. These circulate through the body ready to respond rapidly to later attacks by the same organisms.

As a further refinement in the understanding of the immune system, several key weapons are involved in the process. These include the antibodies, which are circulating freely or membrane-bound receptor molecules that bind specific foreign invaders and thereby tag them for destruction by the complement system or phagocytes. There are the perforin proteins, which are secreted by certain T cells and kill their cellular targets by punching holes in them. Finally, there are the lymphokines and interleukins, which are secretions by which white blood cells communicate with each other. Thus, the immune system has two fighting branches with specificity, and often both are employed against infections and antigens in general. The T cells dominate one part of the system, and when they are activated, it is referred to as a *cell-mediated* response. The B cells dominate the other branch, and events associated with their activation are referred to as *antibody-mediated* response.

Before the broad application of whole genome sequencing, expressed sequence tags (ESTs) of complementary DNA provided shortcuts to uncover a large number of new genes. Similarly, *light-houses* have been developed along the chromosomes to guide the way for sequencing dim restriction maps. DNA research, using the polymerase chain reaction (PCR), has become a powerful tool in forensic and research applications. Based on the principle of PCR, real-time polymerase chain reaction (RT-PCR) or quantitative real time polymerase chain reaction (Q-PCR) has been developed and applied as another powerful technology to detect or quantify one or multiple gene targets precisely and simultaneously. Non-specific fluorescent dyes or sequence-specific DNA probes can be used as indicators. In the clinic, RT-PCR provides rapid and accurate diagnoses.<sup>7</sup>

New publications have described how modern metabolic engineering has brought intermediary metabolism back to life through techniques involving enhancing copies of a gene at a rate-controlling point, adding a gene to remove a poisonous product, or adding several genes to introduce a new pathway into an organism that stops short of the desired product. This metabolic engineering has had numerous practical results in addition to helping develop new theories. DNA technology has been applied to metabolic pathways so that branch point control problems can be solved. Even the insertion of similar enzymes from different species into the studied organism has introduced new flexibility and better metabolic characteristics into the older organism.

This issue also covered the recent developments of the vaccinia virus, so that it now can serve as a molecular vehicle for carrying foreign genes into other organisms. As a means for research, this recombinant vaccinia vector has served as a vehicle for producing live vaccines that would otherwise be difficult to produce. Monoclonal antibodies have also been used successfully in diagnosis and therapy. The monoclonal antibody OKT3 (Reversal of acute kidney transplant rejection, *Ortho Biotech 1986*), the first monoclonal antibody drug for humans, was approved by the FDA in 1986 for treatment of acute renal allograft rejection. Antibody power has been enhanced by attachment of a biological toxin such as ricin, a cytotoxin such as calicheamycin, or a radioisotope such as an alpha emitter. The latter can be used to damage tissue adjacent to that with which the antibody interacts. These are all good examples of combined basic research followed by rapid practical application.

## BIOTECHNOLOGY DRUGS

In terms of drug therapy, the body's ability to remember and identify previous infections already has been exploited through the vaccination technique. This relatively simple procedure involves injecting the person with a weakened or killed pathogen that induces an effective immune response without causing the disease. The procedure gives a lasting immunity through the formation of the memory cells mentioned above. Continued advantage of these natural phenomena (normal immunization through infection) is being taken through the application

of molecular biology and biotechnology. Among the recent and significant developments are the vaccines using genetically engineered pathogen components as antigen to stimulate the body to produce antibodies against the pathogen. For example, Recombivax HB (*Merck*), a hepatitis B vaccine, uses a non-infectious hepatitis B surface antigen (HBsAg)-derived protein fragment produced in yeast cells as the antigen. Figure 34.1 shows the production of a genetically engineered vaccine.

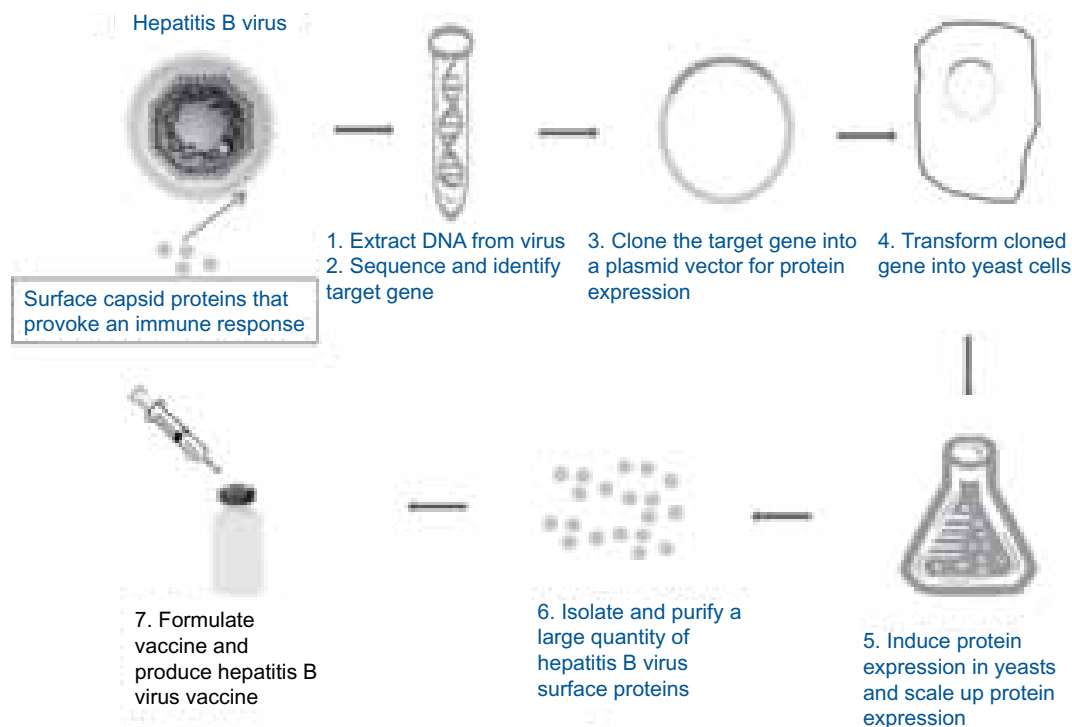

As of 2008, 633 biotechnology medicines were in development for more than 100 diseases, mainly for cancer, infectious diseases, autoimmune diseases, and HIV/AIDS related conditions.<sup>8</sup> In 2010, there were just over 200 biopharmaceutical products on the market.<sup>9</sup> The biopharmaceutical industry represents a fast growing portion of pharmaceutical market. In 2009, the total biological sale reached \$99 billion, including \$38 billion antibody-based drugs and \$61 billion other recombinant therapeutic proteins. The accelerated rise of biological generic drugs (biosimilars) is going to account for a large proportion of biological drugs and decrease the cost of healthcare in the current decade.

In the mid-1990s, the fastest growing category of biotechnology products had been gene therapy; however, the death of an 18-year-old Phase I gene therapy trial participant, Jesse Gelsinger, in 1998 led to a sober reassessment of strategies, precautions, and controls in such trials.<sup>10</sup> The currently fastest growing segments are monoclonal antibodies and vaccines. Vaccine targets are infectious diseases, cancer, AIDS, and autoimmune diseases (rheumatoid arthritis and multiple sclerosis). Monoclonal antibodies have also been instrumental in treating various forms of cancer and autoimmune disorders. Product candidates that are nearly approved also are increasing. By the end of 2010, 41 antibody-based therapeutics had been approved in the USA and Europe.<sup>9</sup> Novel monoclonal antibodies have been entering clinical at a rate of approximately 40 per year since 2007.

All of these agents have been made possible through the biotechnology techniques that allow the isolation, identification, and production of normally minimal amounts of proteinaceous *signal agents* found in the extracellular fluids of the body. Once

the composition and sequence of amino acids is determined for a protein, that protein can be reproduced in the laboratory. Even better, the gene sequence of the protein now can be analyzed readily, the protein sequenced, synthesized, and cloned, allowing another organism to use that part of the code that determines the protein. This has been made possible through the discovery and use by HO Smith of restriction enzymes, which make specific reproducible cuts along DNA strands. Frederick Sanger and co-workers devised procedures for quickly determining the nucleotide sequence of DNA fragments. This allowed the identification of the DNA sequence of complete genes. Now, fully automated and high-throughput sequencing instruments in conjunction with novel sequencing, detection, and analysis methodologies make it possible to sequence the human genome in a short time at low cost.<sup>11</sup> It will open a new avenue for personalized medicine. Also, the discovery of reverse transcriptase by Temin and co-workers became important in biotechnology because it allowed the mass production of genes from mRNA, which led to increased production of a desired protein. Through these procedures it became possible to determine the amino acid sequence of entire proteins via inference of the genetic code.

The 1972–1973 landmark experiments of Stanley Cohen, Herbert Boyer, and Paul Berg applied this technology to produce recombinant plasmid DNA molecules for propagation in *E. coli* and are recognized as the first creation of a genetically engineered organism capable of producing proteins from another species. This hybrid plasmid now could be grown in the common and rapidly producing bacterium, *E. coli*. A plasmid is a circular DNA molecule that carries a few genes that the bacterium perpetuates and is replicated in addition to its own normal chromosomes. More than any other technique, this really heralded the birth of hybrid DNA technology (hybrid DNA is produced by joining pieces of DNA from different sources, and is also designated rDNA technology). This permitted, for the first time, rapid isolation of unique proteins and their mass production by rapidly growing microorganisms. In addition, new organisms having specifically inserted and desired characteristics could be engineered for medical, agricultural, and ecological uses.

**Figure 34-1.** Making a genetically engineered vaccine.

Another important aspect of recombinant DNA technology is the use of antibodies in biotechnology, therapy, and diagnosis. Antibodies are produced by plasma cells (B cells) and are made up of four protein chains interconnected by disulfide bonds. The surface of the antibody possesses a highly specific indentation, or *lock* that can recognize the specific foreign particle (*key*) with which it complexes or binds. It long has been known that different antibodies are produced in each individual for their particular immunological experience with antigens. Hence, perhaps millions of different antibodies may be found in any given individual. For a long time it was not known how the B cells were capable of producing this diversity of antibodies that possessed the ability to recognize almost every possible foreign invader. It also was not known whether each B cell secreted a single or many different antibodies.

Fortunately, through the early *clone selection* theory of MacFarlane Burnet in 1957 came the idea that one cell produces only one type of antibody. And in 1975 Georges Kohler and César Milstein devised a method of growing very large numbers of antibody-producing cells from a single B cell. They did this by the ingenious technique of fusing the B cell to a myeloma cancer cell. The resulting *hybridoma* retained two main features from its two parent cells. It could grow indefinitely like the cancer cell yet also produce and secrete antibodies like the B cell. This was the main discovery leading to hybridoma technology and earned Kohler and Milstein (together with Niels Jerne) the 1984 Nobel Prize in Physiology or Medicine.

The antibodies produced by these hybridomas are called monoclonal antibodies (MAbs) because they are derived from a single hybrid cell. Using the ability to identify directly the genes that code for antibodies, it was found that the antibodies are put together from a large number of different gene fragments. When combined in different ways, they can produce a large number of different antibodies. Those portions of the antibody that contain the antigen-binding site are coded by a combination of hundreds of different gene fragments that get reshuffled and permanently fixed in the B cells. Hence, it has become possible to produce MAbs as key reagents in biotechnology procedures as well as exquisite diagnostic tools and specific drugs of great selectivity. Figure 34.2 shows the basic procedures involved in hybridoma technology.

Antibodies are routinely used in biomedical research for affinity protein purification, diagnosis, drug targeting and delivery, and imaging analysis.<sup>12</sup> In addition, hundreds of antibody drugs are under development for the treatment of various diseases.<sup>13</sup> Muromonab (OKT3) is the first FDA approved monoclonal antibody drug. It is a murine monoclonal antibody against T-lymphocyte CD3 for the reversal of acute kidney transplant rejection. However, using murine antibody in human is associated with the development of human anti-mouse antibody, weak immune response recruitment, and short serum half-life. Genetic and protein engineering methods have been applied to convert murine antibodies into human-like antibodies. Chimeric antibodies are the fusions of murine variable domains (Fv) with human constant domains (Fc). The variable domains of chimeric antibodies can be further modified to adopt human antibody-preferred residues and sequences to create humanized antibodies to minimize immune response and maintain the maximum antigen-binding ability. Furthermore, genetically altered mouse has been used to produce human B cell to create fully human antibodies. In addition, high-throughput peptide display libraries, such as phage display, yeast display, and ribosome display, have been applied to screen Fv domains and construct human monoclonal antibodies.

The phage display approach, described in detail by Rader and Barbas,<sup>14</sup> employs the selectable expression of recombinant antibody molecules on the surface of bacteriophage particles. Generally, random peptide sequences encoding human antibody variable heavy- and light-chain fragments are integrated at a designated position of a surface protein possessed by cells, viruses, or phages through a genetic linkage to the encoding

Figure 34-2. Hybridoma production.

nucleic acid. Once antigen-binding cells, viruses, or phages (*in vitro* as well as *in vivo*) have been isolated through a selection process (biopanning), the sequence of this peptide can be derived. The cells to display peptides can be mammalian, yeast, and bacterial cells. The phages can be M13, T7, and P4 phages. Recently, other display technologies, such as ribosome display, mRNA display, and DNA display (all need to establish physical linkage between the displayed peptide and the encoding RNA/DNA through a chemical or protein modification), have been developed to select high binding affinity antibody Fv domain. The screened domain can be fused with human antibody Fc domain through genetic engineering to create human antibody. Then the antibody gene will be integrated into mammalian cells such as Chinese hamster ovary (CHO) cells to produce antibodies.<sup>12</sup>

Unlike vaccination that uses the selected antigens to stimulate the human immune system to generate antibodies for the purpose of prevention or treatment, antibody therapy uses *in vitro* isolated and purified antibodies as drugs. Inside the human body, antibody can recognize and neutralize its target, or acts as a ligand to either activate or inhibit a cellular receptor. In addition, antibody can also accomplish its therapeutic effects through complement-dependent cytotoxicity (CDC), antibody-dependent cellular phagocytosis (ADCP), and antibody-dependent cellular toxicity (ADCC). Antibody is a glycoprotein. Glycosylation of the Fc portion of IgG is essential for antibody activity as well as immune response. The risk of immune reactions to antibodies is the main safety concern for antibody therapy. The high cost of treatment is obviously another limitation for this kind of therapeutic.<sup>13-15</sup> For example, it costs \$50,000–\$100,000 for one year Herceptin (Trastuzumab for HER2 positive breast cancer) treatment.<sup>13-15</sup>

It already has become possible to tag monoclonal antibodies with radioisotopes that make possible the detection of very small levels of proteins and peptides in body fluids and tissues.

The limits of detection are often as low as one billionth of a milligram (picogram) in the procedure widely used and known as radioimmunoassay (RIA). This is sufficient to detect low levels of hormones and other protein substances in body fluids. Antibodies can also be conjugated with toxins, cytokines, or enzymes to deliver drugs or prodrugs to the targeted cells. Although these approaches have been proposed and tested for a couple of decades, Mylotarg (anti-CD33 antibody gemtuzumab conjugated with ozogamicin, for acute myeloid leukemia, *Wyeth, 2000*), the only antibody-drug conjugate on the market, was withdrawn in 2010 due to severe side effects.<sup>16</sup>

Another exciting area of biotechnology is that of gene diagnostics and therapy. It is believed that there are as many as 4000 locations in the human genome that are related to different genetic diseases. Of this number some 1200 have been mapped and characterized to various degrees of detail. Some of the abnormalities found on the genes are called point mutations, and they involve cases where a single nucleic acid base in a gene is substituted by a different one. This irregularity results in the exchange of a single amino acid in the encoded protein. Too many changes may result in genetic disorders. For example, in the genes encoding the hemoglobin protein sequences, at least 40 point mutations have been located. Sick-cell anemia is related to one of these. It is hoped that detailed knowledge of this type at the molecular level will allow the development of agents that can prevent the typical alteration in the shape of blood cells in sickle-cell anemia. Molecular probing or screening at this level also will reveal such disorders prenatally, or early in life, so that appropriate remedial action or preventative measures can be instituted (viz.,

gene therapy). Figure 34.3 shows how genetic defects may be detected.

Pharmacogenomics is another research area that has sprung from pharmacokinetics to examine the key genes or mutations among a subset of the population that confer relative resistance or hypersensitivity to certain drugs. In the pharmacogenomic context, these mutations are more commonly referred to as polymorphisms and are often observed in genes encoding drug metabolizing enzymes, transporters, receptors, or other drug targets. These variations in DNA sequence are often single-nucleotide polymorphisms (SNPs) and can occur in either the coding region of a gene, causing an amino acid change, or in the regulatory region of a gene, thereby causing an alteration in the absolute amount of protein produced. For example, a patient with a polymorphism in one or both copies of a gene encoding a drug-inactivating enzyme would be at risk for exaggerated pharmacological action and potential toxicity for that drug. These pharmacogenetic differences are likely at the heart of most of the heterogeneity of drug responses observed among large populations and have significant impact on the ordinary practice of medicine and in clinical trials. Specific examples of known polymorphisms and the altered effects they confer are delineated in an excellent review article<sup>17</sup> from a premier PharmD pharmacogenomics expert.

Advances in DNA technology also have made this procedure more rapid, particularly when looking for any one of many individual mutations within a single gene that can give rise to disease. This technology, called high-density DNA affinity arrays,<sup>18</sup> or microarrays, is becoming more widespread and financially accessible to even small research institutions. Individual DNA

Sometimes 'misspellings' occurs in the genetic code and errors creep into the chemical sequence. Such defects can be inherited or caused by chemical change, and give rise to disease. Prenatal screening can find faulty genes and identify individuals likely to contract specific ailments

The genetic dysfunction of the fetal DNA can be identified by single nucleotide polymorphism (SNP), DNA microarray, or whole genome DNA sequence

Figure 34-3. Searching for genetic defects.

targets that each contain one of these mutations are adsorbed onto a glass substrate in an array pattern and then hybridized with a fluorescently labeled probe generated from the gene expressed in the individual being tested. Another adaptation of this technology is to investigate the relative expression level of genes implicated in various disease processes. Some diseases are not due to gene mutations but rather to abnormal over- or underproduction of certain regulatory proteins. DNA arrays permit the screening of literally thousands of genes in a single experiment by comparing genes expressed in normal versus diseased individuals. In fact, the expressed mRNAs from the entire human genome can now be screened on two commercially available "chips" and the race is on for the first manufacturer to put the entire expressed human genome on a single chip. Availability of such technology is expected to allow early diagnosis of many diseases that are due to multiple genetic abnormalities, such as cancer. In one specific case of diffuse B-cell lymphoma patients, microarrays have been used to sub-classify the disease to understand which patients will respond best to chemotherapy.<sup>19</sup> In this manner, patients at greatest risk can be given the most aggressive therapy, while those at lower risk can be spared unnecessary toxicity. Microarrays of gene expression can also be applied in drug discovery; a recent application of this technology has been used to predict the general therapeutic classes into which psychotropic medications fall.<sup>20</sup>

One drawback to microarrays in diagnosis and drug treatment is that gene expression is not always predictive of the amount of protein produced. Moreover, it completely ignores post-translational modification of proteins that can vastly influence biological responses. With advances in mass spectrometry instrumentation, the field of proteomics has emerged as the next means to secure a snapshot of cellular activities and correlate the pattern with specific drug responses or disease processes. Researchers at the US Food and Drug Administration and the National Institutes of Health have recently shown the power of proteomics in early detection of ovarian cancer using simple blood samples.<sup>21</sup> It was demonstrated that cancerous alterations in organ function cause an altered profile of proteins in serum, allowing this disease to be caught long before patients are symptomatic and with a high degree of accuracy, thereby minimizing the false-positive rate associated with many clinical diagnostic tests. The pharmacy practitioner is wisely advised to keep abreast of developments in proteomic technologies as these advances are quite likely to influence other therapeutic areas with equal magnitude.

As the ability to determine genetic defects that cause a variety of disorders emerges, healthcare will improve. However, society must develop policies governing the use and misuse of this information. Baum has reviewed this problem and provides information on some of genetic screening's serious implications. For instance, in the case of DNA fingerprinting, some observers have questioned the reliability of such an analysis carried out on such a large scale. However, it has yet to be shown to fail definitively when carried out properly. Results may affect civil liberties, insurability, guilt or innocence, etc. The 1996 Health Insurance Portability and Accountability Act (HIPAA) prohibits group health insurance providers from using genetic information for determining eligibility or setting premiums but provides no protection for the millions of Americans with individual insurance policies.<sup>22</sup>

As the technique known as restriction fragment length polymorphism (RFLP) analysis develops,<sup>2</sup> it provides markers throughout the genome that vary among individuals. The identification of particular RFLPs that are tightly associated with genes responsible for certain diseases has become possible. Thus, RFLPs provide markers that identify the chromosome that carries the defective gene. But the presence or absence of the marker does not necessarily indicate disease. RFLP analysis must be performed on both parents or two or more grandparents to determine the status of a disorder. Furthermore it is an expensive and complex analysis.

In the mid-1990s, public attention was raised to the applications of genetic polymorphisms for forensic purposes in criminal

investigations. However, RFLP analysis has considerable drawbacks for this purpose. The need for relatively large amounts of non-degraded DNA and the time necessary for multiple allelic comparisons led to a search for other methods of individual genotyping. The most popular recent technology analyzes inter-individual differences in the variable number of tandem repeats (VTNRs), or *DNA fingerprinting*, as it is known to the lay public.<sup>14</sup> A similar name for the same method is amplified fragment length polymorphisms (AMPFLPs). We each possess in our genome a variable number of repeated DNA sequences that, when measured in combination, provide a unique *fingerprint* of our DNA. These repeated sequences are referred to as minisatellites or microsatellites, depending on their size, and are often made up of repeated sequences of 2 to 70 base-pair-length monomeric sequences. Since the location of many of these polymorphisms is known, the polymerase chain reaction (PCR) can be used to amplify these repeated sequences from even the extremely small amounts of blood, tissue, or semen found at crime scenes. Depending on the number of satellite sequences analyzed, the individual source of the DNA can be identified with near absolute certainty. So useful is this technique that it was employed in 1994 to positively identify the remains of the Romanovs, using mitochondrial DNA isolated from the bones of the Russian royal family who were murdered by the Bolsheviks in 1918.<sup>23</sup>

The major diseases of mankind owe much of their origin to heredity, so that it will be exciting in the decades to come to see how molecular biotechnological techniques will allow for early detection, prevention, or even possible cures for many of the maladies of old age such as cardiovascular disease, Alzheimer's disease, diabetes, and cancer. These approaches also are allowing us to understand previous unrecognized causes of diseases. For many years, it has been known that many human leukemias could be diagnosed microscopically on the basis of specific translocations, or rearrangements, of the chromosomes. Today, the abnormal proteins made as a result of these translocations can be identified. Look<sup>24</sup> provides a striking review on the function of these aberrant proteins in leukemogenesis. While many of these proteins lead to uncontrolled growth of leukemia cells, some have been shown to cause leukemia by inhibiting the normal cell death that usually occurs in white blood cell populations. This had led to our reclassification of cancer as a disease not necessarily of abnormal cell division but instead, in some cases, of loss of appropriate cell death. Other articles in the same 1997 issue of *Science* deal with more frontiers in cancer research, showing that molecular biology also has led to our understanding of how cancer can be prevented.

It is hoped that continued approaches based on reverse genetics will be fruitful. So far, these methods have allowed researchers to produce a compilation of the exact locations and even the molecular arrangements of several defective genes that are felt to be responsible for Huntington's disease, retinoblastoma, Duchenne's muscular dystrophy, and polycystic kidney disease, among others. From these studies will come specific and reliable tests for the abnormal genes that will allow genetic counselors to make appropriate recommendations for action. Further in the future will come the new therapeutic models and molecules that eventually will translate into clinically effective drugs.

So far, at least two basic approaches in *genetic medicine* can be envisioned. One involves possibly compensating the defective protein by producing it biotechnologically outside the body (e.g., Humulin (diabetes mellitus, *Lilly*, 1982) is the first FDA approved recombinant human insulin produced in *E. coli*).<sup>25</sup> The same can be done with replacing defective or missing enzymes or altering one that should not be produced. The other basic approach is much more complicated and involves compensating or replacing the defective gene. In the case of gene modification that involves germ-line cells (sperm and eggs), it is called germ line gene therapy. Once a gene is introduced stably into the germ line, every cell of the individual will bear this gene. Presently, this type of therapy poses enormous unresolved ethical and scientific questions

and is restricted. If the therapeutic genes are transferred into the somatic cells (specific body organ cells), it is called somatic gene therapy. Dependent on the type of delivery vectors, such as integrated or non-integrated vector, the gene expression can be transient or permanent. However, the transferred genes cannot be inherited and stay with the treated individual. One of the ways to transfer genes into the targeted cells would be to use genetically altered and *harmless* viruses to insert a corrected gene into the human genome. It can be referred to as viral gene therapy. On the other hand, lipid, polymer, protein, and gold particles have been applied for gene delivery. These approaches are described as non-viral gene therapy. Unfortunately, in most cases, it is not yet understood how the inserted gene will be expressed in these tissues, only where and when they are needed. Some ways to circumvent these difficulties have been found, but they are limited. For example, one way to produce tissue specificity is to take out the tissues to be altered, insert the corrected gene, and place the corrected cells back into the body (*ex vivo* gene therapy). Alternatively, tissue-specific genetic control elements, such as transcription factors, have been identified and can be used to restrict expression of the recombinant gene in the targeted cells.

So far, bone marrow cells can be handled in this manner, and they have been the first somatic cell type submitted to clinical testing of this gene-transfer technique. In one example, the goal is the treatment of an inborn disease affecting bone marrow function and involving an enzyme (adenosine deaminase, ADA) deficiency that produces severe weakening of the immune system. In 1990, 4-year-old Ashanthi DeSilva became the first patient to undergo successful gene therapy using retrovirus to insert a healthy ADA gene into white blood cells. However, due to the random integration of retroviral vectors and alteration of oncogenes, four of ten patients receiving the similar therapy in clinical trials developed leukemia in 2007. In 2003, China's (State Food and Drug Administration (SFDA) approved Gendicine, the first gene therapy drug worldwide. It is an adenovirus-based DNA vector designed to deliver cancer suppressor gene p53 for the treatment of head and neck cancer. So far, no gene therapy has been approved by FDA and EMEA. Overall, gene delivery is still the major obstacle to gene therapy.

One of the goals in biochemistry and pharmacology is to understand the molecular features of cell receptors. These are the *locks* into which the *keys* (drugs) fit that alter or control the function of the cell. While now there exists the capability to determine the basic genetic code and thus learn the sequence of the amino acids that make up the protein, its spatial configuration still is not known. This is called the tertiary structure of the protein, the functional form of the protein after the proper folding of a simple straight-chain of amino acids.

The novel combination of x-ray crystallography, molecular mechanics, calculations, and supercomputers are brought to bear to reveal the folded or three-dimensional arrangement. From this 3-D picture of the *lock*, researchers can design specifically shaped drugs that fit the active sites of the folded protein. This computational chemistry methodology is a leap forward and truly a rational approach in drug design. In like manner, the possibility of cloning *receptor sites* of specific design and function provides the pharmacologist with excellent *in vitro* test systems for pharmacological screening and understanding of the mechanisms of actions of drugs.<sup>26</sup> For example, the solution of the x-ray crystal structure of the HIV protease has led to the rapid development of four FDA-approved drugs that have revolutionized our treatment of AIDS. Saquinavir (*Hoffmann-La Roche, 1995*) is the first FDA approved HIV protease inhibitor. Another example of successful rational drug design is Gleevec (imatinib, *Novartis, 2001*), which inhibits the tyrosine kinase domain of the gene product (BCR-ABL) of a fusion gene of *abl* (Abelson kinase) with *bcr* (breakpoint cluster region) associated with chronic myelogenous leukemia (CML).<sup>27</sup>

In the past few years, several publications have dealt specifically with the pharmacist's role in implementing pharmaceutical care with regard to biotechnology agents. Tami and Evens<sup>28</sup>

recently presented an overview on the evaluation of biotechnology products. The authors first discuss the manufacturing, pharmacokinetics, and stability issues that we present in greater detail below. They specifically made the point that biotechnology product costs often can account for 10% of a pharmacy's total budget. In addition, they discuss pharmacoeconomic studies, availability of alternative agents, concomitant drug costs, special pharmacy procedures, reimbursement, and manufacturer's support. Pharmacists are a particularly important link in assisting patients with reimbursement issues for these expensive drugs.

## UNIQUE PHARMACEUTICAL CHALLENGES OF BIOTECHNOLOGY-DERIVED THERAPEUTICS

The transition of biotechnology from theory to pharmaceutical practicality has posed a whole new series of challenges to those involved in drug development. With classical small molecules possessing formula weights of less than 1000, a series of chemical compounds normally are screened for a particular pharmacological activity and assessed for specificity. The results of these findings then guide fine-tuning of the chemical entity. As advances in combinatorial chemistry are now generating thousands of compounds in a given class, the rate-limiting step in drug development has shifted to high-throughput screening technologies. Natural products are also regaining prominence in drug discovery because they often possess greater molecular diversity than can be obtained with combinatorial compound libraries. It is now rare that pharmaceutical formulation and drug delivery problems limit the success of small molecules.

In contrast, macromolecular agents (e.g., recombinant proteins and vaccines, antisense DNA, gene therapy constructs) already have the advantage, in theory, of possessing inherent selectivity for a particular biological process.<sup>25</sup> By and large, the limitation to the utility of these agents rests with problems related to drug delivery and stability. In fact, it is no surprise that most biotechnology drugs currently approved in the US act at extracellular sites and/or in compartments that are easily accessible, such as the blood-forming elements. In addition, each type of biotechnology agent also is subjected to unique considerations based on our emerging biological understanding of each system. The discussion that follows attempts to address the obstacles to successful therapeutic use of biotechnology products.

Recombinant proteins almost exclusively constitute the currently approved list of biotechnology-derived agents in the US. These proteins usually have resulted from a search for endogenous agents acting by a newly identified physiological mechanism (such as the stimulation of red blood cell production by erythropoietin manufactured in the kidney). Since the therapeutic administration of a recombinant molecule that mimics an endogenous protein carries with it a naturally inherent specificity, it is no surprise that development times for these agents have been considerably shorter than for most conventional small molecules. The probability of regulatory success with recombinant proteins also has been more favorable.<sup>29</sup> While a new, small, organic molecule may have a 10% chance of achieving NDA status, this percentage is near 40% for recombinant proteins. When compared with conventional small molecules, recombinant products reaching the clinical trials in Phase I (25% versus 71%) or Phase III (66% versus 93%) are much more likely to become successful therapeutic agents. Nonetheless, Cho and Juliano<sup>30</sup> state, "The main challenge encountered in development is not so much identifying a bioactive molecule but, rather, how to maintain a therapeutically meaningful concentration of the macromolecule in the vicinity of its target for the desired period of time."

Recombinant protein drugs are produced in various host cells from carefully designed expression systems. For monoclonal antibodies, production is enabled by the genetically engineered mammalian expression systems using Chinese hamster ovary

(CHO) or murine lymphoid cell lines (e.g., NS0, Sp2/0-Ag14).<sup>12</sup> For the bulk of the other recombinant protein drugs, the exploitation of any one of these protein factories begins in a similar fashion. As addressed earlier in the section on gene splicing, the complementary DNA encoding a particular protein product is sub-cloned into a DNA vector. This recombinant vector contains gene regulatory sequences that enable highly efficient transcription and translation of the recombinant gene once the construct is introduced into the appropriate host.

The choice of host system (bacteria, yeast, or mammalian cells) depends highly on the biological requirements of the protein. One major consideration is whether the protein product requires glycosylation, the specific addition of certain sugars, for biological activity.<sup>20</sup> Bacteria like *E. coli* are unable to conjugate such carbohydrates onto recombinant proteins, but yeast possesses a limited ability for glycosylation. However, mammalian cell systems such as CHO cells have the full complement of glycosyltransferase enzymes. For molecules such as the interferons and filgrastim (G-CSF), glycosylation is not necessary for biological activity; therefore these proteins can be produced in less expensive *E. coli* systems. However, erythropoietin requires mammalian glycosylation and must be produced in the more costly CHO cell system. Hamilton and colleagues<sup>31</sup> have recently reported the heroic engineering of the yeast *Pichia pastoris* to encode the entire complement of human N-glycosylation enzymes while deleting the yeast's own glycosylation pathways. Such an organism might represent a more cost-effective host for future manufacture of human therapeutic proteins requiring glycosylation.

These modern protein expression systems have several advantages over trying to isolate the corresponding protein from the organs or tissues of other mammals. First, immune reactivity to a nonhuman protein (human insulin versus porcine insulin) is largely obviated (with exceptions described later). Also, protein drugs can be produced that could never be made by conventional methods (interferons, Granulocyte-Colony Stimulating Factor (G-CSF)) or in quantities previously only available in limited amounts (insulin, growth hormone). Finally, the protein is inherently free of potentially pathogenic human viruses (factor VIII or hepatitis vaccines), although treatments to destroy any zoonotic pathogens are often employed in subsequent processing.

As the biotechnology drug sector has matured, manufacturers have begun to follow conventional small-molecule pharmaceuticals in the production of second-generation agents with improved bioavailability, retention, and/or safety. While the cynic might argue that these innovations are merely spurred by pending patent expiration of first-in-class agents, it seems that most second-generation biotech drugs represent true advances. For example, the treatment of anemia due to kidney disease or cancer chemotherapy has been improved by increasing the bioavailability of erythropoietin (EPO) (e.g., Epogen, anemia, Amgen, 1989) in the second-generation drug, darbepoietin (e.g., Aranesp, long-acting rEPO, Amgen, 2001). Recognizing that N-linked oligosaccharides are essential to the activity of EPO, scientists altered two amino acid residues to accept two additional sialic acid chains. The resulting darbepoietin molecule possesses a three-fold improvement in serum half-life (26.3 h relative to 8.5 h for erythropoietin). This alteration reduces the number of injections necessary for patients to maintain therapeutic hemoglobin levels. While regimens vary by patient and indication, the general rule has been that if a patient had been stabilized previously with three EPO injections per week, only one weekly injection of darbepoietin is now required. From the standpoint of patient quality of life and burden on pharmacy and nursing staff, less frequent dosing has a number of significant advantages.

While scale-up of recombinant protein expression and purification is becoming more routine, these drugs present other challenges not seen with small molecule agents. Issues of proper protein folding, formulation, and stability are proving

as labor-intensive as the initial cloning of the gene itself. Beta-seron (human recombinant interferon 1b, multiple sclerosis, Bayer, 1995) required modification of one amino acid to enhance the yield of properly disulfide-linked protein after refolding processing.<sup>20</sup> This processing modification reflects another advantage of recombinant protein expression that can be employed quite easily, so long as the pharmacological activity of the protein is not compromised. In fact, optimizing the cDNA sequence (and the resulting encoded amino acids) of a recombinant product has resulted recently in the approval of consensus interferon, a single molecule that incorporates the combined activities of multiple interferons.

Manipulation of the expressed gene also can involve the deletion of regions dispensable for biological activity in order to optimize therapeutic utility. Human tissue plasminogen activator (tPA) has been used since 1987 for thrombolytic therapy following myocardial infarction. However, tPA is poorly soluble and must be administered in relatively high concentrations because it is cleared rather rapidly from plasma. Structure-function analysis of individual tPA protein domains allowed the construction of a smaller molecule (reteplase or recombinant plasminogen activator, rPA) that possesses superior solubility and also can be manufactured in *E. coli* (e.g., Rapilysin, acute myocardial infarction, Roche, 1996).

The effects of changes in protein formulation or amino acid substitutions can now be assessed rapidly as a result of advances in protein analytical methodology. Protein secondary structure can be monitored quickly and accurately by such techniques as circular dichroism (CD) spectroscopy and Fourier-transformed infrared spectroscopy (FTIR). This technology has been quite useful in that the structural fidelity of the protein drug can be ensured prior to the initiation of more costly pharmacological evaluation. FTIR also has the advantage of being able to detect protein structure in the lyophilized state, greatly facilitating the optimization of formulations capable of maximal stability.

Pharmacokinetic evaluation of recombinant proteins is also an emerging field of significant relevance to pharmacy.<sup>32</sup> Since most protein drugs cannot be given orally, the impact of other routes of administration must be assessed. It also must be appreciated that for most biotechnologically derived agents, there is a preexisting and nonconstant concentration of the corresponding endogenous molecule present in plasma. Bioanalytical techniques for monitoring concentrations of the agent require optimization for specificity. Unfortunately the specificity of any one method often depends on the particular matrix in which analysis is performed (blood, urine, or the initial formulation).

In addition, the prediction that recombinant human molecules would not be immunogenic has not proven to be the case.<sup>32</sup> Antibodies to several recombinant drugs now are known, but not all neutralize the pharmacological activity of the agent and, in some cases, they can decrease clearance of the agent. These factors obviously complicate the interpretation of pharmacokinetic data. The immunogenicity of a particular protein also may depend on the route of administration. Protein aggregation, known to occur after subcutaneous or intramuscular injection, leads to a greater antigenic response than soluble protein. Finally, the influence of the lymphatic system on protein pharmacokinetics should not be underestimated. After subcutaneous administration, absorption via the lymphatics becomes quantitatively more important than that of blood capillaries as the molecular weight of the drug increases. Because several recombinant protein drugs act primarily through the lymphatics (interferons and interleukins), blood concentrations may be irrelevant to pharmacological activity.

Obviously, there remain immunologic concerns in any instance when a recombinant analog of an endogenous protein is fashioned into a drug product. Known as neoantigenicity, altered protein structure due to amino acid changes, chimeric products (i.e., humanized mouse monoclonal antibodies), or fusion with other constituents could trigger antibody-mediated inactivation of the therapeutic molecule as well as its endogenous

counterpart. In some instances, the very same modification in one context can result in the opposite effect in another. For example, *E. coli* asparaginase had been used to treat certain leukemias based on the observation of their need for the amino acid asparagine. However, some patients experienced immunological reactions to the bacterial protein, and a new product was produced, pegaspargase, where the enzyme was modified by covalent attachment of polyethylene glycol (PEG) molecules. This approach, now known as PEGylation, is also known to improve the efficacy of a number of proteins by reducing their renal clearance.<sup>33</sup> PEGylated therapeutic proteins available in market are: Oncaspar (PEG-asparaginase), Adagen (PEG-adenosine deaminase), Pegasys (PEG-interferon  $\alpha$ 2a), PEG-Intron (PEG-interferon  $\alpha$ 2b), Neulasta (PEG-Granulocyte-Colony Stimulating Factor), and Somavert (PEG-growth hormone receptor antagonist). Except for using N-terminal specific PEGylation for Neulasta, random PEGylation on protein surface residues, such as lysine, histidine, and tyrosine, etc., has been applied to create these PEGylated therapeutics.<sup>34</sup> It will inevitably yield heterogeneous products.

The same PEGylation strategy used to reduce antigenicity in one context recently caused an immunogenic response with another product, megakaryocyte derived growth factor or thrombopoietin. This product had been in development to treat bleeding disorders due to platelet loss in some disease and with chemotherapy, and a PEGylated form being tested in normal volunteers caused inactivating antibodies to be made to their own endogenous thrombopoietin.<sup>33</sup> This example should serve as a reminder that protein modifications do not always have the intended consequences.

In addition to immunogenicity, another obstacle for protein drug development is delivery. Due to the limitations of big molecular weight and bioavailability, subcutaneous and intravenous injection is still the main route of protein drug delivery. Inhalation formulation is indeed another feasible way for macromolecule drug delivery. The first inhaled insulin, Exubera (by Pfizer), was approved by the FDA in September 2006. It opened a new avenue for non-invasive protein drug delivery and spiked a heatwave for protein inhalation formulation. But the surge faded soon after the withdrawal of Exubera in October 2007.<sup>35</sup> Among seven companies developing inhaled insulin, only MannKind still continued its lonely journey. The withdrawal was claimed not to be related with the safety and efficacy issues. The failure of Exubera is attributed to the marketing and result of the products have been analyzed by all news. Exubera inhalation only partially replaced the daily dose of insulin injection, and patients preferred to stay with conventional needle injection. Moreover, the long term use of high-concentration insulin through the lung does trigger concerns of lung cancer.

There are about 200 biological drugs, including around 40 antibodies, available in the market. Patents protecting the IP of these drugs have expired or are close to expiration. The copycat versions of these complicated biological drugs are called biosimilars.<sup>36</sup> Biosimilars are also referred as "similar biological medicinal products" by the European Medicines Agency (EMA) and "follow-on biologics" by the FDA. The globe-wide market for biosimilars (biological generic drugs) has emerged and is growing fast. There is a fundamental difference between biosimilar and chemical generics. Due to the unique structure-function relationship of proteins and complicated post-translational modifications, protein expression system, manufacturing processes, formulation, storage, and product handling will all exert some kinds of effects on the therapeutic efficacy of protein therapeutics. The inherent differences between a biosimilar drug and its reference biological product are reflected in the preclinical development strategies and clinical efficacy. It also determines the case-by-case evaluation styles for all biosimilars. No standard guideline has been formed for biosimilar comparisons in pre-clinical and clinical studies in the US. The first approved biosimilar product Omnitrope (human growth hormone), in 2005 by Australia and in 2006 by Europe, represents

the start of a new sector of biopharmaceutical industry. So far, 14 biosimilar products based on 4 reference products (human growth hormone, granulocyte colony-stimulating factor, erythropoietin, and follitropin beta) have been approved by EMA. The driving force for biosimilars is to significantly trim the high cost of biological drugs. It is estimated that biosimilars would cut spending on prescription drugs in the United States by \$25 billion between 2009 and 2018.

The future of recombinant biological agents continues to evolve. To date, most approved agents have been recombinantly expressed, naturally occurring proteins. To a limited extent, some approved agents represent our venture into *protein engineering*, in which chimeric or fusion proteins (immunotoxin conjugates) or mutated or deleted proteins (consensus interferon and rPA) have been developed as a result of our experiences with first-generation agents. A number of other biotechnology approaches are currently under investigation, often in human clinical trials, and their success remains to be fully realized. These agents include antisense RNA and DNA, small interfering RNA (siRNA), ribozymes, aptamers, and gene therapy.

In 1978, the first *in vitro* experiments in which *antisense DNA* was used for specific repression of gene expression opened the door to the opportunity to block disease-causing genes selectively. The antisense nucleotide approach is based on the use of short oligonucleotides (13–25 base pairs) complementary to a specific mRNA whose protein product is implicated in a disease such as cancer or viral infection.<sup>37</sup> Binding of the antisense molecule to its target mRNA is then believed to inhibit protein translation by interfering with ribosomal function or inducing mRNA degradation through either cytoplasmic nuclease RNAase H or nuclear RNAase P. This approach meets the two crucial criteria in the design of any successful therapeutic agent: the identification of a target implicated in disease etiology and the ability to find a molecule capable of high affinity and selectivity for the target. Although problems of stability, delivery, and specificity have somewhat dulled the initial promise of these agents, several second or third-generation chemically modified antisense molecules (e.g., 2'-O-methoxyethyl-RNA, peptide nucleic acid, morpholino phosphoroamidate) with improved nuclear resistance and distribution profile are in late clinical trials.<sup>38</sup> The first antisense drug, Vitravene (to prevent blindness due to cytomegalovirus infections in HIV-positive patients), was approved in 1998 in the US and subsequently in 1999 in the EU. However, it was voluntarily withdrawn in the EU in 2002 for commercial reasons.

Another encouraging adaptation of antisense therapies is an approach that takes advantage of the Nobel prize-winning discovery of Thomas Cech and Sidney Altman, who demonstrated that certain RNA molecules possess an enzymatic RNA-degrading activity. The RNAs, called *ribozymes*, are directed toward a specific disease-causing RNA by the sequence homology used by antisense molecules. However, the promise of ribozymes relates to their catalytic nature; one ribozyme molecule can lead to the destruction of thousands of target RNA molecules. In addition, ribozyme technology appears to possess greater specificity over some antisense nucleotides. Nonetheless, the instability of RNAs as therapeutic agents is one hurdle that must be overcome before the promise of ribozymes can be fully realized.

Other oligonucleotide technologies also being investigated take advantage of the three-dimensional nature of DNA/RNA molecules. Aptamers are oligonucleic acids specifically selected for high affinity to certain molecular targets. *In vitro* selectivity of these molecules is quite impressive; affinity-selected aptamers can distinguish between theophylline and caffeine, hypoxanthine molecules that differ by only one methyl group.<sup>39</sup> The hope is that such selectivity can be applied to closely related enzymes (i.e., COX-1 and COX-2) or receptor family subtypes. The first FDA approved aptamer is Macugen (Pfizer, 2004), a PEGylated oligonucleotide, which binds specifically to vascular endothelial growth factor for the treatment of age-related macular degeneration.

The most recent, highly-hyped technology to emerge in the late 1990s was the use of small, double-stranded RNA molecules to specifically turn off expression of genes involved in pathogenesis.<sup>40</sup> In 1998, this pathway was first shown to exist in an invertebrate model dear to geneticists, the worm *C. elegans*. Shortly thereafter, it was recognized that mammalian cells possess a similar regulatory mechanism for silencing endogenous genes called RNA interference (RNAi). RNAi is a ubiquitous and fundamental cellular mechanism for gene silencing. While the biological mechanism and consequence of RNAi are still under investigation, RNAi related technologies, such as synthetic small interfering RNA (siRNA) and synthetic or expressed small hairpin RNA (shRNA), are rapidly being developed as therapeutic drugs to specifically and efficiently inhibit disease-related genes. However, converting siRNA or shRNA into a potent therapeutic drug requires addressing problems that are still haunting oligonucleotide drugs (antisense oligonucleotide, ribozyme and aptamer) and gene therapy, such as *in vivo* stability, tissue and cell specificity, intracellular durability, immunogenicity, and toxicity.

siRNA is the functional precursor of RNAi.<sup>41</sup> It is composed of 19–23 base pairs (bp) of double-stranded RNA with 2 bp overhangs at each 3' end. In the cytoplasm, siRNA is processed by Dicer (a RNase III family enzyme) and forms a nuclease complex known as RNA-induced silencing complex (RISC). Subsequently, the RISC endonuclease Ago2 cleaves the sense strand and activates the RISC. Directed by the single-stranded antisense strand, the activated RISC is capable of performing multiple rounds of target mRNA recognition and cleavage. The enzyme-mediated multiple rounds of mRNA cleavage are the key difference between siRNA and antisense oligonucleotide methodologies. siRNA and shRNA are successfully and broadly used to silence target genes for functional validation *in vitro*. Although siRNA is 10–100 times more efficient in gene silencing than antisense oligonucleotide, siRNA and antisense oligonucleotide confront the similar obstacles for therapeutic application *in vivo*. Chemical modifications are usually incorporated into the phosphodiester linkages, the hydroxyl groups of the ribose, the nucleobases and the 3' or 5' terminus of siRNA to improve cellular targeting, mRNA binding, and especially nuclease resistance. All of these modifications have to balance the siRNA activity, cytotoxicity, and pharmacological properties to achieve an optimal efficiency *in vivo*.

Another problem is specificity and the potential for “off-target” gene silencing.<sup>42</sup> The off-target can be due to (1) the short complementary sequence (8 nucleotides); (2) the saturation of endogenous RNAi machinery and subsequent interference with the systemic microRNA and siRNA regulation and function; and (3) the non-specific siRNA binding to Toll-like cellular receptors and subsequent immune stimulation. A number of companies have sprung up hoping to exploit this technology in treating viral diseases, especially HIV/AIDS, and other disorders caused by over-activity of an enzyme or protein. Most of these studies are in Phase II or I clinical trials. As with other revolutionary technologies that propose to realize Ehrlich's dream of the magic bullet, only time and experience will determine the true clinical utility of these agents.

Until the unexpected death of Jesse Gelsinger in a Phase I recombinant adenovirus trial in 1998, the next wave of products seemed destined to be directed toward gene therapy.<sup>43</sup> Many different approaches constitute gene therapy, but the most common is to attempt to replace a nonfunctioning or mutated gene product by the directed expression of a new, non-mutated copy of that gene. In other cases, genes are being introduced to make drug therapy more effective (e.g., HSV thymidine kinase, p53) or gene therapy is combined with other aforementioned approaches (e.g., intracellular expression of antisense RNA to the *ras* oncogene). In general, the DNA encoding these new genes is encoded on a plasmid molecule or is part of a viral vector that can infect cells with the appropriate desirable gene without causing viral disease. (The Gelsinger case points out that the recombinant virus might still be lethal via other mechanisms.)

Delivery methods for these gene sources usually either exploit the DNA delivery tactic of the virus itself or employ cationic liposomal complexes with the DNA to mask the plasmid's negative charge. Obviously, there is substantial concern over the use of modified retroviruses or adeno-associated viruses as gene delivery systems for fear that important host cell genes might be disrupted if the viral DNA is integrated into the host genome. Cationic liposomal strategies have made substantial leaps in the last several years, but their efficiency of gene delivery pales in comparison with viral delivery. Nonetheless, liposome/DNA complexes are amenable to lyophilization and reconstitution, and advances are being made in maximizing the efficiency of these stabilized preparations.<sup>44</sup>

Stem cell therapy is used to introduce new cells to replace the damaged cells in order to repair, recover, and restore the normal function of damaged or diseased tissues or organs and has potential application in the treatment of brain damage, spinal injury, heart damage, blindness and vision impairment, wound healing, and diabetes.<sup>45</sup> It has been the hot topic of public media, political debate, and medical research for the past decade. Stem cells are characterized by their ability of self-renewal and potency to differentiate. Based on differentiation potential, two kinds of stem cells, pluripotent embryonic stem cells and multipotent somatic stem cells, are commonly used in therapy. Embryonic stem cells can be isolated from the inner cell mass of blastocyst-stage embryos obtained either from *in vitro* fertilization or created by somatic cell nuclear transfer. The immune rejection of embryonic stem cells in clinical treatment is a potential problem. Using somatic nuclear transfer to produce embryonic stem cells may avoid this problem, but it is similar to human cloning, and the technique has not been well developed so far. In addition, due to the differentiation potency of stem cells, the development of teratoma from transplanted cells is another valid concern for stem cell therapy. The first clinical trial using embryonic stem cells to repair spinal injury was approved by the FDA in 2009.

In 2007, Dr. Shinya Yamanaka's group at Kyoto University and Dr. James Thomson's group at University of Wisconsin-Madison have published their methods to genetically reprogram somatic cells (e.g. epithelial cells) with transcription factors to convert them into pluripotent stem cells. It bypasses the ethical issue of destroying embryos and provides a brand new opportunity for stem cell therapy. However, it is uncertain whether these induced pluripotent stem cells are completely exchangeable with embryonic stem cells and are safe to be used in humans.

The combination of nanotechnology and biology has resulted in a new and fast growing scientific discipline, nanobiotechnology. Nanotechnology deals with materials in the nano range (1–100 nm) that are supposed to possess unique physical and chemical properties. Application of nanotechnology in biology and medicine may bring about innovative drugs, biomaterials, and medical devices. However, the main efforts and achievements of nanobiotechnology in drug discovery still remain in the development of nanoparticles using all kinds of materials (gold, quantum dot, biopolymers, and polypeptides) and processings. The biological characteristics and their significant consequences of the interfaces between these nanoparticles and biomolecules are not clearly understood.<sup>46</sup> Furthermore, the long term benefits and side effects of nanoparticles on human and environment have not been extensively evaluated. Abraxane (*Abraxis Bioscience*), approved by the FDA in 2005, is claimed as the first nanoparticles drug. It takes advantage of the albumin binding ability of a chemotherapeutic, paclitaxel, to make albumin and paclitaxel nanoparticle complexes. Therefore, it solves the poor solubility problem of paclitaxel and avoids the hyperallergic side effect caused by Cremophor EL in regular paclitaxel formulation. Abraxane has been approved for the treatment of breast cancer and is in clinical trial for other cancer treatment.

Finally, a new area has emerged for the potential application of biotechnology products against bioterrorism. Following the

September 11, 2001, terrorist attacks in New York, Washington, DC, and Pennsylvania and the subsequent anthrax scare, Congress earmarked \$37 billion toward homeland defense of which \$6 billion is targeted to developing biodefense strategies. A little-known provision of new FDA guidelines are that counter-terrorism agents are eligible for expedited review, as seen now for drugs to treat AIDS or cancer. Biotechnological approaches have already been proposed for both the detection and treatment for biological agents most likely to be used in terrorist attacks.

By the end of the first decade of the twenty-first century, merging among big pharmaceutical companies had become a trend. Pfizer merged with Wythe, Merck merged with Schering-Plough, and Roche merged with Genetech. Wythe, Schering Plough, and Genetech all carried successful biological products and possessed rich product pipelines. These mergers undoubtedly secured the biological product pipeline for these big pharma. Meanwhile, because of increased R&D cost and budget cuts, big pharma also like to acquire small or medium biotechnology companies with promising products to continue late phase clinical trials.

### PHARMACOGNOSTICAL APPLICATIONS

In regard to the applications of biotechnology in pharmacognosy (drugs from natural sources), Cordell<sup>47</sup> reports that major efforts in this field are underway in Germany, Japan, and the People's Republic of China. These countries are attempting to use manipulated plant-cell cultures to produce otherwise difficult to extract natural products. In Germany, which has a substantial number of efficacious prescription natural products not available in the US, the pharmaceutical industry and government have joined together to form an institute designed specifically to produce natural products commercially through cell-free systems and gene technology of medicinal plants. One company in Japan reported that it can produce ginseng extract, identical in chemical composition with that from mature 6-year-old root, in 75 000 liter fermenters.

Davies summarized the application of genetic engineering to the production of pharmaceuticals. He pointed out that new drugs traditionally have come from natural product sources, usually followed by improved growing techniques or chemical synthesis. However, while the plant or microorganism strain-improvement procedures have resulted in up to 1000-fold increases in yield, the techniques largely have been empirical. Furthermore, these methods have virtually no genetic or biochemical pedigree for successive improvements.

The organisms currently used to produce antibiotics (e.g. penicillin and tetracycline) on a commercial scale are the same species as those originally collected from the natural state and really have been modified only through forced genetic manipulations (by virtue of the media, etc.), based on strain improvement. Of paramount importance is the fact that while gene cloning and recombinant DNA techniques have been successful for proteins and peptides, the higher plants and microbes producing antibiotics have not been manipulated similarly. This is because an entirely different situation exists when more complex genetic and biochemical processes need to be manipulated. As discussed later, there are also some regulatory assurances that remain to be met, particularly in using transgenic plants as a source of pharmaceuticals.

Antibiotics and alkaloids usually are biosynthesized through multistep pathways possessing complex biogenesis and regulatory circuits. The numerous genes involved in the synthesis of a simple antibiotic are not necessarily present as a single genetic linkage group. Thus, cloning the genes needed would require numerous operations, often without the advantage of selective procedures to detect the presence of the cloned genes. Similarly, the same technical problems associated with multiple components of antibiotic synthesis apply to the genetic engineering of improved yields of many secondary metabolites

like alkaloids from plants. Further complicating the issue is that suitable host-vector systems need to be developed fully for the application of recombinant DNA techniques to plants. However, if there is a single rate-limiting step in the pathway of antibiotic biosynthesis, it might be possible to clone the gene for this step by selecting for increased antibiotic production by *shotgun* cloning back into the producing organism.

An alternative way to achieve increased levels of antibiotic production might be to clone appropriate genes on multicopy or high-expression vectors. Another idea would be to engineer antibiotic-producing organisms to produce hybrid or specifically modified antibiotics. This would result in several model compounds that might have more desirable or better properties than the parent antibiotic. For example, Hailes<sup>48</sup> outlined the directed biotransformation of opiate analogs including morphine and hydromorphone, using genetically engineered bacteria, and discussed the application of this method toward biosynthesis of novel alkaloids. Marsden<sup>49</sup> reported the engineering of broader substrate specificity into a macrolide antibiotic-producing polyketide synthase from the erythromycin producer, *Saccharopolyspora erythraea*. These investigators modified the carboxylic acid acceptor unit of this multicomponent enzyme complex to utilize over 40 alternative branched-chain starter carboxylic acids (as opposed to the two straight chain acids utilized normally). In doing so, a vast number of novel, macrolide antibiotics can now be synthesized.

In the case of plant tissue culture, many compounds such as secondary metabolites have been produced with yields that are equal to or greater than that of parent plants. Staba<sup>50</sup> reports on at least 30 natural products that have been generated through plant-cell culture. Among these are included several well-known, but still difficult to obtain, drugs such as diosgenin-derived steroid hormone precursors, the opium alkaloids, digitalis glycosides, several different essential oils, and the *Catharanthus* alkaloids, vincristine, and vinblastine. However, it has been pointed out that these methods still are not economical when compared with the traditional methods used currently, viz., direct extraction from whole plant materials.

Thus far, only one Asiatic drug, known as shikonin (from *Lithospermum erythrorhizon*), has been produced through plant-cell culture methodology in greater quantities and with substantially lower costs than usual extraction procedures.<sup>51</sup> Certainly, continued efforts expended in the biotechnological manipulation of plant genes will prove more successful as research continues in this area. Table 34.2,<sup>52</sup> shows established hairy root cultures (the result of genetic transformation of the plant by *Agrobacterium rhizogenes*) and examples of secondary product formation.

Finally, even though many efforts are oriented toward the cheap, controlled, pharmaceutical production of secondary plant products, it should be remembered that this new approach can offer a valuable system for basic plant biosynthesis. These techniques offer a means quite suitable for physiological studies as well as for genetic manipulation. For once, it will be possible to have a powerful tool for the study of the control of gene expression at both the cellular and whole plant or organ levels. Beyond this, the increased efficiency with which biosynthetic pathways for desired compounds may be expressed makes plant DNA promising material as a source of mRNA for cloning operations directed at the transfer of specific plant enzymes into microorganisms.<sup>52</sup>

Awad<sup>53</sup> has provided an overview on plant biotechnology that he feels is a field fertile for pharmaceutical research. In addition to providing two tables listing both microorganisms and plants that have been used in agricultural, horticultural, and pharmaceutical research in biotechnology, he shows the major groups of compounds of commercial importance that are derived from plants. These include pharmaceuticals (alkaloids, steroids, anthraquinones), enzymes (papain), latex (rubber), waxes (jojoba, carubaba), pigments (food dyes), oils (olive oil, corn oil, etc.), agrochemicals (pyrethrins), cosmetic substances

**Table 34-2. Established Hairy Root Cultures with Examples of Secondary Product Formation**

Family	Species	Major Secondary Products
Solanaceae	<i>Atropa belladonna</i>	Atropine
	<i>Datura stramonium</i>	Hyoscyamine
	<i>Hyoscyamus muticus</i>	Hyoscyamine
	<i>Nicotiana rustica</i>	Nicotine, anatabine
	<i>N. tabacum</i>	Nicotine, anatabine
	<i>N. hesperis</i>	Nicotine, anabasine
	<i>N. cavicola</i>	Nicotine, nornicotine
	<i>Scopolia japonica</i>	Hyoscyamine
	<i>Solanum laciniatum</i>	Steroidal alkaloids
Apocynaceae	<i>Catharanthus roseus</i>	Ajmalicine, serpentine, vindoline, catharanthine
Chenopodiaceae	<i>Beta vulgaris</i>	Betacyanin, betaxanthin
Polygonaceae	<i>Polygonum hydropiper</i>	
Boraginaceae	<i>Lithospermum erythrorhizon</i>	Shikonin
Compositae	<i>Tagetes patula</i>	Thiophenes
Rubiaceae	<i>Cinchona ledgeriana</i>	Quinoline alkaloids

From Hamill J, Parr A, Robins R *et al.* New Routes to Plant Secondary Products. *Nature Biotechnology* 1987; 5: 800-4.

(essential oils and perfumes), food additives (flavor compounds, non-nutritive sweeteners), and gums (gum acacia and tragacanth). He perceives the major trends in plant biotechnology to include plant-microbe interactions, gene delivery and manipulation, diversity of gene engineering, and microbial and plant secondary metabolites.

Constabel<sup>54</sup> reviewed medicinal plant biotechnology as a revolutionary methodology useful in enhancing the formation and accumulation of desirable natural products and a possible product-modification method. He describes advances in micropropagation that involve plant regeneration from *in vitro* cultured cells. Here the multiplication factor can be high and of great advantage to speed up slow-growing important medicinal plants. Recent studies with ipecac (*Cephaelis ipecacuanha*) yielded 100 plantlets per shoot-tip explant per year or 600 plantlets per axenic shoot. Similarly, *Digitalis lanata* cultivars with high cardenolide content were obtained by inbreeding and subsequent crossing of selected genotypes. The isolation and *in vitro* culture of shoot tips led to the formation of adventitious shoots. Following short- and long-term culture, rooting of these shoots on solid medium established plantlets that were transferred to soil. The cardenolide yields equaled those of the parent plants.

Similar studies showed that axenic shoot-tip cultures also can be stored for long periods of time and even be cryopreserved for gene banks. Some studies also are focusing on overcoming somaclonal variation, so that stable, high-yield chemovariants can be developed. In terms of enhancement of productivity, gene technology has allowed true transgenic plants. Their uniqueness is shown as a change (i.e., enhancement) in plant performance (insect resistance, herbicide) and productivity (storage proteins, pigmentation). Transgenic cell cultures of drug plants with modified or increased productivity and microorganisms producing phytochemicals are conceivable and may further increase the feasibility of phytochemical production by *in vitro* methods. Already key enzymes for biosynthetic pathways in plants have been identified and related to isolated DNA clones and genes. Schell described plant biotechnology as a powerful tool to use plant resources and to improve the environmental impact of agriculture. He described how transgenic plants can be developed to promote insect tolerance, virus resistance, and tolerance to fungal diseases in crop plants. Critics of plant biotechnology raise legitimate concerns over the potential immunogenicity of foreign proteins expressed in foodstuffs. The EU nations have been particularly opposed to the marketing of these so-called "Frankenfoods," but these genetically engineered food crops have now grown to represent more than

40% of the corn and soybeans harvested annually. Similarly reviewed are the enhancement of stress tolerance, development of hybrid seeds, and improvement of nutritional-quality plants. For example, Miller and Ackerman<sup>55</sup> also provided new perspectives on food biotechnology, describing tomatoes that are rot-resistant and animal foods being modified by genetic means.

Plant biotechnology has also been used to omit products that are undesirable in a particular crop. Of greatest pharmaceutical relevance is the presence of caffeine in the coffee plant.<sup>56</sup> Those who wish to avoid the hypertensive and CNS-stimulating effects of this methylxanthine must resort to coffee products that have been decaffeinated by chemical processes that may employ organic solvents, which also remove some components of flavor and aroma. However, Japanese researchers<sup>57</sup> have now succeeded in using RNA interference technology to downregulate one of the three *N*-methyltransferase enzymes required for caffeine biosynthesis in the non-commercial plant, *Coffea canephora*. The resulting transgenic plants exhibited a 50–70% decrease in caffeine content. The remaining challenge is to cross these plants with the more economically important *Coffea arabica* and achieve a 97% reduction in caffeine content as required in the US for "decaffeinated" labeling.

The use of transgenic plants or animals in producing recombinant proteins for pharmaceutical use is called "pharming," a term accepted in the 2001 release of the *The Columbia Encyclopedia*. A 2003 survey by the Pew Initiative on Food and Biotechnology revealed that while 81% of Americans favored tinkering with plant genes to produce medicines, only half felt comfortable making transgenic animals for the same purpose. Proponents of transgenic plants as pharmaceutical sources point out that production of recombinant proteins requires a specialized facility costing \$300–\$500 million and roughly 5 years of set-up. In contrast, transgenic plant or animal scale-up can be done on the scale of tens of millions of dollars and in half the time. However, no recombinant product produced in plants or animals has yet made it to market, and only three plant-produced products are currently in clinical trials. The industry has suffered numerous setbacks,<sup>58</sup> not the least of which relate to concerns on the contamination of food crops with plant-made pharmaceuticals, particularly since some companies are using plants to produce orally-active vaccines. In late 2002, a Texas plant biotechnology company was cited for twice contaminating soybean crops in Nebraska and Iowa with transgenic corn harboring either a pig vaccine or a human protease inhibitor. Plants clearly hold great promise for producing biotechnology drugs, but several hurdles must be overcome before this idea is practically implemented.

## PHARMACOLOGICAL APPLICATIONS

Pharmacologically directed biotechnological methodology also holds much promise for the medical field. Even before completion of the Human Genome Project, genes had been isolated for literally dozens of neurochemical receptor drug targets, ion channels, and transporters. With these sequences in hand, target proteins could be produced *in vitro* or in cellular systems for high-throughput drug screening. Not only do these expressed proteins provide tools for identifying drug molecules active against a certain system, but the availability of other similar gene sequences enables determination of molecular specificity (e.g., dopamine D2 antagonism versus dopamine D1 antagonism). Moreover, these potent drug discovery technologies are no longer exclusive to pharmaceutical companies. Academic researchers in the neuropharmacology area now have access to recombinant protein screening services of the National Institute for Mental Health (NIMH) for novel CNS-active agents. Through an NIMH contract, Drs. Linda Brady and Bryan Roth at Case Western Reserve University maintain cellular systems for assaying drug activity against more than 70 neurochemical receptors and transporters. In fact, this system has recently been used in an attempt to resolve the controversy over the active antidepressant component(s) of extracts from the herbal remedy, St. John's wort.<sup>59</sup>

It should be mentioned that long before their testing as therapeutic agents, antisense oligonucleotides were used experimentally to advance our understanding of physiology and pharmacology. As an example, Pasternak and Standifer<sup>60</sup> have outlined their exploitation of antisense molecules in elucidating the functional biology of opioid receptor subtypes. Using antisense molecules to downregulate certain opioid receptor subtypes (or mRNA-splicing variants of the same receptors), these investigators have been able to differentiate among receptors responsible for morphine-induced spinal analgesia, morphine-induced supraspinal analgesia, and the supraspinal analgesia induced by the active glucuronide conjugate of morphine. A similar approach has been used to investigate dopamine, muscarinic acetylcholine, and NMDA receptors.

Huber<sup>61</sup> provides an excellent review on the therapeutic opportunities involving cellular oncogenes because of the novel approaches fostered by biotechnology. Oncogenes can serve as novel therapeutic targets for cancer diagnosis, prognosis, and treatment. Marx<sup>62</sup> provides another perspective on oncogenes by detailing advances made in our understanding of tumor suppressor genes whose function is inactivated in carcinogenic regression. Tumor suppressor genes are obviously excellent candidates for reintroduction strategies in treating cancer.

## PHARMACEUTICAL MANUFACTURING APPLICATIONS

The use of genetically modified bacteria also has played a part in increasing the efficiency of producing certain pharmaceutically important synthetic organic compounds. For example, researchers have isolated a gene from a species of *Corynebacterium* that codes for 2,5-diketo-D-glucose reductase. This particular enzyme catalyzes the conversion of 2,5-diketo-D-glucose to 2-keto-L-glucose, which is an intermediate in ascorbic acid (vitamin C) production. The scientists successfully have inserted the gene into *Erwinia herbicola* bacteria, via a plasmid. Unchanged *E. herbicola* has the ability to ferment D-glucose into 2,5-diketo-D-glucose. Inserting the new gene provides the changed bacterium with the ability to ferment D-glucose to 2-keto-L-glucose in one step. The second step involved in the production of vitamin C is base- or acid-catalyzed cyclization of 2-keto-L-glucose to the acid. Thus, the genetic engineering process saves at least four steps, compared to the previous procedure. The older Keichstein Grussner process involves six steps in the synthesis of ascorbic acid.<sup>63</sup>

## ORGANIC SYNTHESIS APPLICATIONS

In an interesting synthesis application, Iverson and Lerner<sup>64</sup> report on sequence-specific peptide cleavage catalyzed by an antibody. The monoclonal antibodies necessary for this procedure were produced by immunizing with a Co(III) triethylenetetramine (trien)-peptide hapten capable of catalyzing specific hydrolysis of the GlyPhe bond of peptide substrates at a neutral pH with a metal complex cofactor. As a group, these antibodies are able to bind trien complexes of not only Co(III), but also numerous other metals. At least six peptides were studied as possible substrates with these antibodies as well as various metal complexes. The results of these studies demonstrate the feasibility of using cofactor-assisted catalysis in an antibody-binding site to achieve successful results in difficult chemical transformations.

## MORAL AND ETHICAL QUESTIONS

On the matter of moral and ethical questions of biotechnology applications in medicine, numerous articles appear periodically<sup>10,22,65</sup> to debate the issue. Francis Collins, Director of the National Human Genome Research Institute (NHGRI) has written, "It is estimated that all of us carry dozens of glitches in our DNA—so establishing principles of fair use of this information is important for all of us."

There are many questions, such as the following:

- Does genetic testing constitute invasion of privacy?
- Will there be an increase in abortions that discriminate against the *genetically unfit*?
- Should those destined to be stricken with a fatal genetic disease be informed of their fate,
- especially if there is no remedy available?
- Will these decisions become mandated legally and ultimately demean humans or create a new underclass of the genetically less-fortunate?
- Should gene therapy be used only for treating disease or also for *improving* an individual's genetic legacy?

Currently, most protections on the use of genetic information are regulated at the state level, resulting in uneven application across the population. Senators Jeffords and Daschle recently outlined their respective views on the passage of federal laws that protect the collection and use of genetic information, particularly relating to employment and health insurance.<sup>15</sup> The Human Genome Project's ELSI program (Ethical, Legal, and Social Implications of Human Genetics Research) is now charged with addressing issues that appear as daunting as the sequencing of the genome itself. The benefits of biotechnology in disease prevention and treatment are numerous, and the decoding of the human genome will continue to produce new opportunities to improve our quality of life. But as with all technological advances, safeguards are required to prevent discriminatory and unethical use of this new information.

## APPENDIX A TOP 10 BESTSELLING BIOLOGICAL DRUGS IN 2009.

Brands	Companies	Indications	Sales (\$ billion)
Enbrel	Amgen, Wyeth Takeda	Rheumatoid arthritis	8.2
Remicade	J&J, Schering Plough, Mitsubishi Tanabe	Crohn's disease	6.5
Humira	Abbott	Rheumatoid arthritis	5.6
Avastin	Roche, Genentech	Metastatic colon cancer glioblastoma, metastatic renal carcinoma	5.4
Rituxan	Genebtech, Biogen	IDEC Non-Hodgkin's lymphoma	5.3
Herceptin	Roche, Genentech	HER2 positive metastatic breast cancer	5.2
Lantus	Sanofi Aventis	Diabetes	4.8
Lovenox	Sanofi Aventis	Anticoagulant DVT	4.6
Aranesp	Amgen	Anemia	3.3
Gardasil	Merck	Human papilloma virus vaccine	3.1

The data do not intend to promote the sale of listed representative drugs. It is only for the purpose to show the immense market and profit of biologic drugs.

(Data from Maggon K. *Biotechnology Market Review & Top Ten Biologics 2009*. Web. <http://knol.google.com/k/biotechnology-market-review-top-ten-biologics-2009#>. Accessed 16 December 2011)

# Chapter 35

## Pharmaceutical Packaging

C. Jeanne Taborsky, BSChem and Kathleen Deiss, RN

INTRODUCTION 667

CONTAINER SELECTION BY DOSAGE FORM 668

QUALITY CONTROL 678

OVERVIEW OF TEST METHODS 678

SUMMARY 679

### INTRODUCTION

A container closure system must be designed to protect the drug during actual conditions of storage, shipment, and use and be able to deliver the correct amount of product at the time of use. It must not interact with the product over its shelf life to the extent that it renders the drug ineffective or unacceptable for use. As defined in the USP, “a container, including the closure, does not interact physically or chemically with the pharmaceutical preparation in any manner to alter the strength, quality, or purity beyond the official requirements under ordinary or customary condition of handling, shipment, storage, sale or use.”<sup>1</sup>

The general requirements for containers for foods, including dietary supplements, drugs, cosmetics, and medical devices, are provided in the Food Drug and Cosmetic Act as amended.<sup>2</sup> The regulations are provided in *Code of Federal Regulations* Title 21. The FDA Center for Food Safety and Nutrition (CF-SAN) is responsible for the regulations that apply to foods and dietary supplements. The Center for Drug Evaluation (CDER) and the USP/NF are responsible for the regulations that apply to drug packaging. The Center for Biologics Evaluation and Research (CBER) and USP are responsible for the regulations that apply to biologics. The Center for Veterinary Medicine (CVM) relies on CDER and USP/NF for its packaging requirements. The Center for Devices and Radiological Health (CDRH) uses 21 CFR Subchapter H—Medical Devices, ISO, and ASTM International standards. If a liquid medication dispenser is purchased by a pharmacist, independent of the drug, it is regulated by CDRH. If it is sold with the drug, it is regulated by CDER. If an injection syringe is sold by itself, it is regulated by CDRH, and, if it contains a drug (prefilled syringe), it is regulated by CDER.

The standards for drug packaging in USP/NF include General Notices, General Chapters <87>, <88> Biological Reactivity Testing, <381> Elastomeric Closures for Injection, <660> Containers-Glass, <661> Containers- Plastic, <670> Auxiliary Packaging Components, <671> Containers- Performance Testing, and <698> Deliverable Volume. In addition to these requirements, one must be cognizant of the EPA requirements for monomer content in Polyvinyl Chloride (PVC), waste disposal policies, CONEG (Coalition of Northeastern Governors), and Toxics in Packaging Clearing House (TPCH) requirements. For certain drugs, such as most tablets and capsules, the regulations of the Poison Prevention Packaging Act (PPPA) apply. There are also regulations in 21 CFR §201.25 Barcoding, which require barcoding the National Drug Code (NDC) number on the drug labels, including blisters. On May 2, 2011, the ASTM issued a new standard for Water Vapor Permeation titled D7709—Standard Test Methods for Measuring Water Vapor Transmission Rate (WVTR) of Pharmaceutical Bottles and Blisters.<sup>3</sup> Although these standards are current at the time of publication, it is important to note that the standards in USP and ASTM are evolving, and it is important to refer to the current versions of these standards, which are reviewed and revised routinely. In addition to the law, regulations, ASTM and USP standards, FDA CDER provides guidance in the amount and type of testing required for drug containers.<sup>4</sup>

The amount of effort required to develop or select the appropriate container system is based on a risk assessment considering the route of administration, class of drug product, therapeutic range, and the chemical and physical stability of the drug substance, drug product matrix, packaging components, and the conditions of storage and use. The route of administration determines the degree of testing necessary to determine the acceptability of a container. In some cases, a component, such as a delivery system, will function at one temperature but not another. Therefore, all evaluations must include storage and use temperatures and packaging conditions. The following is a list of dosage forms from highest to lowest risk for use by patients: injectables, implants, inhalation drugs, ophthalmics and otics, oral liquids, oral solids, and transdermals and topical liquids. The concerns about containers have been fostered by actual events of either interaction or the failure to perform. Some examples of those instances are as follows:

- Migration of nitrosamines from rubber;
- Degradation of components from sterilization;
- Reactions to latex allergens in natural rubber;
- Concentration of drug in pouches and PE vials, due to excessive water loss;
- Migration of inks, adhesives, and chemicals in paper into inhalation solutions;
- Migration of vanillin for labels and cartons into inhalation solutions;
- Migration of chemicals from heat seals, plastics, and foils into drugs;
- Presences of vinyl monomer in polyvinyl chloride (toxic);
- Ions and glass in injection solutions;
- Migration of drug to plastic or coating glass;
- Migration of preservatives;
- Migration of plastic additives to drugs;
- Migration of environmental estrogens to drugs;
- Cross-linking of gelatin capsule shells from furfural in Rayon Coil;
- Interaction of residual bleach and dyes in Cotton Coil;
- Failure of a delivery system to deliver the correct dose;
- Low potency or dissolution properties from excess moisture permeation; and
- Degradation from light.

Container designs and materials have evolved to meet new demands and more sophisticated requirements. Due to a tightening of limits on drug product impurities, degradants, and migrants, the selection of containers has become more complicated. Pharmaceutical companies must conduct compendial tests on the containers<sup>5</sup> and compatibility tests<sup>6</sup> on the containers with the actual product, using validated methods. The test methods used by the drug companies to test for impurities and migrants are specific to the pharmaceutical formulation and the packaging material.

Container components must also perform, as needed, to protect the products from physical change, loss of contents, and exposure to moisture, oxygen, and light. To develop the appropriate container closure system, the scientist must know the

critical attributes of the specific drug product and chemical and physical properties of the container options. The importance of selecting the appropriate materials of composition cannot be underestimated. This critical step is often not considered until problematic issues arise. It is essential to consider, first, the container's requirements, and then select materials that fulfill those needs. To determine the appropriate container closure system, one should consider the following:

- Preformulation information on the drug substance (sensitivity to heat, oxygen, humidity, light, glass, metals, pH, reactivity with plastics, metals, or types of glass);
- The nature of the dosage form (solid oral, liquids—aqueous, alcohol, oil, suspensions, inhalation powders, creams, ointments, biodegradable polymers, implants, transdermals, etc.);
- Drug product information (open pan studies on impact of humidity, light, heat, pH, and compatibility studies with the components);
- Container material qualification (CAS number, 21 CFR qualification, USP qualification, etc.);
- Container/product compatibility;
- Impact of the packaging operation on the drug product;
- Ruggedness of the container system under actual conditions of packaging, shipping, storage and use;
- Performance; and
- Cosmetic features.

The drug manufacturer has access to all of the data listed, and the information is reviewed by the FDA in support of their submission. Container manufacturers file Type III Drug Master Files (DMFs) with the FDA, so the information can be reviewed in conjunction with the drug application and FDA can determine if the container is compatible and the information is sufficient for approval of the drug product. The challenge for the repackager, pharmacist, or pharmacy compounder is selecting the appropriate container, when the drug manufacturer does not provide repackaging instructions and the container supplier does not provide chemical or performance information. In these cases, the most conservative approach may be the best approach.

Selecting materials that CDER already approved for use for similar products reduces the risk of component failure. Certain chemicals have become associated with concern regarding their safety and appropriateness of use in packaging drug products. These include, but are not limited to, nitrosamines, BHT, certain carbon blacks, and some antistatic agents. It is best to eliminate these concerns by selecting components manufactured without these chemicals. If possible, the packager should know which 21 CFR references, Food Contact Numbers, and USP or EU requirements the component or material meets. It is advisable to choose materials available commercially. Medical grade materials are preferred, but are often more expensive. The classification of medical grade does not mean the materials are of a particular composition; it means the supplier complies with a change control program. Although selecting medical grade materials is preferable, the materials should, at least, come from a reliable source and be cGMP manufactured. One should know the details of the suppliers change control program. When suppliers are not willing to report changes to the packager or pharmacist or control their changes, the quality of every lot is in question and may require full extensive testing, particularly if it is used to package a high-risk product.

## CONTAINER SELECTION BY DOSAGE FORM

### TABLETS AND CAPSULES

The containers for solid dosage forms are divided into bulk (not for distribution), multiple-unit and unit-dose containers.<sup>7</sup> In the late 1960s, drug manufacturers packaged tablets and capsules in

multiple-unit glass or polystyrene (PS) bottles with continuous thread metal screw caps with pulp liners. Pharmacy containers consisted of yellow to orange polystyrene prescription vials with white polyethylene (PE) snap caps. Unit-dose containers were not as prevalent at this time. They were used mostly by institutional pharmacies, in the form of strips of plastic or foil sealed together or blister packs, plastic sealed with a card.

The protection afforded by a container is a combination of the permeation of the bottle and the efficacy of the seal with the closure. In 1970, the Poison Prevention Packaging Act (PPPA) was passed, requiring child-resistant/adult-friendly packaging for most oral prescription drugs. After PPPA was passed, prescription tablets and capsules, packaged in the smallest commercial size container for dispensing, were required to be packaged in child resistant containers. Once this requirement was implemented, there was a wave of complaints about efficacy and the failure of drugs to perform. The product complaints included discoloration, increased hardness, not dissolving in the digestive track, friability, increased softness, low potency, and increased side effects. This phenomenon was first reported to the FDA National Center for Drug Analysis Laboratory in Washington, DC, and was later investigated at the USP/NF Drug Standards Laboratory in Washington, DC. The results of those studies forever changed the materials of construction, test standards, and design of container closure systems.

### MULTIPLE-UNIT BOTTLES AND PRESCRIPTION VIALS

Prior to 1970, the USP contained chemical standards for glass and plastic, but not performance tests. These standards were general, not based upon end use. Bottles, vials, and prescription vials used by drug manufacturers and pharmacists were composed of either glass or polystyrene. In response to questions about product failures, the Drug Standards Laboratory modified the existing ASTM WVTR method to evaluate the prescription vials and bottles used to package tablets and capsules. Containers on the market were tested, and the results of those studies are the basis for the standards used to qualify containers today (Fig. 35-1).

Observations of the containers supported and explained the permeation results. The glass bottles did not perform as well as anticipated. Although no moisture permeated the glass bottle, the closure and liner did not provide a tight seal. The glass is not compressible and the cap liner was not effective. The polystyrene (PS) containers were observed to have trace cracks in the walls and a defect in the top. The top of the bottles had a small "tail" from the molding process, which cut into the cap, when it was opened and closed. When there was no liner in the cap, or the cap did not fit tightly, the seal was ineffective. Snap caps made of Low Density Polyethylene (LDPE) stretched on repeat use, whereas those made of Polypropylene (PP) were more rigid and better maintained their shape and fit on the vials and bottles.

When the results of the collaborative study were available, the USP/NF Drug Standards Laboratory met with manufacturers of commercial drug bottles and prescription vials. Based on fabrication properties and the ASTM permeation properties, the container manufacturers committed to change to High Density Polyethylene (HDPE) for bottles and PP resin for vials. Table 35-1—Comparison of the ASTM Permeation of Bottle Resins provides a comparison of the properties of the most common plastic bottles for pharmaceuticals, vitamins, and nutraceuticals. These results were determined by the ASTM test methods, not USP methods. The results for containers manufactured of PP are similar to those of HDPE.

With the implementation of the ICH, the stability test conditions were changed. Many drug companies added foil inner seals, to reduce permeation and increase stability during controlled studies. When implementing this change, manufacturers did not consider the stability of the product once the seal was removed, but were only concerned with the conditions impacting on the reported stability testing of the drug on storage. To

Figure 35-1. USP <671> Moisture Permeation—Bottles and Vials.

determine if the test conditions should be changed to match ICH stability test conditions, the actual concentration of moisture in the air for each condition was calculated and is presented in Table 35-2—Concentration of Water in the Air. Permeation testing was conducted using the ICH conditions for accelerated conditions, controlled room temperature conditions, and USP <671> conditions. The data demonstrated that the USP test mimicked the ICH conditions for controlled room temperature. Since the USP test used a common salt solution to generate the humidity, rather than an expensive temperature/humidity cabinet, it was decided that the test should remain unchanged and a salt solution could be used to generate the test conditions. Keeping the test simple and inexpensive enabled pharmacies and repackagers to do the test in-house.

The critical physical attributes of the bottles include the weight, wall thickness, neck finish, and ovality. These measurements are listed on the bottle drawing and should be part of the routine incoming release testing conducted, before a bottle is used to package a drug product. Additionally, prior to packaging

product into containers, they must be inspected and cleaned, due to the potential for grease, fibers, dust, and insects to be present. Often, the bottles are inverted on the filing line to aid in the removal of debris. Plastic shrink-wrap can be used to minimize contamination. Bottles can also be cleaned by blowing filtered, compressed air into them prior to filling. The air should be filtered, because unfiltered, compressed air often contains oil vapors.

Multiple unit bottles used by pharmaceutical manufacturers and commercial repackagers are universally constructed of white HDPE to fit screw closures. The bottle materials of construction must meet 21 CFR requirements for indirect food additives, such as 21 CFR §177.1520. White colorant is added to protect the product from light. Bottles are fabricated by extrusion or injection blow molding. The resin can be homopolymer or copolymer. The most common copolymer is hexane. The white bottle colorant consists of titanium dioxide extruded in LDPE. The bottle may contain zinc or calcium stearate. The stearate is available of animal or vegetable origin. If the stearate

is of animal origin, Bovine Spongiform Encephalopathy (BSE) certification is required. Although some suppliers may say their process would kill the bovine spongiform, there are no test methods that can confirm this and the process cannot be validated. At the present time, most countries, except Brazil, have reported the presence of the disease, and, for this reason, the FDA may ask for the location and name of the farm from which the material originated to approve the source. (See Table 35-3—Information on Typical Materials of Construction for Bottles.)

For product sales within the United States and member countries, the testing requirements used to qualify the HDPE bottles are located in USP <661> Containers-Plastics.<sup>8</sup> These specifications include tests and limits and are the result of the extensive collaborative study sponsored by the Drug Standards Laboratory, which included the USP, FDA, and industry participation.<sup>9</sup> A second collaborative study was conducted in 1997 by the FDA Center for Drug Evaluation and Research (CDER), which confirmed the original results, while further investigating the impact of injection versus blow molding and the use of regrind.<sup>10-14</sup>

USP tests are not required on all shipments of components for tablets; however, if tested, they must pass. The USP <661> physicochemical tests are used to qualify the containers for use in contact with tablets and capsules, and need to be repeated when a change occurs, or to comply with an internal requirement for retesting. The USP tests include two tests for identification: measurement of the infrared spectrum and thermal analysis by differential scanning calorimeter against the USP reference standard. The USP testing also includes the measurement of extractables in hexane, alcohol, and water.

USP <671> requires Moisture Permeation and Light Transmission testing be conducted on all plastic containers, regardless of the resin type or dosage form to be packaged. The USP <671> currently specifies several methods for Moisture Permeation based not only on dosage form, but also on the packaging size and type of configuration (e.g., multiple-unit). The USP Moisture Permeation test was developed for and applies to polyethylene, polypropylene, PET/PETG and glass bottles, and commercial and prescription containers. These test methods for commercial container/closures systems are to be performed with and without seals (Fig. 35-2).

USP <671> Light Transmission test involves cutting a portion of the bottle, mounting it in a holder in a spectrophotometer, and measuring the amount of light that penetrates through the wall of the bottle. The amount of light transmission measured from 290 to 450 nm (ultraviolet/visible) cannot exceed 10%.

Most white HDPE bottles pass this test requirement, although, when the standard was first implemented for HDPE bottles, some did fail.

A study was conducted on white HDPE bottles, PP vials, and PET bottles of various colors to determine if they would pass USP Light Transmission requirements.<sup>15</sup> The bottles included those promoted for use for drugs, nutraceuticals, and prescription vials. All of the white HDPE bottles and PP prescription vials passed USP limits. The results are provided in Figures 35-3 through 35-5. The same could not be said for the various colors of PET bottles, where many failed 10% and one bottle exceeded 60%. The results confirm the premise that, just because the bottles are tinted or contain a colorant, does not guarantee they are light resistant.

Prescription vials and caps are sold together by the manufacturer. Prescription vials are manufactured of amber polypropylene and available with a white polypropylene child resistant closure or a white low density polyethylene snap cap. After the passage of PPPA, the market was flooded with CRC prescription vials, many of which although protecting the child, did not protect the drugs. The amount of moisture that permeated the system varied greatly. Most of the PS prescription vials were removed from the marketplace, since they would not pass USP "tight" limits (see Fig. 35-1). Later testing on marketed prescription vials showed a definite improvement in the protective properties. In most cases, the child resistant closure protects the product better than the non-child resistant closure, since the cap does not get stretched from repeat use.

Closures for bottles are manufactured from white polypropylene and are child resistant (CRC) or standard continuous thread. The smallest container sizes intended for dispensing to the consumer must meet CRC regulations.<sup>16</sup> The CRC is two parts: the outer cap is white polypropylene, and the inner cap is clear polypropylene. The closures are fitted with liners and, in most cases, with heat seals. The liner may be held in place with glue. The cap seal is heat-sealed at the time the bottle is filled and removed by the consumer at the time of use. Thereafter, the cap liner is affecting the seal (see Fig. 35-2).

Cap liners can be manufactured of pulp board, foamed polystyrene, or foamed polyethylene. Pulp board can also be coated with wax. The choice of liner is critical to the protection of the drug from moisture. Although drug stability studies are conducted by the manufacturer with the heat seal in place, once the bottle is opened and the seal removed, it is the cap liner performance that is critical. The cap liner should be able to contract and re-expand after multiple openings and closings. Some cap liners, once compressed, will not re-expand, and the protection from moisture may be compromised. USP <661> Extractables testing, when applied to cap liners, have been known to fail, but these components have not been evaluated by the USP, and specifications relating directly to liners and inner seals have not been listed. The importance of choosing the correct liner and heat seal cannot be overemphasized.

The container closure system design and integration of the bottle, closure, liner, and seal have a major impact on permeation. The repeated opening and closing of a container can create wear on the closures and liners. Removing a heat seal can leave deposits on the container that impact the seal integrity of the closure and liner with the bottle. The permeation results with the seal in place and with the seal removed and closure on the bottle were different. The standards were, therefore, revised

**Table 35-3. Information on Typical Materials of Construction for Bottles**

to provide for testing under both conditions. Testing of the condition with the seals removed is similar to that for a prescription vial (see Fig. 35-2).

It is important to note that the largest and smallest containers are not really bracketing the permeation data, and, therefore, testing the largest and smallest container on stability will not always incorporate the worst case results. It is more meaningful to test the containers, select the worst case, and conduct stability studies on product packaged in this container. As an added benefit, testing on the worst case scenario would significantly reduce the time and cost of conducting stability studies.

### Auxiliary Components for Solid Oral Dosage Forms

In addition to bottles and closures, solid dosage forms may be packaged with pharmaceutical filler or desiccant.

Cotton, Rayon, and Polyester Coil are used in bottles of solid oral dosage forms to prevent tablets from breaking during shipping and handling. Filler, or pharmaceutical coil, is available as cotton, rayon, or polyester. Being of plant origin, the Cotton Pharmaceutical Coil is bleached and treated to remove plant residue and other impurities.<sup>17</sup> Rayon Pharmaceutical Coil is essentially rayon fibers, a fibrous form of bleached, regenerated cellulose. Polyester Pharmaceutical Coil is a synthetic polymer that may be treated with various chemicals. It is difficult to identify which coil is used, since all pharmaceutical coils closely resemble each other. There is an identification test that can be conducted, where a drop of dye turns a different color and polyester will burn differently from cotton and rayon. The standards for these materials are provided in USP <670> Auxiliary Packaging Components.

There are advantages and disadvantages of each pharmaceutical coil. Purified Cotton should not be used, if it contains a bluing agent or if there are traces of bleach, which can react with the product. Rayon Pharmaceutical Coil has been found to be a potential source of dissolution problems for gelatin capsules or gelatin-coated tablets, resulting from gelatin cross-linking, due to the production of furfural. Both Purified Cotton and Rayon contain moisture, which can migrate to the product. Polyester contains essentially no moisture. Most of the reactive chemicals have been removed. Polyester filler should be provided by a reputable supplier, where it is known to never have been intended for use as carpet fiber and treated with other chemicals. The finish on fibers used for processing should comply with FDA food contact regulations. (See Table 35-4—Comparison of Pharmaceutical Coils.)

Desiccants are used to reduce the amount of moisture in the head space of the bottle. Desiccants should be removed, once the bottle is open, or they can over absorb moisture and desorb moisture to the product. Only desiccants manufactured for contact with drugs should be used. The shape of the desiccant should

be clearly distinguishable from the shape of the medication to prevent accidental consumption, particularly by the visually impaired. The most common bottle desiccant is filled in a small HDPE canister, which easily fits in the bottle. The amount of desiccant depends on the size of the bottle and is measured in grams.

Desiccants should not be placed in the bottle under the tablets. This practice is detrimental, as moisture is pulled through the tablets, and the tablets act as desiccants for the desiccant. The desiccant should be placed in the bottle on top of the tablets, where it can perform its intended task and be easily discarded when the closure is removed. Desiccants should be stored in a clean, dry place and need checked to determine they have not been exposed to excessive moisture prior to use. An alternative to using a separate desiccant is to use a multi-layered bottle, where the desiccant is incorporated into the inner layer of the bottle.

Oxygen Scavengers are used to remove oxygen molecules from the head space containers of products sensitive to oxidation. Oxygen scavengers can be added to the container closure system or can be incorporated into the container itself. These auxiliary components are available as packets, canisters, or films. Oxygen is removed from the container through irreversible bonding of the oxygen molecules with the oxygen scavenging chemicals. Oxygen scavengers help extend the efficacy and shelf life of oxygen sensitive drug products. Oxygen scavengers and desiccants are also available as a combination product capable of removing both oxygen and moisture.

### COMMERCIAL CONTAINERS VERSUS PRESCRIPTION VIALS AND STABILITY

Drug companies and some repackagers conduct stability studies on the product stored in the market containers. The studies conducted by the drug company are used to establish the expiration date in those containers. For an NDA, 6 months of accelerated testing are provided, and, for an ANDA, 3 months of accelerated testing are provided. If the product passes the accelerated testing, it is approved with a 2-year expiration date for the labeled conditions of storage. As long as a repackager uses the same container as used for the stability studies, they can transfer the manufacturers' expiration date.<sup>18</sup> When the standards in USP <671> were first crafted, they were based on a usual dose for 30 days, and the limits for the commercial container with the heat seal and the limits for the drug stored for 30 days without a seal were established. Since that time, dispensing practice has changed, and many prescriptions are now dispensed with 90 tablets for a 3-months' supply, with a discard date of 1 year, not to exceed the expiration date.

### UNIT-DOSE CONTAINERS

Unit-dose containers can be configured as blister packs, pouches, strip seals, cups, or blister cards. Commercially, drug

**Table 35-4. Comparison of Pharmaceutical Coils**

Test	Cotton	Rayon	Polyester
Residual Hydrogen Peroxide Concentration	NMT 50 ppm is found using either method	Not applicable for rayon	Not applicable for synthetic coil
Loss on Drying <731>	Dry 5.00 g of fibers in an oven at 105° to constant weight: it loses NMT 8.0% of its weight	Dry 5.00 g of fibers in an oven at 105° to constant weight: it loses NMT 11.0% of its weight	Dry 5.00 g of fibers in an oven at 105° to constant weight: it loses NMT 0.5% of its weight
Residue on Ignition <281>	NMT 0.20% on a 5.0 g sample	NMT 1.50% on a 5.0 g sample	NMT 0.5% on a 5.0 g sample
Water-Soluble Substances	The residue weighs NMT 0.35%	The residue weighs NMT 1.0%	Not applicable for synthetic coil
Fatty Matter	The weight of the residue of a 10.00 g sample does not exceed 0.7%	The weight of residue of a 5.00 g sample does not exceed 0.5%	Not applicable for synthetic coil
Possible additives of chemicals which could react	Bleach and dyes	Furfural	Antistatic Agents

companies and repackagers use unit-dose blisters or small unit dose foil pouches. The materials used by drug companies and commercial repackagers are a printable foil/polyester lidstock. The blister can be constructed of polyvinyl chloride (PVC), PVC/polyvinylidene chloride (PVDC), PVC/Aclar, or cold form foil, with PVC being the most permeable and cold form being the least permeable. The commercial small foil pouches are created not from strips, but from wider sections of foil, and the units are cut from the web after they are sealed. The best protections for the product, from light and moisture, the “tightest” containers are the foil-to-foil pouches and the cold-form foil-to-foil blisters. The disadvantage of these configurations is that you cannot see the product to verify its appearance and identity. As part of the development of the USP <671> for unit-dose containers, hospitals and pharmacies in the area were visited and unit dose containers from a wide range of configurations were selected for testing.<sup>19</sup> In some cases, the permeation was so high that the testing had to be suspended before the test period ended. A polystyrene clam shell, polyethylene bag, and PVC cup with a paper lidstock exceeded 20 mg/day.<sup>20</sup> In other cases, such as the foil-to-foil strip seals, the testing was comparable to the tightest commercial packages. Based on the results, some of the container manufacturers made substantial improvements in the materials or designs (Fig. 35-6).

B blister cards are sometimes used in the pharmacy setting, where they are packaged on demand, pursuant to a prescription, for assisted living facilities. They contain a dosing regimen of 30 tablets packaged in a PVC blister sealed to a card. Standard heat seal cards, where the blister adheres to the card are available in 30-day, 31-day, 32-day, 60-day, 62-day, and 90-day formats. The PVC layer can be various thicknesses; however, for best protection, it should be 10-mil thickness. The usual failure of these systems is due to the inadequate thickness of the film or an insufficient seal. The blister is set in a template, the tablets are hand filled and the pharmacist places the lidstock on top and sets it in the sealing apparatus. The amount of time it is heated is subjective. The process is not usually validated, but the sealing can be checked by sealing an empty card,

letting it cool, and pulling it open. The lidstock should adhere to the blister. The USP <671> Containers—Performance Testing, Permeation studies can be performed in a pharmacy setting to verify the performance. It is also important in a pharmacy setting to store the packaging materials in a cool dry place so the materials will not pick up moisture and pass it to the drug during and after packaging. Since small quantities are packaged at a time, the impact of permeation under long term storage is lessened. The advantage of these systems is patient compliance, which can outweigh other considerations (Fig. 35-7).

Strip seal pouches and cups are more commonly used in hospital settings. Strip seals (unit-dose pouches) are formed by two rolls of material fed between two sealing wheels. The backing of the strip seal is paper coated foil, but it can be plastic as well. There are a large number of materials that have been used in the past. The sealing temperature, wheel alignment, and the cleanliness of the sealing wheels are the most critical aspects. This machine requires more attention than the blister card heat sealing machine. Again, the materials should be stored in a clean dry place, and the packaging operation should be done in a dry area.

Unit-dose cups are used in hospitals for both liquids and solids. The cups can be manufactured of a number of materials and the lidstock can be paper or foil. The lidstock is attached with an adhesive that is coated on the lidstock. These containers have improved, since they were first launched, and have the advantage that they can easily be filled on demand in the hospital pharmacy and transported to the patient’s room without the chance of product “mix-up” or loss.

### NON-STERILE LIQUIDS

Non-sterile liquids encompasses a wide range of products, including, but not limited to, oral liquids, eye drops, nasal and throat sprays, oral powders for reconstitution, and topical preparations. Aqueous liquid products include suspensions (including magmas or milks), elixirs, emulsions, syrups, solutions, and powders for reconstitution. Liquids are often the preferred oral dosage form for pediatric and geriatric consumers and those

Figure 35-6. USP <671> Moisture Permeation of Pharmacy Unit-Dose. Class A limit: 0.5 mg/day. Class B: 5 mg/day.

Figure 35-7. USP <671> Moisture Permeation in Blister Packs.

who struggle with swallowing solid oral products. Pursuant to a prescription, pharmacies have had to compound and package oral liquids from tablets and capsules.

The development of suitable and compatible packaging for liquid dosage forms requires greater planning than for solids. The potential for interaction between the packing materials and product are greater, but the health risk is less than that for inhalation and injection products. Challenges encountered with the packaging of liquid products involve the fill of unit dose products, water weight loss, stability, potency, and protection from microbiological contamination. To ensure the liquid product meets its label claim, testing to confirm uniformity of fill and unit dose sampling is required. In many cases, these products do not require a CRC. The fit of the cap is essential to prevent leaking. The thread area for liquids is higher than the SP400 used for tablets. It is important that the top or the bottle fit snugly against the cap liner to affect a suitable seal to prevent leakage.

The main performance concern with aqueous liquids is water loss from the drug and container. The containers should pass USP <661> Containers—Plastic for the type of plastic used. The Buffering Capacity test should also be performed. In most cases, this testing demonstrates the suitability of the container from a physicochemical point-of-view. Polyethylene and polypropylene are common plastics for these containers. The container closure system for a liquid dosage form must be developed based on the product's sensitivities, including, but not limited to, moisture, light, gases, ions, and oxygen.

Additionally, the component composition, risk, and rate of migration under storage and shipment conditions must be considered. Although the primary source of migrants is the imme-

diante container, potential sources of migrants in liquids include inks from labels, additives from adhesives on labels, additives to plastic coatings, such as the inner layer of foil pouches, solvents, plastic additives, vanillin from paper and cartons, and phthalates from shrink sealed bands. It is possible for the product to fail specifications, pose a health risk, and necessitate a recall, if the container components have not been properly tested and the product is not protected (see Fig. 35-8).

For liquid products, the permeation limit is based on the upper limit for assay of the product. Moisture permeation testing conducted on containers intended to package liquid products calculates the moisture permeability of the container as a percentage of water weight loss per year. If the product were to maintain its stability, the potency or assay could exceed the upper limit, if the weight loss of the liquid exceeded 5.0% per year for 2 years, resulting in increased potency through loss of water. If the product degrades while the container loses water, the results give a misleading appearance of stability.

#### NON-STERILE LIQUIDS—CONTAINING ALCOHOL

Some liquid drug products contain alcohol. Bottles, closures, inner seals, liners, and glue can all interact with alcohol containing products. For products that contain alcohol, the potential for leachables and the risk of interaction with the container are slightly greater than for those that do not contain alcohol. This should come as no surprise, since alcohol is one of the solvents used to test for extractables to determine the suitability of polyethylene and polypropylene.<sup>21</sup> Testing by USP <661> and <671> are applicable, but compatibility testing is required as well. The results for aqueous and alcohol extractables may demonstrate that a HDPE or LDPE bottle is not suitable. PET

Figure 35-8. USP <671> Containers—Performance Testing. Moisture Permeation Water Weight Loss Percent per Year in Liquid Products.

and PETG bottles are used more often for alcohol containing products, because they are less prone to interact. Compatibility testing with the cap, liner, and glue should be conducted as well. Qualification of the packaging components for these products would require testing and evaluating the extract with alcohol or alcohol/water mixtures at the level at which alcohol would be in the product.

### NON-STERILE LIQUIDS—OIL-BASED

Bottles, closures, inner seals, liners, and glue can all interact with an oil based product. Mineral oil products are notorious for interacting with polyethylene, polypropylene, pulp liners, and glue. Use of these materials, even in the manufacturing process, can result in contaminants and loss of drug from transfer lines and holding tanks. Testing by USP <661> Extractables for liquids does not provide any assurance that the components manufactured of these materials will perform satisfactorily with oil based products. Actual contact of the container component with the drug product and placebo (or primary vehicle) under the anticipated conditions are the only meaningful studies that can be used to qualify the components. USP <671> Permeation studies are not applicable.

For these products, the least reactive container is glass or PET. This material is also used to package oil-based food products, such as vegetable oil and salad dressing. The potential migrants are substantially less than those in polyethylene or polypropylene. Polypropylene closures with reduced additives are the only option at present. Most standard closures contain too many additives that can migrate, even if they are not in direct contact with the product. The foamed polyethylene liners have been demonstrated compatible, but, again, testing is necessary to qualify these components for use with a particular product.

### Auxiliary Components for Oral Liquids

Dosage delivery devices can include components, such as bulbs, glass and plastic pipettes, closures, glass and plastic droppers, dropper tip caps, optical droppers, eye cups, spoons, blisters, and oral syringes. These components are referred to as liquid medication dispensers, when they are sold independent of a drug product (21 CFR §880.6430). When they are sold as the packaging components for the drug product, they are referred to as dosage delivery systems. The devices are used to dispense liquid drugs and are in contact with the drug during that time. The devices have limited contact with the drug product, except when they are part of the immediate container closure system, such as dropper assemblies. Each component should meet the appropriate USP test based on its composition.<sup>22</sup> Suitability and compatibility testing is the responsibility of the end user, not the device manufacturer.

Development and calibration of the dosage delivery systems is a critical aspect of the packaging configuration. The delivery system must assure the proper dosage is delivered to the consumer. The properties of the drug and degree of accuracy required for dosing should be considered, when developing the delivery system. Dosage delivery devices sold with the drug product are custom-made and calibrated for the particular drug product. Pipettes and oral syringes are branded with inks or tapes to indicate calibration lines. Oral syringes provide the more accurate dosing than spoons or cups.

### CREAMS, LOTIONS, AND OINTMENTS

Cream, lotion, and ointment products are packaged in glass, PP or PE jars, or plastic-coated aluminum or PE tubes. These products pose a packaging problem, as they tend to shear and

lose viscosity during the packaging operation and tend to migrate during storage. Creams and lotions are aqueous with surfactants and may contain parabens, perfumes, or essential oils, which also tend to migrate, especially into polyethylene. The assay of the parabens tends to drop within 24-hours of packaging but stabilizes thereafter. Creams may set-up differently and have different stability in glass versus plastic; these factors should be considered when selecting packaging materials. A variety of closures can be selected for use with jars. However, tubes are sold as a set with the cap in place. The tube neck finish and cap can be of various designs. Tubes are provided with various closure fitments. In some cases, the tubes are provided with a standard screw cap, with or without a heat seal. In other cases, the tubes are provided with a metal seal, which is punctured by the cap when it is opened by the consumer. The contact layer of the container can impact the product stability and should be evaluated and controlled, as well as influence the choice of materials.

As stated previously, USP testing <660> or <661> needs performed for glass and plastic, respectively. If the product is aqueous-based, USP <661> Buffering capacity testing needs performed. This testing is not required for ointments, because they do not experience any weight loss. The micro challenge test is required for all aqueous-based lotions and creams.

### TRANSDERMAL PRODUCTS

FDA classifies transdermal products as topical delivery systems that are self-contained, discrete forms, designed to deliver drug through intact skin or body surfaces into systemic circulation.<sup>1</sup> Transdermal products originally developed through the course of clinical practice, when liquid or ointment drug products were applied directly to gauze or dressings and then affixed to the patient's skin for absorption. For transdermals, it is sometime hard to tell where the product stops and the packaging starts. These products are typically packaged in a continuous process at the time they are manufactured, and repackaging is not common. Transdermal packaging includes a protective liner, a contact adhesive, a drug reservoir, which may or may not include a rate controlling membrane, and an outer barrier.<sup>2</sup> Transdermal products are packaged individually into foil or foil-lined pouches, but thermoformed trays have also been used. Ethylene vinyl acetate is a common choice for the construction of the dose controlling membrane. The protective barrier is often composed of PVDC, aluminum foil, or metallized film. The protective liner is constructed from LDPE and is removed immediately prior to the application to the consumer's skin. Polyurethane monomers can be used effectively, due to their high permeability enabling the diffusion of the drug product across the membrane into the consumer's skin.

Extraction and toxicology studies should be conducted early in the packaging development phase. Transdermal products have direct contact with the consumer's skin, often for a considerable length of time. Extractable studies are needed to determine which chemicals have the potential to migrate from the packaging materials to the drug product and, subsequently, to the consumer. Toxicology studies are then conducted on the identified migrants to determine if the levels of exposure are safe for consumers. Additionally, studies are needed to determine if the proposed packaging configuration is capable of protecting the product from losses.

### INHALATION AND NASAL SPRAYS

These products are considered high risk, due to the route of administration and the sensitivity of the patient population. Therefore, the container requires more stringent physico-chemical and performance testing. Unlike the reduced testing requirements for oral solids and liquids, these components may require testing of every lot, until the company can demonstrate the components are being manufactured under tight controls. The degree of testing is based on which components have drug or patient contact. The components should all meet or exceed

the requirements listed in USP <381> Elastomeric Closures, <661> Plastics, and the requirements of USP <87>, <88> Biological Reactivity Testing for drug contact components. Since different routes of administration can target different organs and have different rates of absorption, impurities and migrants are of greater concern with these products. Migrants that may be acceptable for an oral liquid may be unacceptable at the same level for nasal sprays or inhalation products.

Spray devices are complex and may contain multiple components, including, but not limited to, rubber, stainless steel, PE, PP, and, in some cases, polycarbonate and styrene butadiene. Some of these materials may not have Drug Master Files and may not be medical grade. In those cases, extra vigilance is required on the part of the drug manufacturer to control the critical attributes of these materials. Testing and knowledge of the inks, dyes, resins, rubber, and thermoform resin compounds, stainless steel quality, and the impact of changes must be understood and incorporated into the packaging design. Components in direct contact with the drug must pass suitability and compatibility testing. Testing of the pump components in contact with the drug product and vehicle under stress conditions will demonstrate the potential for migration.

The chemical nature of extractables may need determined, and a toxicological evaluation be performed. Those materials with no contact may not require extractables testing. Those with patient contact should meet indirect food additives requirements and be latex free. In addition to extractables, it is also important to consider and set limits for particulates that can arise from the rubber and plastic components.

The dose is delivered by the device, and delivered amount, spray patterns, and particle size play a part in qualifying the device for use with the individual. The performance of the dosing system must be evaluated over the predicted expiration period under the conditions of use. To ensure delivery of the prescribed dose of medication, testing needs to be performed on the efficacy of the device, including pump delivery, spray pattern and plume geometry, spray content uniformity, and droplet size distribution. Detailed information can be located in the FDA Guidance for Nasal Spray and Inhalation Solution, Suspension, and Spray Drug Products.<sup>23</sup>

Some products for inhalation are packaged in LDPE nebulers. These containers are designed for use with a nebulizer. Nebules are automatically packaged using an aseptic form-fill-seal (blow molding) system for rigid containers or a seal-fill-seal system for pouches. These containers are permeable and very prone to weight loss and absorption; therefore, they must have low levels of extractables in the resin and be stored in the appropriate conditions. They have been shown to absorb chemicals from paper, ink, glue, and cartons. In the United States, they are packaged in a foil overwrap that contains the label information. The inner layer of the foil must be free of chemicals that can migrate, such as LDPE that is additive free. Additional information can be imposed on the bottom of the nebulers. There are Mylar-backed labels available that help reduce the migration of inks and paper chemicals. They must be tested on the component to verify they are safe and effective for use. These containers are susceptible to product misidentification. Proper precautions need taken to maintain identification, strength, lot number, and expiration date.

### LARGE AND SMALL VOLUME PARENTERALS

Before the switch to plastics in the 1970s, glass was the most commonly used packaging material for drugs. It was used to fabricate containers for oral liquids, solids, parenteral products, cartridges (prefilled syringes), ampules, and droppers. Glass is still the preferred material used to manufacture containers for many droppers and injectable drugs. Glass is easily cleaned and sterilized. It is transparent, relatively inert, resistant to most liquids, and impermeable to gases. There is no moisture permeation through the container; however, the integrity of the closure's seal to the container can be a source of loss. Stress

cracks can occur, and, sometimes, glass can react with products and result in flaking into the product.

The physicochemical standards for glass are provided in USP <660> Containers—Glass. Glass is typed based on the hydrolytic chemical durability and composition. Conventional inorganic glass consists of a mixture of crystalline oxides, carbonates, and others melted by heating to a viscous liquid state. Glass consists mainly of silicone dioxide, but the composition varies widely within each type. Medical glass can be composed of either borosilicate glass or soda-lime glass. Properties, processing, and melting temperatures vary, depending on the composition of the glass. Glass vendors and their respective formulations are not interchangeable. Formulations can meet the same Type I glass standards, but they are chemically different. Durability is determined by the ability of the glass to resist the release of soluble mineral substances into water. Sometimes, the inner surface of glass containers can interact with neutral parenteral preparation. Some glasses are available with a silicon dioxide coating on the inner surface, which reduces the risk of interaction and migration, thereby increasing the chemical resistance of the glass. Factors, such as composition, treatments, forming, or secondary processes, can impact the surface quality of glass components. The products can be rendered unacceptable for use, when small amounts of alkali and other ions leach into the product from the container. The intensity of the chemical attack in comparable conditions depends on the nature of the product, the composition of the glass type, the surface treatment, and the method of manufacture.

All three types of glass are available in clear and amber light resistant styles. Testing for light resistance is provided in USP <671> Light Transmission. Type I glass is preferred for use with sterile injectable products, due to its high chemical resistance. Type II glass is made from a high-grade commercial soda-lime glass. The inner surface is treated with sulfur dioxide to dealkalinize the glass. Type II glass can be used for most neutral aqueous or acidic preparations, which can include parenteral products. Type III glass has a higher level of resistance to chemical attack than common commercial glass. It can be used for solid or oral liquid dosage forms and some parenteral products. Some glasses are available with a silicon dioxide coating on the inner surface, which reduces the risk of interaction and migration, which increases the chemical resistance of the glass. Containers with this coating are used to package products of high sensitivity, aggressive buffer systems, high pH, radiopharmaceuticals, and complex agents or those products with a tendency to adsorb to glass surfaces. Glass can degrade as the glass absorbs products. This type of degradation is known as sloughing or weathering. These physical attacks on the glass by the products they package can result in sloughing and delamination, which produce glass particles in the product. These potential events can be controlled by the manufacturer by their selection of composition, secondary processes, and forming processes. Additional information on glass is provided in USP <660>.

Most small volume parenterals are still packaged primarily in glass vials, meeting the standards provided. These vials are sealed, using rubber stoppers and aluminum seals. Although natural rubber was used successfully for many years, it fell out of favor, due to the concern about latex allergy. Even though hard latex rubber is processed to the point at which the allergen was not detected, companies changed to other forms of rubber, such as butyl rubber.

There are different formulations of rubber, and it is best to consult with the manufacturer to determine the best form to use based on the pH of the product and the processing, such as terminal sterilization. Rubber components must meet the 21 CFR requirements, as well as those of USP <381> Elastomer Closures. Rubber is also available with treatments, such as siliconization. It is important to determine if these treatments would cause problems if the chemicals migrated to the drug product. Stoppers are also available with different styles, including those designed for lyophilization. USP also provides

requirements for Biological Reactivity. The colors added to the rubber must meet 21 CFR indirect food additive standards. In some cases, the method of manufacture may be an issue, such as for carbon black. Some methods of manufacture for carbon black preclude it from contact with drug products. If the material meets the limits for *in vitro*, then *in vivo* testing may not be required. There are various colors and styles of aluminum seals. The style of the vial must be considered when the seal is selected, so it can crimp properly on the vial. Cosmetic considerations may apply. For example, a certain color may indicate a certain drug, or a certain design may be preferred for ease of use in different environments, such as an operating room.

Plastic bags and vials have been used successfully to package injectable products or implants. The bags may be manufactured of HDPE, PVC, or LDPE; the vials have been manufactured of PP or multiple layers; and PET trays have been used to package implants. The materials must meet 21 CFR requirements, the applicable sections of <661>, and Biological Reactivity Testing USP <87>, <88>. The bags are prone to the same problems discussed for liquids in permeable plastics. Permeation and excessive weight loss and migration of chemicals into the product can be significant. If the bags are stored unprotected at an elevated temperature, the problem is exacerbated. The more permeable containers are packaged in a foil overwrap. Again, as discussed, the foil overwrap should not contain chemicals that can migrate into the product. If the water weight loss is too great in an IV bag and a drug is injected into it, it is possible for the excipients or drug to fall out of solution. The solutions become super saturated, and crystals form. In some climatic conditions, it is still, therefore, preferred to use glass IV bottles in which the weight loss is not problematic. The actual product in the proposed package configuration should be evaluated under actual conditions of use, including shipping and storage, to ensure product integrity throughout its shelf life.

## QUALITY CONTROL

Characterization analysis should be conducted to provide assurances that the proper polymer type is used and that the physical parameters, which could impact the product efficacy and the container configuration suitability for use, are considered. For drug product manufacturers and commercial repackagers, techniques, such as infrared spectrometric analysis, density, melt-flow, and thermal and rheological tests, can assist in providing the necessary assurances of identity and performance. For pharmacists, the quality of the incoming components can be established through comparisons with control samples, weight, physical measurements, fit tests of caps with bottles, and verifying purchase information. Plastic parts or packages should be inspected routinely, on an incoming basis, for dimensional and attribute variability against statistically accepted sampling plans.

## OVERVIEW OF TEST METHODS

### IDENTITY

Though this may seem obvious, a basic identity test is critical to verify the material received corresponds to the material requested in the purchase order. The identity test can be the most important test performed. There have been cases in which the incorrect material has been shipped. Critical inspection of the materials and accompanying certificates of analysis from the supplier is essential to verify the receipt of the correct material. Errors can occur with the cap liner and heat seal, the neck finish, bottle weight, dropper assembly, and pharmaceutical coil. A fitness test should be performed for closures and dropper assemblies with the bottles. Material treatments must be verified, for example, whether a rubber stopper has been siliconized or not or whether a blister foil has the correct plastic coating. USP <661> contains identity tests based on materials

of construction. It is important to note that there is currently no reference standard for linear low density polyethylene (LLDPE). LLDPE passes infrared spectroscopy but fails differential scanning calorimetry.

### EXTRACTABLES (MIGRANTS)

Extractables, migrants, and leachables are all interchangeable terms. The risk of drug failure from migrants in an HDPE bottle and a PP closure are extremely low, if the source of the bottles is from the United States or India. Since the implementation of USP <661> Plastics, most of these bottles, if tested, would pass. These same bottles may perform well with aqueous liquids, if they pass USP <661> and buffering capacity. Many of the bottle manufacturers conduct this testing and can provide the results at the point of sale. When contacting a closure supplier, it is important to inform them of the end use, so they can properly advise regarding material selection. The end use is an important determining factor in the selection of closure and liner materials based on the supplier's knowledge of the additives in their materials.

Oil based products require extra precautions and actual testing with the placebo and product to ensure compatibility and stability. The USP <661> Extractable testing is not applicable for oil-based products, because the extracting solvents do not replicate product contact. Oil-based products are notorious for leaching large amounts of chemical additives from the plastic and pulp. PET or glass is a better choice for the containers for oil-based products than polyethylene, polypropylene, and PVC.

For inhalation, injection, and implant products, the extractables testing is more critical, and the requirements are more stringent. It is important that suppliers understand the end use of the materials. Selecting materials with a minimum of leachable additives helps provide superior protection to the product. It is important to bear in mind that all packaging components in direct contact with the drug or device have the potential for chemical migration and should be carefully selected.

If the nebulers (LDPE form-fill-seal unit dose for liquids) are packaged with a foil overwrap, the inner layer of the foil should be free of additives. LDPE is available to coat the foil, to prevent additives migration. There are many different formulations for the types of glass. Some are more reactive than others, and it is important to learn the difference and use this information, when selecting appropriate containers for products.

### LIGHT TRANSMISSION

When trying to protect the drug from light, the container providing optimum protection is a sealed foil pouch or cold-form-blister. The next best protection is afforded by containers composed of amber glass, white HDPE, or amber PP. Many amber blisters, amber PS bottles, or PET bottles of various colors will not meet the USP <671> Light transmission limits of not more than 10%. Clear blisters are considered, by FDA, to be light resistant, when they are stored in cartons. Some drugs are highly light sensitive and require tighter limits than the current USP limits of not more than 10%. These requirements should be considered, when selecting suitable containers for these products.

### PERMEATION

Moisture permeation data has been extensively provided in this chapter. For both tablets and aqueous liquids, permeation is a critical issue. Moisture permeation is measured two ways, based on dosage form. For solid dosage forms, it is measured as moisture moving into the container from humidity in the air or from the container itself. For aqueous liquids (calculated as weight loss), it is measured as water migrating from the product to the container's exterior and into the atmosphere. Glass, HDPE, and PP provide sufficient protection against weight loss. Protecting against weight loss is critical to avoid overconcentration of the drug product. Unfortunately, many liquids, such as ophthalmic, otics, eye drops, and nebulers for inhalation products, are all packaged in LDPE. LDPE is considered a semipermeable plas-

tic. The integrity of the container system and wall thickness must be sufficient to protect the drug from excessive water loss over the shelf life.

### SUMMARY

When selecting a container closure system, it is important to know the regulations, the product's critical attributes, and the ability of the container to meet the efficacy, stability, storage conditions, and delivery requirements of the drug product. For each product class, there are certain known critical attributes. It is also critical to know the properties of the materials of construction. (Refer to Table 35-5—Summary of Information on Materials of Construction.) For tablets and powders, there are standard HDPE bottles and PP closures that can meet the requirements for protection from light and permeation. There are multiple sources of closure heat seals and liners, which can meet the product requirements. Based on the product, pharmaceutical coil can be added to reduce breakage of friable tablets, and desiccant can be added (on top of the tablets) to remove humidity in the headspace of the bottles. If pharmaceutical coil is needed for highly moisture sensitive products, Polyester Coil is recommended, because it has essentially no moisture. Once the container is opened, the desiccants and coil should be discarded. If the product is repackaged, the manufacturer's expiration date is only meaningful, if the protection afforded by the new container is the same. For prescription vials, the child resistant closures perform better than the LDPE snap caps under repeat use. There are prescription vials on the market that can protect from light and perform as well or better than the manufacturer's container with the heat seals removed.

Containers manufactured of semipermeable plastics, such as PVC, PET, and LDPE, are at greater risk. These issues are less problematic, if HDPE or PP can be used, but that is not always the case. Squeeze bottles, dropper bottles, nebulers, and pouches may all be constructed of these materials. The wall thickness or film thickness of these containers must be such that they meet the permeation limits. In some cases, the permeation can be reduced by the use of an over wrap. If used, the testing must be done with the wrap in place to demonstrate its effectiveness. As with permeation, migration of chemicals into these containers also requires additional attention. Ink from the carton and chemicals from the paper and the glue have been detected in LDPE containers.

The contact surface of glass containers is a critical determining factor to the stability of the medical products packaged within them. Chemical and physical durability indicate the degree to which the product and container interact. Chemicals from the glass can migrate or leach into the product from the container. In unbuffered solutions, the migrating ions can cause a shift in the pH. Migrants can also cause aggregation, precipitation, and degradation in the product, thereby rendering it unacceptable for use.

Different types of unit dose packaging that lend themselves to the sophistication of the packaging operation are available. Drug manufacturers and commercial repackagers have the ability to choose from PVC, PVC/PVDC, PVC/Aclar, and cold form films for blister films and a number of foil lidstocks. The manufacturers and repackagers have the design and manufacturing support required for this sophisticated type of packaging configuration. They also have the equipment and validation support necessary to form-fill and seal the blisters in such a way as to demonstrate the efficacy of the system. The manufacturers and repackagers have the ability to print the bar codes for the NDC number on the back of each blister unit of the blister pack.

Hospitals and neighborhood pharmacies have less sophisticated designs and materials at their disposal. In these cases, the products are stored for shorter periods of time and, in many cases, are packaged pursuant to a prescription. Hospitals may use multiple systems, such as strip seals, blister cards, and cups. The strip machines have a number of materials available.

**Table 35-5. Summary of Information on Materials of Construction**

Common name	Abbrev.	CAS #	Structure	Uses	Products
Aclar/with PVC	NA	NA	NA	Blister film	Oral solids, tablets, capsules
Aluminum foil	Al	NA	Al	Tubes	Ointments, creams, lotions (treated)
				Foil-lid stock	Solids and liquids unit dose blister, pouches
Glass		NA	Type I	Vials, syringes Drug delivery systems Droppers, Bottles	Most products, including parenteral
			Type II		Most acidic and neutral aqueous preparations, including some parenterals
			Type III		Non-aqueous parenterals, powders, excluding freeze-dried preparations, and non parenterals
Polyethylene—high density	PE, HDPE	9002-88-4	$(\text{CH}_2\text{CH}_2)_n$ branched Homopolymer or hexane copolymer	Bottles	solid oral and aqueous liquids
				Bags	Bulk pouches for tablets
				Tubes	Aqueous based lotions, ointments
				IV bags	IV solutions
Polyethylene—low density	PE LDPE	9002-88-4	$(\text{CH}_2)_n$ linear	Nebules	Liquids for inhalation
				Flexible containers	Eye drops, squeeze bottles,
				Bottles, caps, tubes, dosage delivery systems	Nasal and throat sprays, topical liquids
				Film	
Polyethylene—linear low density	PE, LLDPE	9002-88-4	$(\text{CH}_2\text{CH}_2)_n$ linear	Film, coatings	Bulk bags for tablets
				Heat seals	Inside caps for tablets, capsules and aqueous liquids, pouches
Polypropylene	PP	9003-07-0	$(\text{CH}_2(\text{CH}_3)\text{CH})_n$ Homopolymer, Random copolymer	closures	Tablets, capsules, non-sterile liquids, powders for reconstitution
				Tubes, jars	Creams, ointments
				Prescription vials	Tablets and capsules
Polyvinyl chloride	PVC	9002-86-2	$(\text{CH}_2\text{CHClCH}_2\text{CHCl})_n$	IV bags	IV solutions and drugs
				Blister film	Solid oral dosage forms
				bottles	Some liquids
Polyvinyl pyrrolidone with PVC	PVDE	9003-39-8	$(\text{C}_6\text{H}_9\text{NO})_n$	Blister film	Tablets, capsules
Polystyrene	PS	9003-53-6	$(\text{CH}(\text{C}_6\text{H}_5)\text{CH}_2)_n$	Blister packs bottles	
Polyethylene terephthalate	PET	25038-59-9	$(\text{C}_{10}\text{H}_8\text{O}_4)_n$	Calm shells trays	Implant drugs
				bottles	
Polyethylene terephthalate Glycolate	PETG	25038-59-9	$(\text{C}_{10}\text{H}_8\text{O}_4)_n$	Calm shells, trays	Implant drugs
				Bottles	Alcohol and oil based liquids
Rubber	Rubber	NA	NA	stoppers	Injections
				O rings	For drums Powders, tablets, capsules-
				Bulbs for dosage delivery systems	Non-sterile liquids

Foil-to-foil strips, if properly sealed, afford the maximum degree of protection. Pharmacies packaging for rehabilitation centers or assisted living facilities may use blister cards. There are methods for sealing and barrier materials that can protect the products for the shorter times they are in use.

For all aqueous liquid products, water weight loss is a critical attribute. Unlike solids, such as tablets and powders in which the critical amount of moisture permeation is different for each product, for liquids, the limits are based on the upper limits for potency. The usual limits of 90–110% mean that, if a product

does not degrade and the expiration date is 24 months, the container must not lose more than 10% of the net contents through its walls. If the potency limits are tighter than 110%, then the limits for moisture permeation must likewise be tighter.

The packaging or repackaging of non-aqueous liquids requires more attention and knowledge of the container components. Permeation of an oil-based product is not normally an issue. Oil-based products extract chemicals from components, such as HDPE, PVC, and PP bottles, pulp liners, and LDPE and PP caps. The safest choice for bottles is PET or glass. The closures

should be manufactured with lower amounts of additives than standard closures. Liners should be tested, since they are a primary contact surface. PET and glass bottles that meet light resistance standards can be purchased.

Selecting appropriate liquid medication dispensers depends on the therapeutic dosing requirements and the accuracy of the dispenser. It is important that the dosage delivery system be calibrated to deliver the prescribed dosage of the drug product. Not all syringes deliver the amount indicated by the calibration line, not all droppers have the same drop size, and not all cups and spoons deliver the prescribed dosage of the drug product. There should be administration instructions provided for the drug product.

As with all packaging components, it is, ultimately, the responsibility of the packager to determine a container's compatibility and suitability for use in the packaging of any given product.

**ACKNOWLEDGMENTS:** We would like to acknowledge Ed McKinley and Mary Foster for their research contribution and collaboration over the years. We would like to acknowledge Brian Reamer for his research on light transmission of bottles, and Elizabeth Deiss for her editorial review.

## INTRODUCTION

The practice of pharmacy is an ever-evolving profession. A non-scientific survey of community pharmacies has revealed that extemporaneously compounding of prescriptions increasingly occurs. Whether this is a result of the physician not writing for compounded medicines or the pharmacy not interested in preparing such medicines is a topic for discussion elsewhere. It is, however, undoubtedly driven by the pharmaceutical industry, addressing many disease treatment and prevention efforts by commercially manufacturing products for mass distribution by the healthcare system in the United States.

The Food and Drug Administration has levied large fines on manufacturers who have failed to comply with what are known as current Good Manufacturing Practices (cGMP). Several companies have been forced to operate under what is known as a "Consent Decree," due to significant deficiencies in cGMPs. Additionally, the FDA's approval of new products is trending downward, this being a result of companies focusing research and development activities on the next "blockbuster" compound and the Agency frequently issuing "not approvable" letters, requiring the sponsor company to conduct additional studies. At the community level, more independent pharmacies are closing their doors or selling their patient lists to national or regional chains. Hospital settings are seeing a greater degree of mergers, so economics are more favorable, and an influx of patients using the facility as a clinic, rather than an acute care provider.

In addition to the profession of pharmacy and pharmacy education has undergone dramatic changes in the United States, since the last edition of the *Remington* was published. The PharmD degree has been the entry-level degree for anyone intending to practice pharmacy for well over a decade. Many practicing pharmacists pursue certification in sub-specialties, such as diabetes or cancer. The focus of pharmacy education has become even more clinically oriented on outcomes and patient interactions. This focus comes at the expense of basic pharmaceuticals, and in some instances, due to course loads, electives, such as industrial pharmacy courses, are not considered by students. The pharmaceutical industry used to be able to hire graduates with pharmacy degrees for positions in production, quality control, and dosage-form development, due to the breadth of understanding the graduate had of pharmaceutical processes. Unfortunately, gaining this knowledge as a PharmD has become increasingly difficult, unless the student pursues an advanced degree in industrial pharmacy or pharmaceuticals. However, many schools of pharmacy have introduced new degree programs focusing on the pharmaceutical sciences. These programs provide a foundation in the sciences that the industry requires of new hires: pre-formulation, analytical chemistry, formulation development, and manufacturing science.

It is imperative that pharmacists in all practice settings know it is their obligation to understand what is used to prepare a medication, whether by commercial means or by extemporaneously compounding it in a practice setting. This chapter does not address the legal aspects of community compounding by a pharmacist, nor does it explain all the specifics of formulating a product for commercial manufacturing. The information contained in these material summaries is intended to provide the practicing pharmacist sufficient background to address questions from an ever more interested patient about what some

of the ingredients in the products they are prescribed or purchasing over the counter are. A more detailed review of these excipients and their commercial applicability to dosage form development can be found in the *Handbook of Pharmaceutical Excipients* (Rowe, Sheskey, and Quinn, eds.), as well as other chapters in this edition of *Remington*.

These excipients, ingredients other than the active pharmaceutical ingredient, in a dosage form have different functionalities, depending on how they are used in a formulation or the type of formulation they are incorporated into. For a more in-depth discussion addressing dosage form development and manufacturing concerns around excipient choice and use, refer to the chapter on Industrial Pharmacy in this edition of *Remington's* or the current edition of the *USP-NF* General Information Chapter <1059>. Every effort has been made to obtain structural forms of the excipients discussed in this chapter. In some instances, the structures have been obtained from references, such as the *Merck Index*, the *Handbook of Pharmaceutical Excipients*, past editions of *Remington's*, or other recognized references. The categories of excipients and the names of the chemicals that fit into each category are subsequently listed:

## ANTIOXIDANTS

Such materials, when added to a product, prevent the active from degrading in the presence of oxygen or peroxides.

### Excipients

- Butylated Hydroxyanisole (BHA)
- Butylated Hydroxytoluene (BHT)
- Citric acid
- Sodium Metabisulfite

## BINDERS

These can be incorporated into a formulation either as a wet material, such as a starch paste or povidone solution, for wet granulation processes, or as a dry powder, such as microcrystalline cellulose, for direct compression or dry granulation processes.

### Excipients

- Alginate
- Sodium alginate
- Carboxymethyl cellulose sodium (CMC)
- Microcrystalline cellulose (MCC)
- Powdered cellulose
- Confectioner's sugar
- Dextrin
- Dextrose
- Ethylcellulose
- Guar gum
- Hydroxypropyl cellulose (HPC)
- Hypromellose (HPMC)
- Lactose
- Maltodextrin
- Methylcellulose
- Povidone
- Starch
- Tragacanth
- Zein

## COATING AGENTS

Similar to taste masking technology, the first coatings were solutions of sucrose (12–20%). Once polymers were discovered and understood, they were applied in low concentrations (1–3%) using organic solvents. Current technology uses polymers manufactured as latex or pseudo-latex dispersions to avoid the use of organic solvents. Depending on the application, aesthetic or functional coating, the use levels can range from 2 to 20% of the weight of the material being coated.

### Excipients

- Carboxymethyl cellulose sodium (CMC)
- Carnauba Wax
- Cellulose acetate phthalate (CAP)
- Ethylcellulose
- Gelatin
- Hydroxypropyl cellulose (HPC)
- Hypromellose (HPMC)
- Maltodextrin
- Methylcellulose
- Starch
- Sucrose
- Zein

## COLORS AND PIGMENTS

There are two basic types of coloring agents for pharmaceutical products: dyes and lakes. Dyes are soluble forms of a particular color. They go into solution and can result in very deep, vibrant colors. Lakes are dyes that undergo a processing step that adheres them onto insoluble substrates, such as aluminum or calcium salts. Dyes are usually used in liquid products, whereas lakes are used in chewable products and coating solutions for tablets.

## DILUENTS/FILLERS

When considering solid dosage forms, such as tablets and capsules, these ingredients function as a bulking agent for low dose actives, facilitating compression or encapsulation. Diluents are also used in lyophilized products, serving the same purpose of providing bulk to the product, but might be different materials.

### Excipients

- Calcium carbonate
- Calcium sulfate
- Microcrystalline cellulose (MCC)
- Powdered cellulose
- Dextrates
- Dextrin
- Dextrose
- Kaolin
- Lactose
- Maltodextrin
- Mannitol
- Starch
- Sucrose

## DISINTEGRANTS

These materials facilitate the breakdown of oral solid dosage forms in the gastrointestinal tract. Tablets and capsules must breakdown from their original form to large particles and then to small particles, increasing surface area from which drug can dissolve. Early disintegrants included different types of starch, as a dry addition to a formulation, due to the ability of the starch to swell. Significant improvement in disintegrant performance was achieved with the introduction of the first super-disintegrant, sodium starch glycolate. There are also newer, polymeric disintegrants, such as croscarmellose sodium. These super-disintegrants exhibit significantly superior swelling and water wicking capability, compared to starch, and can be used at much lower concentrations.

## Excipients

- Alginic Acid
- Sodium alginate
- Microcrystalline cellulose (MCC)
- Croscarmellose sodium
- Crospovidone
- Guar gum
- Polyacrilin Potassium
- Sodium Starch Glycolate

## EMOLLIENTS

These materials are usually used in conjunction with emulsifying agents in the preparation of topical products. An emollient is intended to impart a soft, supple feeling to the skin, helping the skin to retain moisture and natural flexibility.

### Excipients

- Glycerin
- Glyceryl monostearate
- Isopropyl Myristate
- Petrolatum
- Polyethylene Glycols

## EMULSIFIERS

These materials typically exhibit some surfactant characteristics but also facilitate micelle formation, which allows for stable uniform products consisting of oil-in-water or water-in-oil biphasic emulsions or tri-phasic emulsions.

### Excipients

- Carbomer
- Carrageenan
- Lanolin
- Lecithin
- Mineral Oil
- Oleic Acid
- Oleyl alcohol
- Pectin
- Poloxamer
- Polyoxyethylene Sorbitan Fatty Acid Esters
- Sorbitan Esters
- Triethanolamine

## FLAVORS

These materials were originally natural products; however, many companies have been created to develop synthetic versions of different flavors. Most manufacturers of finished products provide these Flavor Houses with samples of in-process material for flavoring. By using a Flavor House, unique flavor notes can be imparted to the product that will facilitate brand recognition.

## GLIDANTS/ANTIADHERENTS

These products facilitate the movement of the powder or granulation prior to compaction, compression, or encapsulation. Some of these materials possess moisture scavenging capabilities similar to desiccants. By facilitating flow of the material, there is less weight variability of the dosage form, resulting in more consistent dosing of the active ingredient(s). Additionally, by controlling the amount of moisture available to interact with the active ingredient(s) and other excipients, the product's stability is enhanced.

### Excipients

- Colloidal silicon dioxide
- Talc

## HUMECTANTS

These materials promote the retention of moisture. They are necessary in some semi-solid products (creams and gels) to prevent the dosage form from drying out. They also help prevent

a phenomenon known as cap-locking. Cap-locking involves liquid products that recrystallized at the bottle-cap interface and makes opening the bottle difficult after prolonged periods of non-use. These materials are hygroscopic and should be stored in well closed containers prior to use.

### Excipients

- Glycerin
- Propylene Glycol
- Sorbitol
- Triethanolamine

### LUBRICANTS

These materials facilitate compression/compaction of tablets and consolidation of capsule plugs. Lubricants are used in small quantities in the formulation. One could think of a particle of lubricant as a deck of cards. When the deck is undisturbed, it has a very small coverage area; however, when the individual cards are randomly tossed on a table the coverage area is greatly increased. That is how lubricants, like Magnesium, stearate function. Other lubricants, such as Stearic acid, melt during compaction/compression and exert their lubricant effects in that manner. Many lubricants are hydrophobic—water repellent. If used at too high a concentration or blended for too long, tablet hardness and/or dissolution could be negatively affected.

### Excipients

- Calcium stearate
- Glyceryl monostearate
- Isopropyl Myristate
- Magnesium stearate
- Polyvinyl Alcohol
- Sodium Stearyl Fumarate
- Stearic Acid
- Talc

### PLASTICIZERS

Plasticizers lower the glass transition temperature of polymers, specifically polymers used for coatings. By lowering the glass transition temperature, the polymers can partially melt, and the droplets can coalesce to form a completely sealed coating on a tablet or spheroid at a lower temperature, thus, preventing the active from being exposed to elevated processing temperatures. This affords better, more consistent release of the active.

### Excipients

- Glycerin
- Propylene Glycol
- Triacetin
- Triethanolamine

### PRESERVATIVES

If these materials prevent the initiation and growth of microorganisms in products, they are known as bactericidal preservatives. Some preservatives, either by concentration or activity, may only maintain the bacteria level in the product at the time of manufacture and are referred to as bacteriostatic preservatives.

### Excipients

- Alcohol
- Benzalkonium chloride
- Boric acid
- Butylated Hydroxyanisole (BHA)
- Butylated Hydroxytoluene (BHT)
- Butylparaben
- Methylparaben
- Phenol
- Phenethyl Alcohol
- Potassium Sorbate

- Propylene Glycol
- Propylparaben
- Sorbic Acid

### PROPELLANTS

These materials are found exclusively in aerosolized delivery systems. Early propellants were CFCs—chlorinated fluoro-carbons—now many non-CFC products have reached the market and are known as HFCs.

### Excipients

- Difluoroethane
- Nitrogen

### PROTECTIVE COLLOIDS

These materials are added to suspensions to protect the suspending agent and other colloidal sized particles from settling. These work in conjunction with the suspending agents or viscosifiers.

### Excipients

- Hydroxypropyl cellulose (HPC)
- Hypromellose (HPMC)
- Methylcellulose

### SIALAGOGUES

These materials are usually acidic, and their purpose in a formulation is to stimulate the production of saliva. They are mostly found in chewable products for children or in gum-based products. By facilitating the production of saliva, the masticated product is swallowed more readily, limiting the objectionable flavor of the active from lingering too long.

### Excipients

- Citric acid
- Fumaric acid
- Tartaric acid

### SURFACTANTS

Surfactants function by decreasing the surface tension of a material, coating agent, and a substrate, a tablet. By reducing the surface tension, the coating can more uniformly cover the tablet surface, resulting in a more aesthetically pleasing product. When used in suspension, the surfactant facilitates the wetting of the drug particle, facilitating its ability to go into solution.

### Excipients

- Polyethylene Glycols
- Polyoxyethylene Sorbitan Fatty Acid Esters
- Sodium Lauryl Sulfate
- Sorbitan Esters

### SUSPENDING AGENTS

Suspending agents are similar to viscosifiers in a formulation. They function by keeping small particles of active, and possibly other excipients, suspended during the shelf life of the product.

### Excipients

- Acacia
- Agar
- Carbomer
- Carboxymethyl cellulose sodium (CMC)
- Carrageenan
- Microcrystalline cellulose and Sodium Carboxymethyl cellulose Co-processed
- Colloidal silicon dioxide
- Dextrin
- Guar gum
- Hydroxypropyl cellulose (HPC)
- Hypromellose (HPMC)

Kaolin  
Methylcellulose  
Pectin  
Polyvinyl Alcohol  
Povidone  
Tragacanth

## SWEETENERS

Sweeteners are materials used in both solid and liquid dosage forms that impart sweetness to the product. Sucrose is the standard against which all sweeteners, both natural and artificial, are measured. In addition to being many more times sweeter than sucrose, artificial sweeteners have the advantage of not impacting blood sugars of diabetic or pre-diabetic patients, and they are considered non-cariogenic.

## Excipients

Acesulfame Potassium  
Aspartame  
Confectioner's sugar  
Dextrates  
Dextrose  
Fructose  
Mannitol  
Saccharin  
Sorbitol  
Sucralose  
Sucrose  
Xylitol

## TASTE-MASKING AGENTS

The original taste maskers were very high concentrations of sweeteners. The next generation of taste-masking technology involved polymers that coated particles of active ingredients. Newer taste-masking technology involves enveloping/cloaking polymers that hide the particle of active from the taste buds.

## Excipients

Confectioner's sugar  
Polyacrilin Potassium  
Poloxamer

## VISCOSIFIERS

Viscosifiers (thickening agents) are similar in function to suspending agents; both impart thickness to liquid products. Some viscosifiers go into solution, such as certain cellulose based polymers, resulting in a Newtonian-type viscosity. Other materials increase viscosity, while imparting a yield stress to the suspension. This type of product is known as thixotrope.

## Excipients

Acacia  
Agar  
Sodium alginate  
Bentonite  
Carbomer  
Carboxymethyl cellulose sodium (CMC)  
Guar gum  
Hydroxypropyl cellulose (HPC)  
Hypromellose (HPMC)  
Methylcellulose  
Pectin

## MATERIAL SUMMARIES

### OFFICIAL NAME: ACACIA

INN: Acacia  
Synonyms: Gum Arabic  
Chemical Name & CAS Number: Acacia (9000-01-5)

**Molecular Formula:** A complex containing principally calcium, magnesium, and potassium salts of the polysaccharide *arabic acid*, which on acid hydrolysis yields L-arabinose, L-rhamnose, D-galactose, and an aldobionic acid containing D-glucuronic acid and D-galactose.

**Structure:** A very complex gum, which has no specific structural formula

**Description:** White to yellowish white, angular microscopic fragments, spheroidal tears or powder

**Properties:** Soluble 1 in 20 of glycerin and propylene glycol, Insoluble in alcohol (ethanol 95%) and 1 in approximately 2.7 of water at room temperature; 5% aqueous solution pH 4.5–5.0; moisture content 8–13%; specific gravity 1.35–1.49; Solution viscosity varies, depending upon the source of the material, presence of salts (calcium, sodium, etc.), the pH of the solution, and storage conditions of the acacia prior to use.

**Incompatibilities:** Alcohol or alcoholic solutions precipitate acacia as a stringy mass, when the alcohol amounts to more than about 35% of the total volume. Solution is affected by dilution with water. The mucilage is destroyed through precipitation of the acacia by heavy metals. Borax also causes a precipitation that is prevented by glycerin. It contains calcium and, therefore, possesses the incompatibilities of this ion.

**Uses:** As a suspending agent for insoluble substances in water, in the preparation of emulsions.

### OFFICIAL NAME: ACESULFAME POTASSIUM

INN: Acesulfame Kalicum

Synonyms: Ace-K, Acesulfame-K

**Chemical Name & CAS Number:** 6-Methyl-1,2,3-oxathiazin-4(3H)-one-2,2-dioxide potassium salt (55589-62-3)

**Molecular Formula:** C<sub>4</sub>H<sub>4</sub>KNO<sub>4</sub>S

**Structure:**

**Description:** A white colored powder

**Properties:** Solubility approximately 1 in 3.7 of water at 20°C, 1 in 1000 of ethanol; exhibiting 200 times the sweetening ability of sucrose

**Incompatibilities:** No known incompatibilities

**Use:** Sweetening Agent

### OFFICIAL NAME: AGAR

INN: Agar-Agar

Synonyms: Agar, Vegetable Gelatin; Gelosa; Chinese or Japanese Gelatin

**Chemical Name & CAS Number:**

**Molecular Formula:** Varies, but the commonality is a 1–3 linked β-D-galactopyranosyl unit joined by a 1–4 linkage to a 3,6-anhydro α-D-galactopyranosyl unit

**Structure:** Varies greatly, depending on the source of the material

**Description:** A white to off-white hygroscopic powder

**Properties:** Insoluble in cold water and alcohol; slowly solubilizes in hot water to approximately 1–1.5% w/w. When cooled, the solution produces a stiff gel that can melt at 60–100°C, depending on composition.

**Incompatibilities:** Salt solutions can impact the gel formation of the polymer

**Use:** Substitute for gelatin, gelling agent

### OFFICIAL NAME: ALCOHOL

INN: Alcohol; Ethanol; Ethanolum

Synonyms: Ethanol; Ethyl alcohol, grain alcohol

**Chemical Name CAS Number:** Ethanol (64-17-5)

**Molecular Formula:** C<sub>2</sub>H<sub>6</sub>O

**Description:** A clear, volatile liquid with a characteristic odor and burning taste

**Properties:** Miscible with water and glycerin; boiling point 78°C

**Incompatibilities:** Acacia solutions (precipitation of the acacia gum), oxidizing materials while in acidic conditions

**Use:** As a preservative in concentration greater than 10%; as a disinfectant in concentrations of 60–90%; as a co-solvent for certain active pharmaceutical ingredients or in film coating and tablet printing unit operations; and as a vehicle for both oral and topical finished products

### OFFICIAL NAME: ALGINIC ACID

**INN:** Acidum alginicum

**Synonyms:** L-gulo-D-mannoglycuronan; Kelaid, polymannuronic acid; Satialgine

**Chemical Name & CAS Number:** Alginic acid [9005-32-7]

**Molecular Formula:** Mixtures of  $\beta$ -(1-4)-D-mannosyluronic acid and  $\alpha$ -(1-4)-L-gulosyluronic acid. The general formula is  $[C_6H_8O]_n$ .

**Structure:**

**Description:** A fibrous powder that is white to yellow-white that is odorless and tasteless

**Properties:** pH of 1.5-3.5 of a 3% aqueous dispersion. The powder has a density of approximately 1.6 g/cc with a moisture content of 7%. The powder is soluble in alkali solutions; practically insoluble in ethanol and other organic solvents. The powder does not dissolve in water, but swells by absorbing 200–300 its weight in water.

**Incompatibilities:** Strong oxidizing agents and alkaline earth metals; in the presence of di- and tri-valent ions, forms a gelatinous white precipitate.

**Uses:** In solid dosage forms, as either a binder (as a solution) or as a disintegrant (in dry form), as a viscosifying agent in oral liquids, and a stabilizer for emulsions

### OFFICIAL NAME: SODIUM ALGINATE

**INN:** Alginic acid; Natrii Alginas

**Synonyms:** Algin, Kelcosol, sodium polymannuronate

**Chemical Name & CAS Number:** Sodium alginate [9005-38-3]

**Molecular formula:** The purified carbohydrate product extracted from brown seaweeds. It consists chiefly of the sodium salt of alginic acid, a polyuronic acid composed of beta-D-mannuronic acid residues, linked so the carboxyl group of each unit is free, while a glycosidic linkage shields the aldehyde group.

**Description:** An odorless, tasteless, white to yellow-white powder that is hygroscopic

**Properties:** A 1% solution has an approximate pH of 7.2; the material is soluble in ethanol and other organic solvents and aqueous solutions with a pH of less than 3. The material is slowly soluble in water, forming a viscous solution at concentration up to 1%

**Incompatibilities:** As for Alginic acid

**Uses:** As a binder or disintegrant in oral solid dosage forms; as a thickening agent for topical dosage forms; as an adhesive/reservoir agent for transdermal patches; and as an encapsulating agent for novel drug delivery

### OFFICIAL NAME: ASPARTAME

**INN:** Aspartame; Aspartamum

**Synonyms:** NutraSweet; Equal; Tri-Sweet

**Chemical name:** N- $\alpha$ -L-Aspartyl-L-phenylalanine 1-methyl ester (22839-47-0)

**Molecular Formula:**  $C_{14}H_{18}N_2O_5$

**Structure:**

**Description:** White to off-white crystalline powder that is approximately 200 times more sweet than sucrose

**Properties:** Density is between 0.2 and 0.7 g/cc, depending on the grade; only slightly soluble in ethanol and sparingly soluble in room temperature water

**Incompatibilities:** Some reactions have been recorded with sugar alcohols (sorbitol and mannitol), magnesium stearate, and dicalcium phosphate. Aspartame should not be used when a solution requires heating as degradation does occur.

**Uses:** As a sweetening agent

### OFFICIAL NAME: BENTONITE

**INN:** Bentonite; Bentonitum; Bentonite

**Synonyms:** Wilkinite; Soap Clay; Mineral Soap; Vee gum HS

**Chemical Name & CAS Number:** Bentonite [1302-78-9]

**Molecular Formula:**  $Al_2O_3 \cdot 4SiO_2 \cdot H_2O$

**Description:** An odorless, very fine crystalline, clay-like material gray colored with an almost bi-modal particle size distribution of 1-2 $\mu$  and 50-150 $\mu$ . Bentonite has a slight earthy taste.

**Properties:** Very hygroscopic material, with a moisture content of 5–12% at ambient relative humidity but capable of increasing its moisture content to 20% at 90% relative humidity. Insoluble in all known solvents, swells to about 12 times its original volume in water. A 2% aqueous dispersion has a pH of  $\approx$ 10. Viscosity increases with increasing concentration.

**Incompatibilities:** Bentonite suspensions are precipitated by acids. Additionally, mixing alcohol into a bentonite suspension will result in precipitation.

**Uses:** Used in topical formulations to form the gel or suspension. Prior to more effective methods, it was used for taste masking oral preparations.

### OFFICIAL NAME: BENZALKONIUM CHLORIDE

**INN:** Benzalkonium chloride; Benzalkonii chloridum

**Synonyms:** Alkylbenzyltrimethylammonium chloride; BKC; BAC

**Chemical Name & CAS Number:** alkyltrimethyl(phenylmethyl) ammonium chloride (8001-54-5)

**Molecular Formula:**  $[C_6H_5CH_2N(CH_3)_2R]Cl$ , where R can be  $-C_8H_{17}$ ,  $C_{12}H_{25}$ ,  $C_{14}H_{29}$  and  $C_{16}H_{33}$

**Structure:**

**Description:** A white to yellow-white powder, flake, or gel

**Properties:** 10% solution pH 5–8; hygroscopic; soapy to touch; density 0.98g/cc; very soluble in water and alcohol

**Incompatibilities:** Aluminum salts, anionic surfactants, citrates, iodides, hypromellose, hydrogen peroxide, lanolin, nitrates, and nonionic surfactants in high concentrations, proteins, permanganates, salicylates, and tartrates

**Use:** Preservative

### OFFICIAL NAME: BORIC ACID

**INN:** Boric acid; Acidum boricum

**Synonyms:** Boracic Acid; Orthoboric Acid; Boracic acid; boron trihydroxide

**Chemical Name & CAS Number:** Boric acid (10043-35-3)

**Molecular Formula:**  $H_3BO_3$

**Description:** Hygroscopic white crystalline powder

**Properties:** Soluble 1 g in 18 mL water, 18 mL alcohol; 5% solution pH 3.5-4.1; density 1.435 g/cc

**Incompatibilities:** Strong bases, alkali, reacts violently with potassium and acid anhydrides and complexes with glycerin

**Uses:** As a buffer and preservative for eye drops

#### OFFICIAL NAME: BUTYLATED HYDROXYANISOLE

**INN:** BHA; Butylhydroxyanisolum; Butylated hydroxyanisole

**Synonyms:** BHA; Sustane; Tenox

**Chemical Name & CAS Number:** 2-tert-Butyl-4-methoxyphenol (25013-16-5)

**Molecular Formula:**  $C_{11}H_{16}O_2$

**Structure:**

**Description:** White or slightly yellow, waxy solid, having a faint, characteristic odor

**Properties:** Insoluble in water; 1 g in 4 mL alcohol, 2 mL chloroform or 1.2 mL ether; antimicrobial activity against molds and gram positive bacteria.

**Storage:** In a tightly sealed container, which will protect the material from light. Exposure to light causes discoloration and decreased activity.

**Incompatibilities:** Avoid use with peroxides and permanganates; contact with oxidizing agents may result in spontaneous combustion. Avoid iron salts, as these reduce effectiveness.

**Uses:** As an antioxidant and antimicrobial agent in liquid and semi-solid preparations

#### OFFICIAL NAME: BUTYLATED HYDROXYTOLUENE

**INN:** Butylhydroxytoluenem; Butylated hydroxytoluene

**Synonyms:** Agidol, BHT

**Chemical Name & CAS Number:** 2,6-Di-tert-butyl-4-methylphenol (128-37-0)

**Molecular Formula:**  $C_{15}H_{24}O$

**Structure:**

**Description:** White, tasteless crystals with a mild odor; stable in light or air

**Properties:** Melts at 70°C; insoluble in water; 1 g in 4 mL alcohol, 1.1 mL chloroform, or 1.1 mL ether

**Incompatibilities:** Avoid use with peroxides and permanganates, contact with oxidizing agents may result in spontaneous combustion. Avoid iron salts, as these reduce effectiveness.

**Uses:** As an antioxidant

#### OFFICIAL NAME: BUTYLPARABEN

**INN:** Butyl Parahydroxybenzoate; butylparaben

**Synonyms:** Butoben, 4-hydroxybenzoic acid butyl ester

**Chemical Name & CAS Number:** Butyl-4-hydroxybenzoate (94-26-8)

**Molecular Formula:**  $C_{11}H_{14}O_3$

**Structure:**

**Description:** White to off-white crystalline powder that is odorless and tasteless

**Properties:** Very slightly soluble in water or glycerin, freely soluble in propylene glycol, melting range 68-72°C

**Incompatibilities:** Avoid nonionic surfactants, as these reduce antimicrobial effectiveness, due to micellization. Possible absorption of butylparaben by plastic bottles is under investigation.

**Use:** Antimicrobial preservative for liquid and semi-solid preparations

#### OFFICIAL NAME: CALCIUM CARBONATE

**INN:** Carbonic acid, calcium salt; Calcium carbonate

**Synonyms:** Cal-Carb; precipitated calcium carbonate

**Chemical Name & CAS Number:** Carbonic acid calcium salt (471-34-1)

**Molecular Formula:**  $CaCO_3$

**Description:** Odorless and tasteless white powder, crystals, or granules

**Properties:** Moisture content less than 1%, insoluble in all pharmaceutical solvents; particle size can vary depending upon grade. Reacts with acids to release carbon dioxide.

**Incompatibilities:** All acids and ammonium salts

**Uses:** As a diluent in tablet formulations and as an opacifier in tablet coatings. It does have therapeutic uses as a nutritional supplement and as an antacid.

#### OFFICIAL NAME: CALCIUM STEARATE

**INN:** Octadecanoic acid, calcium salt; Calcium stearate

**Synonyms:** Calcium distearate; stearic acid, calcium salt

**Chemical Name & CAS Number:** Calcium stearate [1592-23-0]

**Molecular Formula:**  $C_{36}H_{70}CaO_4$

**Structure:**

**Description:** A very fine white to off-white powder that is tasteless, but does have a slight characteristic odor

**Properties:** Practically insoluble in water and ethanol, an approximate surface area of 4.7-8.0 m<sup>2</sup>/g and a moisture content of approximately 3%.

**Incompatibilities:** No known incompatibilities

**Use:** As a tablet and capsule lubricant at levels of less than 3%

#### OFFICIAL NAME: CALCIUM SULFATE

**INN:** Calcium sulphate dihydrate; Calcium sulfate

**Synonyms:** Sulfuric acid, calcium salt (1:1); Gypsum; Terra Alba

**Chemical Name & CAS Number:** Calcium sulfate [7778-18-9];  $CaSO_4$  dihydrate [10101-41-4]

**Molecular Formula:**  $CaSO_4$  and  $CaSO_4 \cdot 2H_2O$

**Description:** Fine, white to slightly yellow-white, odorless powder or granule

**Properties:** Dissolves in diluted HCl; slightly soluble in water; free flowing powder/granule with a density of 2.3 g/cc

**Incompatibilities:** Forms complexes with amines and amino acids, when excessive moisture is present, certain antibiotic preparations (i.e., tetracycline, erythromycin, which complex with calcium containing products)

**Uses:** As a diluent in the manufacture of compressed tablets

#### OFFICIAL NAME: CARBOMER

**INN:** Carbomer; Carbomera

**Synonyms:** Acrylic acid polymer; carboxyvinyl polymer; carboxy polymethylene; polyacrylic acid

**Molecular Formula:** A synthetic high-molecular-weight cross-linked polymer of acrylic acid; contains 56-68% of carboxylic

acid (COOH) groups. The viscosity of a neutralized preparation of carbomer 934P (2.5 g/500 mL water) is 30,000–40,000 mPa.s.

**Structure:**

**Description**—White, fluffy powder with a slight, characteristic odor; hygroscopic

**Properties:** Dissolves in water, alcohol, or glycerin, when neutralized with alkali hydroxides or amines; 0.5% dispersion pH 3; specific gravity about 1.41; moisture content 2%; viscosity varies depending upon grade, salt type and concentration, and pH of solution

**Incompatibilities:** Resorcinol, phenol, cationic polymers, strong acids, and high levels of electrolytes

**Uses:** As a thickening, suspending, dispersing, emulsifying agent and gel former

### OFFICIAL NAME: CARBOXYMETHYLCELLULOSE SODIUM

**INN:** Carmellose sodium

**Synonyms:** Cellulose gum, CMC sodium

**Chemical Name & CAS Number:** Cellulose, carboxymethyl ether, sodium salt [9004-32-4]

**Structure:**

**Description:** Depending on the grade, CMC is a white to off-white odorless powder of varying particle size

**Properties:** This hygroscopic material should contain less than 10% water, density of 0.7 g/cc (tapped), viscosities of a 1%w/w aqueous solution can range from 10 to 8000 mPa.s, depending on the grade being evaluated.

**Incompatibilities:** Strongly acidic solutions and soluble salts of iron, aluminum, zinc, and mercury. Complexes can be formed with gelatin and pectin.

**Uses:** As a suspending agent for liquid formulations, as a binder for tablets or capsules (in solution) and as a coating agent on tablets

### OFFICIAL NAME: CARNAUBA WAX

**INN:** Carnauba wax; Cera wax; Cera carnauba

**Synonyms:** Brazil wax, caranda wax

**Chemical Name & CAS Number:** Carnauba wax (8015-86-9)

**Description:** Light-brown to pale-yellow, moderately coarse powder; characteristic bland odor;

**Properties:** Insoluble in water; specific gravity about 0.99; melts at about 84°C

**Uses:** As a polishing agent in the manufacture of coated tablets

### OFFICIAL NAME: CARRAGEENAN

**INN:** Carrageenan

**Synonyms:** Chondrus crispus, Irish moss, pearl moss

**Chemical Name & CAS Number:** λ-Carrageenan (9064-57-7)

κ-Carrageenan (11114-20-8)

ι-Carrageenan (9000-07-1)

**Molecular formula:** It is a variable mixture of potassium, sodium, calcium, magnesium, and ammonium sulfate esters of galactose and 3,6-an-hydrogalactose copolymers, the hexoses being alternately linked at the α-1,3 and β-1,4 sites in the polymer chain.

**Structure:**

*Kappa*

*Iota*

*Lambda*

**Description:** Yellow-brown to white, coarse to fine powder; odorless; tasteless. The three main types of copolymers present are *kappa*-carrageenan, *iota*-carrageenan, and *lambda*-carrageenan, which differ in the composition and manner of linkage of monomeric units and the degree of sulfation (the ester sulfate content for carrageenans varies from 18% to 40%). *Kappa*-carrageenan and *iota*-carrageenan are the gelling fractions; *lambda*-carrageenan is the non-gelling fraction.

**Properties:** All carrageenans hydrate rapidly in cold water, but only *lambda*-carrageenan does not require the presence of cations to initiate functionality. Gelling carrageenans require heating to about 80°C for complete solution when potassium and calcium ions are present.

**Incompatibilities:** All carrageenans are reactive with cationic materials, resulting in complexation.

**Uses:** As an emulsifying, suspending, and gelling agent

### OFFICIAL NAME: CELLULOSE ACETATE PHTHALATE

**INN:** Cellacefate, cellacephate; Cellulose acetate phthalate

**Synonyms:** Acetyl phthalyl cellulose; CAP; cellulose acetate hydrogen 1,2-benzenedicarboxylate

**Chemical Name & CAS Number:** Cellulose, acetate, 1,2-benzenedicarboxylate (9004-38-0)

**Structure:**

**Description:** Free-flowing, white powder; may have a slight odor of acetic acid

**Properties:** Insoluble in water or alcohol; soluble in acetone; moisture content of approximately 2.2%, a bulk density of approximately 0.26g/cc

**Uses:** As an enteric tablet coating material

### OFFICIAL NAME: MICROCRYSTALLINE CELLULOSE

**INN:** Microcrystalline cellulose; Cellulosum microcrystallinum

**Synonyms:** Cellulose gel; crystalline cellulose; Avicel PH

**Chemical Name & CAS Number:** Cellulose [9004-34-6]

**Molecular Formula:**  $(C_6H_{10}O_5)_n$ , where  $n = 220$

**Structure:**

**Description:** Fine, white, odorless, crystalline powder; consists of free-flowing, non-fibrous particles

**Properties:** Insoluble in water, dilute acids, or most organic solvents; slightly soluble in NaOH solution (1 in 20); density approximately 1.5120-1.668 g/cc; moisture content (grade specific) ranges from 1.5–5.0%; particle size varies by grade from <math>20\text{--}200\mu\text{m}</math>

**Incompatibilities:** Strong oxidizing agents

**Uses:** As a tablet diluent, disintegrant, and dry binder

#### OFFICIAL NAME: MICROCRYSTALLINE CELLULOSE AND SODIUM CARBOXYMETHYLCELLULOSE CO-PROCESSED

**Synonyms:** Cellulose gel

**Description:** Tasteless, odorless, white to off-white, coarse to fine powder

**Properties:** pH (dispersion) 6–8; swells in water, producing, when dispersed, a white, opaque dispersion; at concentrations above 2%, can form a thixotropic gel; insoluble in water, organic solvents, and dilute acids; soluble in strong acids. Temperature of liquid at time of dispersion will affect viscosity.

**Incompatibilities:** High concentrations of dissolved salts

**Uses:** As a thixotropic suspending agent

#### OFFICIAL NAME: POWDERED CELLULOSE

**INN:** Powdered cellulose

**Synonyms:** Elcema, Solka-Floc

**Chemical Name & CAS Number:** Cellulose [9004-34-6]

**Molecular Formula:**  $(C_6H_{10}O_5)_n$

**Structure:**

**Description:** White, odorless substance, consisting of fibrous particles, exhibiting degrees of fineness, ranging from a free-flowing dense powder to a coarse, fluffy, non-flowing material

**Properties:** Insoluble in water, dilute acids, and nearly all organic solvents; slightly soluble in NaOH solution (1 in 20); poorly flowing, due to its fibrous nature, but compressible; particle size is dependent upon the grade

**Incompatibilities:** No known incompatibilities

**Uses:** As a tablet diluent, binder, or adsorbent

#### OFFICIAL NAME: CETYL ALCOHOL

**INN:** Cetanol

**Synonyms:** Cetostearyl Alcohol; Palmityl Alcohol; Aldol 52

**Chemical Name & CAS Number:** 1-Hexadecanol (36653-82-4)

**Molecular Formula:**  $C_{16}H_{34}O$

**Structure:**

**Description:** Unctuous, white flakes, granules, cubes, or castings; faint characteristic odor and a bland, mild taste; consisting of a mixture of not less than 90% of cetyl alcohol, the remainder being mostly stearyl alcohol

**Properties:** Melts at 45–52°C; freely soluble in ethanol, practically insoluble in water; miscible with other melted waxes

**Solubility:** Insoluble in water; soluble in alcohol, chloroform, ether, or vegetable oils

**Uses:** As a base for suppositories, creams, and lotions; as a stabilizer in water-in-oil emulsions, due to its high water absorption characteristics and emollient

#### OFFICIAL NAME: CITRIC ACID

**INN:** Citric acid

**Synonyms:** 2-Hydroxypropane-1,2,3-tricarboxylic acid monohydrate

**Chemical Name & CAS Number:** 1,2,3-Propanetricarboxylic acid, 2-hydroxy-, Citric acid [77-92-9]  $C_6H_8O_7$ ; monohydrate  $C_6H_8O_7 \cdot H_2O$  [5949-29-1]

**Molecular Formula:** Citric acid  $C_6H_8O_7$ ; monohydrate  $C_6H_8O_7 \cdot H_2O$

**Structure:** Citric acid

**Description:** A white, granular to fine crystalline powder; odorless; strongly acid taste

**Properties:** 1 g in 0.5 mL water, 2 mL alcohol; density 1.5 g/cc

**Uses:** As an acidifier, antioxidant, buffering agent, and sialogogue

#### OFFICIAL NAME: COCOA BUTTER

**INN:** Cacao Butter

**Synonyms:** Cacao Butter; Theobroma Oil; Oil of Theobroma

**Chemical Name & CAS Number:** Theobroma Oil

**Molecular Formula:** It is a mixture of stearin, palmitin, olein, laurin, linolein, and traces of other glycerides.

**Description:** Yellowish, white solid; faint, agreeable odor; bland (if obtained by extraction) or chocolate-like (if obtained by pressing) taste; obtained from the roasted seed of *Theobroma cacao* Linné (Fam *Sterculiaceae*)

**Properties:** Usually brittle below 25°C; specific gravity 0.858-0.864 at 25°C; refractive index 1.454-1.458 at 40°C; slightly soluble in alcohol; not soluble in water

**Uses:** As a base for suppositories, creams, and lotions; essentially replaced by less variable semi-synthetic materials today

#### OFFICIAL NAME: COLLOIDAL SILICON DIOXIDE

**INN:** Colloidal anhydrous silica; Silica colloidalis anhydrica; Colloidal silicon dioxide

**Synonyms:** Colloidal silica; fumed silica; light anhydrous silicic acid; silicic anhydride

**Chemical Name & CAS Number:** Silica (7631-86-9)

**Structure:**  $SiO_2$  (60.08)

**Description:** Light, white, non-gritty powder

**Properties:** Insoluble in water or acids (except hydrofluoric); dissolved by hot solutions of alkali hydroxides; particle size approximately 15 nm; 4% solution pH 3.5-4.4

**Incompatibilities:** Diethylstilbestrol (DES)

**Uses:** As a moisture scavenger, glidant, or anti-caking agent in tablets and powders; as a suspending and thickening agent in liquid and semi-solid preparations

**OFFICIAL NAME: CONFECTIONER'S SUGAR**

**INN:** None

**Synonyms:** Icing sugar, powdered sugar

**Chemical Name & CAS Number:** A mixture of sucrose and corn starch, such that not less than 95% of the mixture is sucrose

**Description:** Fine, white, odorless powder; sweet taste; stable in air

**Solubility:** The sucrose portion is soluble in cold water; this is entirely soluble in boiling water.

**Uses:** As a binder in tablets, carrier in taste masking, a sweetening agent

**OFFICIAL NAME: COTTONSEED OIL**

**INN:** Cottonseed oil

**Synonyms:** Cotton Seed Oil; Cotton Oil

**Chemical Name & CAS Number:** Cottonseed Oil (8001-29-4)

**Molecular formula:** A mixture of mono-, di- and tri-glyceride fatty acid esters, comprising 39.3% linolenic acid, 33.1% oleic acid, 19.1% palmitic acid, 1.9% stearic acid, 0.6% arachidic acid, and 0.3% myristic acid

**Description:** Pale yellow, oily liquid with a bland taste; odorless or nearly so

**Properties:** Slightly soluble in alcohol; miscible with ether, chloroform, solvent hexane, or carbon disulfide; particles of solid fat may separate below 10°C; solidifies at about 0 to -5°C; specific gravity 0.915-0.921; viscosity approximately 70 mPa s

**Use:** As a solvent and vehicle for injections, emollient

**OFFICIAL NAME: CROSCARMELLOSE SODIUM**

**INN:** Carmellosum natricum conexum

**Synonyms:** Crosslinked Carboxymethylcellulose sodium; modified cellulose gum; Ac-Di-Sol

**Chemical Name & CAS Number:** Cellulose, carboxymethyl ether, sodium salt, crosslinked (74811-65-7)

**Structure:** Crosslinked polymer of carboxymethylcellulose sodium

**Description:** An odorless white to off-white powder

**Properties:** Density approximately 0.53 g/cc; particle size varies, depending on manufacturer; insoluble in water, though rapidly swells to 4–8 times its original size

**Incompatibilities:** Complexes with amine containing drugs

**Use:** A tablet/capsule disintegrant (super disintegrant due to its low use level (<2%))

**OFFICIAL NAME: CROSPROVIDONE**

**INN:** Crospovidone, Crospovidonum

**Synonyms:** Crosslinked povidone, crosslinked PVP, polyvinylpyrrolidone, PVPP; Polyplasdone XL; Kollidon CR

**Chemical Name & CAS Number:** 1-ethylene-2-pyrrolidinone homopolymer (9003-39-8)

**Molecular formula:** (C<sub>6</sub>H<sub>9</sub>NO)<sub>n</sub> > 1,000,000

**Description:** White to off-white, free flowing, tasteless/odorless, hygroscopic powder

**Properties:** Insoluble in water, although rapidly swells and wicks fluid into the center of a dosage form facilitating disintegration; particle size is dependent on the grade and manufacturer.

**Incompatibilities:** No known incompatibilities

**Uses:** As a tablet/capsule disintegrant (super disintegrant due to its low, <2% use level)

**OFFICIAL NAME: CYCLODEXTRIN**

**INN:** β-cyclodextrin, betadex

**Synonyms:** cycloamylose; cycloglucan

**Chemical Name & CAS Number:** β-cyclodextrin (7585-39-9)

**Molecular Formula:** β-cyclodextrin consists of 7 glucose units connected in a circle

**Structure:**

**Description:** Cyclodextrin is a cyclic oligosaccharine occurring as a white, almost odorless crystalline powder, having a slightly sweet taste

**Properties:** solubility 1 in 50 parts of water, 1 in 200 parts of propylene glycol, practically insoluble in ethanol; 13–15% moisture; particle size ranges from 7 to 45μ

**Incompatibilities:** Cyclodextrin can impact some antimicrobial agents, when both are in solution

**Uses:** As a solubility enhancer by way of inclusion complexation

**OFFICIAL NAME: DEXTRATES**

**INN:** Dextrate

**Synonyms:** Emdex, Corn Syrup Solids

**Chemical Name & CAS Number:** Dextrates (39404-33-6)

**Molecular Formula:** Purified mixture of saccharides (hydrated or anhydrous), with a dextrose equivalent of NLT 93% and NMT 99%

**Description:** A white, free-flowing, odorless powder that is sweet tasting. Dextrates are comprised of dextrose and 3–5% maltose and lesser amounts of higher dextrose oligomers (maltotriose, maltotetraose, etc.)

**Properties:** 1 in 1 parts in water, insoluble in ethanol; mean particle size of approximately 200μ; flow 9.3 g/sec

**Incompatibilities:** Incompatible with oxidizing agents and under the proper conditions primary and secondary amines

**Uses:** As a tablet diluent and sweetening agent for chewable tablets

**OFFICIAL NAME: DEXTRIN**

**INN:** Dextrin

**Synonyms:** British Gum; Starch Gum

**Chemical Name & CAs Number:** Dextrin (9004-53-9)

**Molecular formula:** (C<sub>6</sub>H<sub>10</sub>O<sub>5</sub>)<sub>n</sub>

**Structure:**

**Description:** White or yellow, amorphous powder (white: practically odorless; yellow: characteristic odor); dextrorotatory; does not reduce Fehling's solution; gives a reddish color with iodine

**Properties:** Soluble in boiling water (forming a gummy solution); less soluble in cold water; moisture content of 5%; density approximately 1.5 g/cc

**Incompatibilities:** Strong oxidizing agents

Uses: As a tablet diluent and binder; as a suspending agent

### OFFICIAL NAME: DEXTROSE

INN: Glucose; Glucose monohydrate; Dextrose; Glucosum monohydricum

Synonyms: Blood Sugar; Anhydrous Dextrose; Dextrose Monohydrate; D-(+)-Glucopyranose monohydrate; Medicinal Glucose; Purified Glucose; Grape Sugar; Bread Sugar; Cere-lose; Starch Sugar; Corn Sugar

Chemical Name & CAS Number: D-Glucose monohydrate (5996-10-1); anhydrous (50-99-7)

Molecular Formula: Monohydrate:  $C_6H_{12}O_6 \cdot H_2O$

Structure:

Description: White, odorless, sweet tasting crystalline or granular powder

Properties: Solubility 1 g in 1 mL of water or 100 mL of alcohol; more soluble in boiling water or boiling alcohol; density of 1.5 g/cc; melting point 83°C

Incompatibilities: Aldehyde form interacts with amines, amides, amino acids, peptides, and proteins. Novobiocin sodium, warfarin sodium, and kanamycin sulfate

Uses: As a filler/binder in solid dosage forms; sweetening agent for liquids and chewable tablets; and a tonicity agent and vehicle in parenteral formulations

### OFFICIAL NAME: DIFLUOROETHANE

INN: None

Synonyms: HFC 152A; halocarbon 152A

Chemical Name & CAS Number: 1,1-Difluoroethane (75-37-6)

Molecular Formula:  $C_2H_4F_2$

Structure:

Description: Liquefied gas at room temperature under its own vapor pressure. The liquid is odorless and tasteless.

Properties: Boiling point -24.7°C; critical temperature 113.5°C; surface tension 11.25 dynes/cm; viscosity 0.243 mPa.s

Uses: As an aerosol propellant

### OFFICIAL NAME: EDETIC ACID

INN: Edetic Acid; Acidum edeticum

Synonyms: EDTA; Ethylenediaminetetraacetic acid

Chemical Name & CAS Number: N,N'-1,2-ethanediybis[N-(carboxymethyl)glycine] (60-00-4)

Molecular Formula:  $(HOOCCH_2)_2NCH_2CH_2N(CH_2COOH)_2$

Structure:

Description: White, crystalline powder

Properties: Very slightly soluble in water; soluble in solutions of alkali hydroxides; pH of a 0.2% solution 2.2

Incompatibilities: With polyvalent ions, alkali containing products, strong oxidizers

Uses: As a metal complexing agent

### OFFICIAL NAME: ETHYLCELLULOSE

INN: Ethylcellulose

Chemical Name & CAS Number: Cellulose ethyl ether (9004-57-3)

Molecular Formula:  $C_{12}H_{23}O_6(C_{12}H_{22}O_5)_n$

Structure:

Description: Free-flowing, tasteless white to light tan powder

Properties: Practically insoluble in water, glycerin and propylene glycol; density 0.4g/cc;  $t_g$  129–133°C

Uses: As a tablet binder for modified release tablets, film-coating tablets, and taste-masking barrier for chewable products

### OFFICIAL NAME: ETHYL OLEATE

INN: Ethyl oleate; Ethylis oleas

Synonyms: Oleic acid, ethyle ester, Ethyl 9-octadecenoate

Chemical Name & CAS Number: (Z)-3,9-Octadecenoic acid, ethyl ester (111-62-6)

Molecular formula:  $C_{20}H_{38}O_2$

Structure:

Description: Mobile, practically colorless liquid, with an agreeable taste

Properties: Specific gravity 0.866-0.874; acid value not greater than 0.5; iodine value 75–85; does not dissolve in water; miscible with vegetable oils, mineral oil, alcohol, or most organic solvents

Incompatibilities: May cause some types of rubber to dissolve or swell

Uses: As a vehicle for certain parenteral preparations

### OFFICIAL NAME: FRUCTOSE

INN: Fructose; Fructosum

Synonyms: Fruit sugar, levulose, fructopyranose

Chemical Name & CAS Number: D-Fructose (58-48-7)

Molecular Formula:  $C_6H_{12}O_6$

Structure:

Description: Odorless crystals or powder with a very sweet taste

Properties: pH 5.35 of a 9% solution; density 1.58g/cc; solubility: 1 part in .3 parts water, 15 parts of ethanol

Incompatibilities: Forms brown color in the presence of strong acids or alkalis, aldehyde can react with amines

Uses: As a sweetening agent in tablets and liquids

### OFFICIAL NAME: FUMARIC ACID

INN: Fumaric Acid

Synonyms: Allomaleic acid; boletic acid

Chemical Name & CAS Number: (E)-2-Butenedioic acid (110-17-8)

**Molecular Formula:**  $C_4H_4O_4$

**Structure:**

**Description:** White odorless granules or crystals

**Properties:** Solubility 1 part in 200 of water, in 33 parts propylene glycol; saturated aqueous solution pH 2.45; density 0.93g/cc

**Uses:** As an acidifier in liquid products; flavor enhancer in some formulations; and a sialogogue

### OFFICIAL NAME: GELATIN

**INN:** Gelatin

**Synonyms:** Gelatin

**Chemical Name & CAS Number:** Gelatin (9000-70-8)

**Molecular Formula:** Purified proteins obtained by acid hydrolysis (Type A) or alkaline hydrolysis (Type B) of animal collagen

**Description:** Slightly yellow to amber brittle solid mass that is tasteless. It can be sold in powdered or granular form.

**Properties:** 1% solutions have a pH of 3.8-6.9 for type A and 5.0-7.4 for Type B; iso-electric points are 7-9 and 4.7-5.3 for Types A and B, respectively; moisture content for both Types is 9-11%. Both types are soluble in hot water, cooling into a solid gel mass below 35°C; viscosities vary, depending on the concentration, water hardness, and temperature.

**Incompatibilities:** Gelatin will cross-link in the presence of aldehydes, resulting in poor product dissolution; will react with plasticizer resulting in altered performance (i.e., soft gel capsules); can degrade when exposed to acids and bases or prolonged heating of aqueous solutions; hydrolysis can occur by proteolytic enzymes.

**Uses:** As a base for the manufacture of hard and soft gel capsules, as a coating on tablets (Gel-tabs)

### OFFICIAL NAME: GLYCERIN

**INN:** Glycerol, Glycerin

**Synonyms:** Glycerine, trihydroxypropane glycerol

**Chemical Name & CAS Number:** 1,2,3-Propanetriol (56-81-5)

**Molecular formula:**  $C_3H_8O_3$

**Structure:**

**Description:** Clear, colorless, syrupy liquid with a sweet taste and not more than a slight, characteristic odor, which is neither harsh nor disagreeable; when exposed to moist air, it absorbs water and such gases as  $H_2S$  and  $SO_2$ ; solutions are neutral; specific gravity not less than 1.249 (not less than 95%  $C_3H_5(OH)_3$ ); boils at about 290°C under 1 atm, with decomposition, but can be distilled intact in a vacuum

**Properties:** Miscible with water, alcohol; density 1.26 g/cc at room temperature; very hygroscopic

**Incompatibilities:** An explosion may occur, if it is triturated with strong oxidizing agents, such as chromium trioxide, potassium chlorate, or potassium permanganate. In dilute solutions, the reactions proceed at a slower rate, forming several oxidation products. Iron is an occasional contaminant and may be the cause of a darkening in mixtures containing phenols, salicylates, tannin, etc. With boric acid or sodium borate, it forms a complex, spoken of as glyceroboric acid, which is a much stronger acid than boric acid.

**Uses:** For its humectant and emollient activity in topical formulations; as a solvent in parenteral formulations and a plasticizer for gelatin and other polymeric coatings

### OFFICIAL NAME: GLYCERYL MONOSTEARATE

**INN:** Glycerol monostearate

**Synonyms:** GMS; stearic monoglyceride; monostearin; glycerol stearate

**Chemical Name & CAS Number:** Octadecanoic acid, monoester with 1,2,3-propanetriol (31566-31-1)

**Molecular Formula:**  $C_3H_5(OH)_2C_{18}H_{35}O_2$

**Structure:**

**Description:** White, wax-like solid or occurs in the form of white, wax-like beads, or flakes; slight, agreeable, fatty odor and taste; affected by light

**Properties:** Insoluble in water, but may be dispersed in hot water; does not melt below 55°C; dissolves in hot organic solvents, such as alcohol, mineral, fixed oils, etc.; HLB value of 3.8

**Incompatibilities:** Most acidic substances

**Note:** There are available self-emulsifying grades of glycerol monostearate that contain an additional surfactant/emulsifier.

**Uses:** As a thickening and emulsifying/emollient agent for ointments; tablet and capsule lubricant; plasticizer/matrix forming agent in some sustained release products

### OFFICIAL NAME: GUAR GUM

**INN:** Guar Gum, Guar galactomannan

**Synonyms:** Guar flour, jaguar gum

**Chemical Name & CAS Number:** Galactomannan polysaccharide (9000-30-0)

**Molecular Formula:**  $(C_6H_{12}O_6)_n$

**Structure:**

**Description:** Odorless, white to off-white, bland tasting powder

**Properties:** 1% dispersion pH 5.0-7.0; density 1.492 g/cc; insoluble in hot or cold water, but will swell to form a thixotropic gel

**Incompatibilities:** Alcohol, acetone, tannins, strong acid, or alkalis will cause the gel to break up; guar interferes with the absorption of penicillins

**Uses:** As a binder or disintegrant in tablets and capsules; suspending and thickening agent for liquids

### OFFICIAL NAME: HYDROCHLORIC ACID

**INN:** Hydrochloric acid

**Synonyms:** Chlorhydric Acid; Muriatic Acid

**Chemical Name & CAS Number:** Hydrochloric acid (7647-01-0)

**Molecular Formula:** HCl

**Description:** Colorless, fuming liquid; pungent odor; fumes

**Properties:** pH 0.1 (10% v/v solution), miscible with water soluble in alcohol

**Incompatibilities:** reacts violently with alkalis resulting in release of large amounts of heat

**Uses:** As an acidifying agent

#### OFFICIAL NAME: HYDROXYETHYL CELLULOSE

**INN:** Hydroxyethylecellulose; Hydroxyethyl cellulose

**Synonyms:** HEC; Cellulose, hydroxyethyl ether

**Chemical Name & CAS Number:** Cellulose, 2-hydroxyethyl ether (9004-62-0)

**Structure:**

R is H or  $[-CH_2CH_2O-]_m H$  where  $m$  is a common integral number of cellulose derivatives.

**Description:** White to off-white, odorless, tasteless, hygroscopic powder

**Properties:** 1% solution pH 5.5–8.5 (depending upon grade); density approximately 0.6g/cc; moisture content of NMT 5%; particles size can be grade specific; soluble in both hot and cold water, creating a clear solution; viscosity varies, depending upon grade

**Incompatibilities:** Zein, sodium pentachlorophenate

**Uses:** Pharmaceutically, as a thickener, protective colloid, binder, stabilizer, and suspending agent in emulsions, ointments, lotions, ophthalmic solutions, suppositories, and tablets; has been used as a controlled release agent in tablets

#### OFFICIAL NAME: HYDROXYPROPYL CELLULOSE

**INN:** Hydroxypropylcellulose; hydroxypropyl cellulose

**Synonyms:** Cellulose, hydroxypropyl ether; HPC; hyprollose; hydroxypropylated cellulose

**Chemical Name & CAS Number:** Cellulose, 2-hydroxypropyl ether (9004-64-2)

**Description:** Off-white, odorless, tasteless powder; softens at 130°C; burns completely at about 475°C in  $N_2$  or  $O_2$ ; refractive index (2% solution) about 1.337; pH (aqueous solution) 5–8.5; solutions are nonionic

**Structure:**

R is H or  $[CH_2CH(CH_3)O]_m H$  where  $m$  is a common integral number of cellulose derivatives.

**Properties:** Soluble in water below 38°C (insoluble above 45°C); soluble in many polar organic solvents; pH 5.0–8.5 for 1% aqueous solution; density 0.5g/cc.

**Uses:** As a binder, granulating agent, and film-coating agent in the manufacture of tablets; an alcohol-soluble thickener and suspending agent for elixirs and lotions; and a stabilizer for emulsions

#### OFFICIAL NAME: HYDROXYPROPYL METHYLCELLULOSE (HYPROMELLOSE)

**INN:** Hypromellose; Hydroxypropyl methylcellulose; Hydroxypropylmethylcellulose

**Synonyms:** HPMC; MHPC

**Chemical Name & CAS Number:** Cellulose, 2-hydroxypropyl methyl ether (9004-65-3)

**Structure:**

where R is H,  $CH_3$ , or  $CH_3CH(OH)CH_2$

**Description:** White to slightly off-white, fibrous or granular, free-flowing powder

**Properties:** Swells in water and produces a clear to opalescent, viscous, colloidal mixture; undergoes reversible transformation from sol to gel on heating and cooling, respectively. 1% aqueous solution pH 5.5–8.0; density 1.326g/cc; particle size and viscosity will vary, depending upon the grade

**Uses:** As a protective colloid that is useful as a dispersing and thickening agent, also used in the preparation of sustained release matrix tablets and as a film coating material

#### OFFICIAL NAME: ISOPROPYL MYRISTATE

**INN:** Isopropyl Myristate

**Synonyms:** Isopropyl ester of myristic acid; myristic acid isopropyl ester; tetradecanoic acid, 1-methylethyl ester

**Chemical Name & CAS Number:** 1-Methylethyl tetradecanoate (110-27-0)

**Molecular formula:**  $CH_3(CH_2)_{12}COOCH(CH_3)_2$

**Structure:**

**Description:** Liquid of low viscosity; practically colorless and odorless; congeals at about 5°C and decomposes at 208°C; withstands oxidation; and does not readily become rancid

**Properties:** Soluble in alcohol, acetone, chloroform, ethyl acetate, toluene, mineral oil, castor oil, or cottonseed oil; practically insoluble in water, glycerin, or propylene glycol; dissolves many waxes, cholesterol, or lanolin; viscosity 5–7 mPa s at 25°C

**Use:** As a pharmaceutical aid used in cosmetics and topical medicinal preparations, as an emollient, as a lubricant, and to enhance absorption through the skin

#### OFFICIAL NAME: KAOLIN

**INN:** Heavy Kaolin, Kaolin

**Synonyms:** Bolus alba; china clay; kaolinite; porcelain clay; weisser ton; white bole

**Chemical Name & CAS Number:** Hydrated aluminum silicate (1332-58-7)

**Molecular Formula:**  $Al_2H_4O_9Si_2$

**Structure:**  $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$

**Description:** White to off-white powder that develops an odor of clay when moistened

**Properties:** pH 4.0–7.5 for 20% slurry; particle size 0.6–0.8 $\mu$

**Incompatibilities:** Kaolin has been known to influence to absorption of certain drugs: amoxicillin, cimetidine, digoxin, and phenytoin to name a few

**Uses:** As a diluent in tablets and capsules; as a suspension vehicle in liquids

**OFFICIAL NAME: LACTIC ACID**

INN: Lactic acid; Acidum lacticum

Synonyms: 2-hydroxypropanoic acid;  $\alpha$ -hydroxypropionic acid; 2-hydroxypropionic acid; racemic lactic acid

Chemical Name & CAS Number: 2-Hydroxypropionic acid (50-21-5)

Synonyms: Propanoic acid, 2-hydroxy-, 2-Hydroxypropionic Acid; Propanoic Acid; Milk Acid

Molecular formula:  $\text{CH}_3\text{CH}(\text{OH})\text{COOH}$

Structure:

Description: Colorless or yellowish, nearly odorless, syrupy liquid

Properties: Miscible with water, alcohol, or ether; insoluble in chloroform; boiling point 122°C; specific gravity 1.21; viscosity of 85% aqueous solution 28.5 mPa s

Incompatibilities: Oxidizing agents, iodides, and albumin. Reacts violently with hydrofluoric acid and nitric acid

Uses: As an acidifier; substrate for biodegradable microspheres (poly-lactic/poly glycolic acid co-block polymers)

**OFFICIAL NAME: LACTOSE**

INN: Lactose; Lactose monohydrate; Lactosum

Synonyms: Milk sugar

Chemical Name & CAS Number:

O- $\beta$ -D-Galactopyranosyl-(1-4)- $\alpha$ -D-glucopyranose anhydrous (63-42-3)

O- $\beta$ -D-Galactopyranosyl-(1-4)- $\alpha$ -D-glucopyranose monohydrate (64044-51-5)

Molecular Formula:  $\text{C}_{12}\text{H}_{22}\text{O}_{11} \cdot \text{H}_2\text{O}$

Structure:

Description: White or creamy white, hard, crystalline masses or powder; odorless; faintly sweet taste

Properties: 1 g in 5 mL water or 2.6 mL boiling water; very slightly soluble in alcohol; pH 4–6.5 of a 10% aqueous solution; density 1.552g/cc; moisture of 1% for anhydrous and NMT 5% for monohydrate

Incompatibilities: Maillard reaction with amine containing compounds; amino acids, aminophylline and amphetamines

Uses: As a diluent in tablet and capsule formulations. The amorphous and mono-hydrate forms are used in wet granulation processing of materials, whereas the spray-dried anhydrous type is used in direct compression formulations. It is an ingredient of the medium used in penicillin production. It is used extensively as an addition to milk for infant feeding.

**OFFICIAL NAME: LANOLIN**

INN: Wool Fat; Purified lanolin; Adeps lanae; Lanolin

Synonyms: Lanolin anhydrous; purified lanolin; refined wool fat

Chemical Name & CAS Number: Anhydrous Lanolin (8006-54-0)

Description: Yellowish white, ointment-like mass, with a slight, characteristic odor

Properties: Insoluble in water; soluble in chloroform or ether with separation of its water of hydration; density 0.932-0.945 g/cc at 15°C

Uses: As an emulsifying agent, ointment base

**OFFICIAL NAME: LECITHIN**

INN: Lecithin

Synonyms: Egg lecithin; mixed soybean phosphatides; ovolécithin; soybean phospholipids

Chemical Name & CAS Number: Lecithin (8002-43-5)

Structure:

Description: Varies greatly, depending on the free fatty acid content; could be a free flowing powder or a viscous dark brown to black syrup-like liquid; changes color (oxidation) quickly when exposed to air

Properties: Powder: density of 0.5g/cc, insoluble in water and polar solvents; liquid: density 0.97 g/cc

Incompatibilities: Will oxidize when exposed to air; hydrolyzes when exposed to esterases

Uses: As an emollient, emulsifying agent, and solubilizing agent

**OFFICIAL NAME: MAGNESIUM STEARATE**

INN: Magnesium stearate; magnesia stearas

Synonyms: Magnesium octadecanoate, stearic acid magnesium salt; octadecanoic acid magnesium salt

Chemical Name & CAS Number: Octadecanoic acid magnesium salt (557-04-0)

Molecular Formula:  $\text{C}_{36}\text{H}_{70}\text{MgO}_4$

Structure:  $[\text{CH}_3(\text{CH}_2)_{16}\text{COO}]_2\text{Mg}$

Description: Fine, white, bulky powder; faint, characteristic odor; unctuous, adheres readily to the skin and free from grittiness

Properties: Insoluble in water and alcohol; density of 1.092g/cc; very poorly flowing; surface area 1.6–14.8 m<sup>2</sup>/g.

Uses: As tablet and capsule lubricant

**OFFICIAL NAME: MALTODEXTRIN**

INN: Maltodextrin

Synonyms: Numerous trade names

Chemical Name & CAS Number: Maltodextrin (9050-36-6)

Molecular Formula:  $(\text{C}_6\text{H}_{10}\text{O}_5)_n \cdot \text{H}_2\text{O}$

Structure:

**Description:** Non-sweet, odorless, white powder or granules  
**Properties:** Density range 0.13-0.58 g/cc, depending on manufacturer; freely soluble in water; slightly soluble in ethanol; viscosity varies, depending on manufacturer  
**Incompatibilities:** Certain conditions might result in a discoloration with amino acids and amines  
**Uses:** As a coating agent for tablets; tablet and capsule diluent; tablet binder and viscosity modifier

### OFFICIAL NAME: MANNITOL

**INN:** Mannitol; d-Mannite; Mannitolum  
**Synonyms:** Cordycepia acid; d-mannitol; manna sugar; mannite  
**Chemical Name & CAS Number:** D-Mannitol (69-65-8)  
**Molecular Formula:** C<sub>6</sub>H<sub>14</sub>O<sub>6</sub>  
**Structure:**

**Description:** White, odorless crystalline powder or free flowing granules with a sweet taste and a cooling effect  
**Properties:** Density 1.514 g/cc; heat of solution -120.9J/g; particle size varies, depending on manufacturer; solubility in water is 1 in 5.5, in ethanol 1 in 83, and glycerin is 1 in 18.  
**Incompatibilities:** None reported in dry applications; at concentrations above 20% in solution, salting effects might be seen with potassium or sodium  
**Uses:** As a sweetening agent for chewable tablets and oral liquids; tablet/capsule diluent; tonicity agent; vehicle for lyophilized products

### OFFICIAL NAME: METHYLCELLULOSE

**INN:** Methylcellulose; Methylcellulosum  
**Synonyms:** Benecel; MC; Methocel  
**Chemical Name & CAS Number:** Cellulose methyl ether (9004-67-5)  
**Molecular Formula:** Long chain substituted cellulose, where 27-32% of the hydroxyl groups are in the form of methyl ether  
**Structure:**

**Description:** White to off-white, odorless, tasteless granule or powder  
**Properties:** pH of 1% solution 5.5-8.0; density 1.341 g/cc; insoluble in hot water (disperses), in cold water disperses to form a colloidal dispersion that is clear  
**Incompatibilities:** High concentrations of electrolytes increase viscosity; incompatible with aminacrine hydrochloride, chlorocresol, mercuric chloride, phenol, tannic acid, and paraben preservatives  
**Uses:** As a protective colloid for many types of dispersed substances; an effective stabilizer for oil-in-water emulsions; a granulating solution for tablets and capsules. It has been formulated into many coating systems.

### OFFICIAL NAME: METHYL PARABEN

**INN:** Methyl hydroxybenzoate; methyl parahydroxybenzoate; Methylis parahydroxybenzoas  
**Synonyms:** 4-hydroxybenzoic acid methyl ester; methyl-*p*-hydroxybenzoate  
**Chemical Name & CAS Number:** Methyl 4-hydroxybenzoate (99-76-3)  
**Molecular Formula:** C<sub>8</sub>H<sub>8</sub>O<sub>3</sub>  
**Structure:**

**Description:** White to off-white crystalline powder that has a slight burning taste  
**Properties:** Antimicrobial activity against most organisms, most effective in pH range of 4-8; density of 1.352 g/cc; pK<sub>a</sub> 8.4 at 22°C; solubility in water 1 in 400, in propylene glycol 1 in 5, in glycerin 1 in 60, in ethanol 1 in 2  
**Incompatibilities:** Nonionic surfactants (e.g., polysorbate), talc, bentonite, tragacanth gum, sodium alginate, sorbitol, and methylcellulose  
**Uses:** As an antimicrobial preservative in all known delivery systems

### OFFICIAL NAME: MINERAL OIL

**INN:** Liquid paraffin; Paraffin liquidum; Mineral oil  
**Synonyms:** Mineral hydrocarbons; heavy mineral oil; liquid petrolatum; paraffin oil; white mineral oil  
**Chemical name & CAS Number:** Mineral oil (8012-95-1)  
**Molecular Formula:** A refined mixture of liquid hydrocarbons (C<sub>14</sub> to C<sub>18</sub>) obtained from petroleum  
**Description:** Colorless, transparent, oily liquid, odorless and tasteless when cold, and develops not more than a faint odor of petroleum when heated  
**Properties:** Insoluble in water, glycerin, or alcohol; miscible with most fixed oils, but not with castor oil; soluble in volatile oils; specific gravity 0.818-0.880; kinematic viscosity not more than 33.5 centistokes at 40°C.  
**Incompatibilities:** Strong oxidizing agents  
**Uses:** As an emulsifying agent and emollient in topical formulations mostly ointments

### OFFICIAL NAME: NITROGEN

**INN:** Nitrogen; Nitrogenium  
**Synonyms:** Azote  
**Chemical Name & CAS Number:** Nitrogen [7727-37-9]  
**Molecular Formula:** N<sub>2</sub>  
**Description:** Naturally occurring in the atmosphere at about 78%; Nonreactive noncombustible, colorless, tasteless, and odorless gas  
**Properties:** Insoluble in water, unless under pressure; non-flammable; density 0.967 g/cc  
**Uses:** To replace air in the containers of substances that would be affected adversely by air oxidation (nitrogen layer packaging); as a propellant for aerosol drug delivery

### OFFICIAL NAME: OLEIC ACID

**INN:** Oleic acid; Acidum oleicum  
**Synonyms:** Elaic acid; *cis*-9-octadecenoic acid; 9,10-octadecenoic acid; olenic acid  
**Chemical Name & CAS Number:** (*Z*)-9-Octadecenoic acid (112-80-1)  
**Molecular Formula:** C<sub>18</sub>H<sub>34</sub>O<sub>2</sub>  
**Structure:**

**Description:** Colorless to pale yellow, oily liquid; lard-like odor and taste

**Properties:** Specific gravity 0.889-0.895; congeals at a temperature not above 10°C; pure acid solidifies at 4°C; at atmospheric pressure, it decomposes when heated at 80–100°C; on exposure to air, it gradually absorbs oxygen, darkens, and develops a rancid odor; practically insoluble in water; miscible with alcohol, chloroform, ether, benzene, or fixed and volatile oils

**Incompatibilities:** Reacts with alkali to form soaps. Heavy metals and calcium salts form insoluble oleates. Iodine solutions are decolorized by formation of the iodine addition compound of the acid. It is oxidized to various derivatives by nitric acid, potassium permanganate, and other agents.

**Uses:** As an emulsifying agent for topical; a penetration enhancer for poorly soluble actives (both topical and oral); a vehicle in soft gelatin capsules

### OFFICIAL NAME: OLEYL ALCOHOL

**INN:** Alcohol oleicus

**Synonyms:** *cis*-9-octadecen-1-ol; oleic alcohol; oleo alcohol; oleol

**Chemical name & CAS Number:** (*Z*)-9-Octadecen-1-ol (143-28-2)

**Molecular Formula:** C<sub>18</sub>H<sub>36</sub>O

**Structure:**

**Description:** Clear, colorless to light yellow, oily liquid; faint characteristic odor and bland taste; iodine value between 85 and 90; hydroxyl value between 205 and 215.

**Properties:** Soluble in alcohol, ether, isopropyl alcohol, or light mineral oil; insoluble in water; boiling point 182–184°C.

**Use:** As an emollient, emulsifying agent

### OFFICIAL NAME: PARAFFIN

**INN:** Hard Paraffin; Paraffin; Paraffin solidum

**Synonyms:** Mineral hydrocarbons; hard wax; paraffin durum; paraffin wax

**Chemical Name & CAS Number:** Paraffin (8002-74-2)

**Molecular Formula:** Purified mixture of saturated hydrocarbons having the formula C<sub>n</sub>H<sub>2n+2</sub>

**Description:** Colorless or white, more or less translucent mass with a crystalline structure; slightly greasy to the touch; odorless and tasteless

**Properties:** Freely soluble in chloroform, ether, volatile oils, or most warm fixed oils; slightly soluble in dehydrated alcohol; insoluble in water or alcohol; congeals 47–65°C; density 0.84-0.89 g/cc

**Incompatibilities:** No known incompatibilities

**Uses:** As an ointment base

### OFFICIAL NAME: PEANUT OIL

**INN:** Arachis Oil; Peanut Oil; Arachis oleum

**Synonyms:** Arachis Oil; Groundnut Oil; Nut Oil; Earth Nut Oil; katchung oil

**Chemical Name & CAS Number:** Peanut Oil (8002-03-7)

**Molecular Formula:** A mixture of mono-, di- and tri-glyceride esters of fatty acids comprising a combination of arachidic, behenic, palmitic, stearic, lignoceric, linoleic, and oleic acids

**Description:** Colorless or pale yellow, oily liquid, with a characteristic nutty odor and a bland taste

**Properties:** Insoluble in water; very slightly soluble in alcohol; miscible with ether, chloroform, or carbon disulfide; specific gravity 0.912-0.920; viscosity approximately 35 mPa s at 37°C

**Incompatibilities:** Aalkali hydroxides will saponify the oil

**Uses:** As a solvent for sustained release IM injections

### OFFICIAL NAME: PECTIN

**INN:** Pectin

**Synonyms:** Citrus pectin; methopectin; methyl pectin; methyl pectinate; pectinic acid

**Chemical Name & CAS Number:** Pectin (9000-65-5)

**Molecular Formula:** Repeating linear units of (1-4)-linked α-D-galactopyranosyluronic acid units with some carboxyl groups esterified with methanol

**Structure:**

**Description:** Off-white, odorless powder that has a mucilaginous feel when moistened

**Properties:** Soluble in water; insoluble in most organic solvents; slightly acidic in solution; solubilizes more easily when mixed with glycerin or 1:3 parts of sucrose to prevent clumping

**Incompatibilities:** High concentration of alcohol cause precipitation; hydrolysis in the presence of alkalis; high temperatures promotes hydrolysis

**Uses:** As an emulsifying agent, thickening agent for suspensions

### OFFICIAL NAME: PETROLATUM

**INN:** Yellow soft paraffin; Yellow petrolatum; Petrolatum

**Synonyms:** Yellow Soft Paraffin; Amber Petrolatum; Yellow Petrolatum; Petroleum Jelly; Paraffin Jelly; Mineral Jelly; vaselinum flavum

**Chemical Name & CAS Number:** Petrolatum (8009-03-8)

**Molecular Formula:** Purified mixture of saturated hydrocarbons with the general formula C<sub>n</sub>H<sub>2n+2</sub>

**Description:** Unctuous mass of yellowish to light amber color; not more than a slight fluorescence after being melted; transparent in thin layers; free or nearly free from odor and taste

**Properties:** Insoluble in water; almost insoluble in cold or hot alcohol or in cold dehydrated alcohol; specific gravity 0.815-0.880 at 60°C; melts between 38 and 60°C

**Uses:** As an ointment base, emollient

### OFFICIAL NAME: PHENOL

**INN:** Phenol; Phenolum

**Synonyms:** Carboic Acid; hydroxybenzene; oxybenzene; phenic acid; phenyl hydrate; phenyl hydroxide; phenylic acid; phenylic alcohol

**Chemical Name & CAS Number:** Phenol (108-95-2)

**Molecular Formula:** C<sub>6</sub>H<sub>6</sub>O

**Structure:**

**Description:** Colorless to light pink, interlaced, or separate, needle-shaped crystals, or a white or light pink, crystalline mass; characteristic odor; when undiluted, it whitens and cauterizes the skin and mucous membranes; when gently heated, phenol melts, forming a highly refractive liquid; liquefied by the addition of 10% of water

**Properties:** Solubility 1 g in 15 mL water; very soluble in alcohol, glycerin, chloroform, ether, or fixed and volatile oils; sparingly soluble in mineral oil; vapor is flammable; gradually darkens on exposure to light and air; specific gravity 1.07; boils at 182°C; congeals at not less than 39°C

**Incompatibilities:** Produces a liquid or soft mass when triturated with camphor, menthol, acetanilide, acetophenetidin,

aminopyrine, antipyrine, ethyl aminobenzoate, methenamine, phenyl salicylate, resorcinol, terpin hydrate, thymol, and several other substances, including some alkaloids. It also softens cocoa butter in suppository mixtures. Traces of iron in various chemicals (such as alum, borax, etc. may produce a pink to violet color.

**Uses:** As a caustic, disinfectant, topical anesthetic; a preservative for some injections; used in several proprietary antiseptic mouthwashes, hemorrhoidal preparations, and burn remedies

### OFFICIAL NAME: PHENYLETHYL ALCOHOL

**INN:** Phenylethyl alcohol

**Synonyms:** Benzeneethanol; phenethanol; benzyl carbinol; benzylmethanol;  $\beta$ -hydroxyethyl benzene; 2-phenylethyl alcohol; phenylethanol; PEA

**Chemical Name & CAS Number:** Phenethyl alcohol [60-12-8]

**Molecular Formula:**  $C_8H_{10}O$

**Structure:**

**Description:** Colorless liquid with a rose-like odor and a sharp, burning taste

**Properties:** Solubility is 1 g in 60 mL water or 1 mL alcohol, chloroform, or ether; very soluble in fixed oils, glycerin, or propylene glycol; slightly soluble in mineral oil; solidifies at 27°C; specific gravity 1.017-1.020

**Uses:** As an antimicrobial preservative

### OFFICIAL NAME: PHOSPHORIC ACID

**INN:** Phosphoric acid; Acidum phosphoricum concentratum

**Synonyms:** Orthophosphoric Acid; Syrupy Phosphoric Acid; Concentrated Phosphoric Acid; hydrogen phosphate

**Chemical Name & CAS Number:** Orthophosphoric acid (7664-38-2)

**Molecular Formula:**  $H_3PO_4$

**Description:** Colorless, odorless liquid of a syrupy consistency

**Properties:** Miscible with water or alcohol, with the evolution of heat; specific gravity about 1.71; boiling point 118°C

**Uses:** As an acidulant

### OFFICIAL NAME: POLYACRILIN POTASSIUM

**INN:** Polacrilin potassium

**Synonyms:** Methacrylic acid copolymer with divinylbenzene, potassium salt; polacrilinum kalii

**Chemical Name & CAS Number:** 2-Methyl-2-propenoic acid polymer with divinylbenzene, potassium salt (39394-76-5)

**Structure:**

**Description:** White to off-white, odorless, tasteless, free flowing powder; bitter taste in an aqueous solution

**Properties:** Particle size range from 50 to 250 $\mu$ ; practically insoluble in water and most other liquids; swells rapidly in the presence of water

**Incompatibilities:** Strong oxidizing agents; amines (particularly tertiary amines)

**Uses:** As a tablet disintegrant; taste masker; complexing agent; sustained release ion exchange resin

### OFFICIAL NAME: POLOXAMER

**INN:** Poloxamer

**Synonyms:** Poloxalkol; polyethylene-propylene glycol copolymer; polyoxyethylene-polyoxypropylene copolymer

**Chemical Name & CAS Number:**  $\alpha$ -Hydroxyhydroxypoly(oxyethylene)poly(oxypropylene) poly(oxyethylene) block copolymer (9003-11-6)

**Molecular Formula:**  $HO(C_2H_4O)_a(C_3H_6O)_b(C_2H_4O)_aH$

**Structure:**

**Description:** Waxy appearing, white colored, freely flowing prilled granules

**Properties:** 2.4% aqueous solution pH of 5.0–7.4; density 1.06 g/cc; HLB value 0.5–30, depending on grade; moisture content approximately 0.5%; all grades are freely soluble in water, solubility in other solvents is grade dependent

**Incompatibilities:** Phenols and parabens

**Uses:** As nonionic emulsifiers and solubilizing agents; tablet binders and coating agents; thermally inverse gelling agents (grade dependent)

### OFFICIAL NAME: POLYETHYLENE GLYCOLS

**INN:** Macroglol; Marcogolum; Polyethylene glycol

**Synonyms:** PEG; polyoxyethylene glycol

**Chemical Name & CAS Number:**  $\alpha$ -Hydroxyhydroxypoly(oxy-1,2-ethanediyl) (25322-68-3)

**Molecular Formula:**  $HOCH_2(CH_2OCH_2)_mCH_2OH$

**Description:** Polyethylene glycols 200, 300, 400, and 600 are clear, viscous liquids at room temperature. Polyethylene glycols 900, 1000, 1450, 3350, 4500, 6000, 8000 and 20000 are white, waxy solids.

**Properties:** All members of this class dissolve in water to form clear solutions and are soluble in many organic solvents. As their molecular weight increases, water solubility, vapor pressure, hygroscopicity, and solubility in organic solvents decrease, whereas freezing or melting range, specific gravity, flash point, and viscosity increase.

**Incompatibilities:** Some colors may react with these materials, due to the terminal hydroxyl groups; reduced penicillin activity occurs with these materials as is preservative effectiveness of parabens

**Uses:** As a viscosifier for liquid products; a solubilizer for topical products; a vehicle for some parenteral products; an emollients and suppository bases in semi-solid products; a tablet/capsule lubricant; a solubilizing agent for oral drug delivery.

### OFFICIAL NAME: POLYOXYETHYLENE SORBITAN FATTY ACID ESTERS

**INN:** Polysorbate; Polysotbatum

**Synonyms:** Crillet; Alkamuls; Atlas; Tween

**Chemical Name & CAS Number:**

Polyoxyethylene 20 Sorbitan monolaurate (9005-64-5)

Polyoxyethylene 20 Sorbitan monopalmitate (9005-66-7)

Polyoxyethylene 20 Sorbitan monostearate (9005-67-8)

Polyoxyethylene 20 Sorbitan monooleate (9005-65-6)

**Structure:** Sorbitan esters, poly(oxy-1,2-ethanediyl) derivatives

**Description:** All polysorbates (20,40,60 & 80) are slightly yellow, oily liquids exhibiting a faint, characteristic odor; and somewhat bitter taste

**Properties:** Very soluble in water, producing an odorless and nearly colorless solution; soluble in alcohol, cottonseed oil, corn oil, ethyl acetate, methanol, or toluene; insoluble in mineral oil; specific gravity 1.07-1.09; pH (1:20 aqueous solution) 6-8; viscosity range 400-600 mPa s

**Uses:** As emulsifying agents, forming O/W emulsions; wetting agents in coating applications; solubilizing agents for oil-soluble APIs

#### OFFICIAL NAME: POLYVINYL ALCOHOL

**INN:** Polyvinyl alcohol

**Synonyms:** PVA; vinyl alcohol polymer

**Chemical Name & CAS Number:** Ethenol, homopolymer (9002-89-5)

**Molecular Formula:** (C<sub>2</sub>H<sub>4</sub>O)<sub>n</sub>

**Structure:**

**Description:** White to cream-colored powder or granules; odorless

**Properties:** Freely soluble in water; insoluble in organic solvents; solution effected more rapidly at somewhat elevated temperatures; viscosity is grade dependant

**Use:** As a suspending agent; a lubricant and protectant in ophthalmic and nasal preparations, such as artificial tears, contact-lens cleaners, and nasal sprays

#### OFFICIAL NAME: POTASSIUM SORBATE

**INN:** Potassium sorbate; Kalii sorbas

**Synonyms:** 2,4-hexadienoic acid (E,E)-potassium salt; potassium (E,E) sorbate

**Chemical Name & CAS Number:** Potassium (E,E)-hexa-2,4-dienoate (24634-61-5)

**Molecular Formula:** C<sub>6</sub>H<sub>7</sub>KO<sub>2</sub>

**Structure:**

**Description:** White crystals or powder with a characteristic odor

**Properties:** Solubility 1 g in 1.7 mL water, 1.8 mL of propylene glycol or 35 mL alcohol; density 1.36 g/cc; melting point ca. 270°C with decomposition

**Uses:** As a preservative

#### OFFICIAL NAME: POVIDONE

**INN:** Povidone; Polyvidonum

**Synonyms:** poly[1-(2-oxo-1-pyrrolidinyl)ethylene]; polyvidone; polyvinylpyrrolidone; PVP; 1-vinyl-2-pyrrolidinone polymer

**Chemical Name & CAS Number:** 1-ethenyl-2-Pyrrolidinone homopolymer (9003-39-8)

**Molecular Formula:** (C<sub>6</sub>H<sub>9</sub>NO)<sub>n</sub>

**Structure:**

**Description:** White to creamy white, odorless powder, hygroscopic powder

**Properties:** Soluble in water, alcohol, or chloroform; insoluble in ether; pH (1 in 20 solution) 3-7; density 1.18 g/cc; melting point 150°C; particle size is grade dependant

**Uses:** As a suspending agent in liquid products and a binder in wet granulation processes

#### OFFICIAL NAME: PROPYLENE GLYCOL

**INN:** Propylene glycol; Propyleneglycolum

**Synonyms:** 1,2-Dihydroxypropane; 2-hydroxypropanol; methyl ethylene glycol; methyl glycol; propane-1,2-diol

**Chemical Name & CAS Number:** 1,2-Propanediol (57-55-6)

**Molecular Formula:** CH<sub>3</sub>CH(OH)CH<sub>2</sub>OH

**Structure:**

**Description:** Clear, colorless, viscous, and practically odorless hygroscopic liquid; with a slightly acid taste

**Properties:** Miscible with water, alcohol, acetone, or chloroform; soluble in ether; dissolves many volatile oils; immiscible with fixed oils; specific gravity 1.035-1.037; viscosity approximately 58 mPa s

**Uses:** As a solvent; preservative; humectant

#### OFFICIAL NAME: PROPYL PARABEN

**INN:** Propyl hydroxybenzoate; Propyl parahydroxybenzoate; Propylis parahydroxybenzoas; Propylparaben

**Synonyms:** 4-hydroxybenzoic acid propyl ester; propagin; propyl p-hydroxybenzoate

**Chemical Name & CAS Number:** Propyl 4-hydroxybenzoate (94-13-3)

**Molecular Formula:** C<sub>10</sub>H<sub>12</sub>O<sub>3</sub>

**Structure:**

**Description:** White crystalline odorless and tasteless powder

**Properties:** Very poorly soluble in water, 1 in 250 of glycerin, 1 in 4 of propylene glycol; density 1.288 g/cc

**Incompatibilities:** Nonionic surfactants (incorporation into micelles); may be absorbed by some plastics and discolors in the presence of iron

**Use:** As an antimicrobial agent

#### OFFICIAL NAME: SACCHARIN

**INN:** Saccharin; Saccharinum

**Synonyms:** 1,2-Benzisothiazolin-3-one 1,1-dioxide; benzoic sulfimide; benzosulfimide; saccharin insoluble; o-Benzosulfimide

**Chemical Name & CAS Number:** 1,2-Benzisothiazol-3(2H)-one, 1,1-dioxide (81-07-2)

**Molecular Formula:** C<sub>7</sub>H<sub>5</sub>NO<sub>3</sub>S

**Structure:**

**Description:** White crystalline, odorless powder; Calcium and Sodium salts have a similar description and use

**Properties:** Solubility 1 g in 290 mL water, 31 mL alcohol, or 25 mL boiling water; 0.35% aqueous solution pH 2.0; moisture content 0.1%

**Incompatibilities:** Large molecules resulting in precipitates

**Uses:** As a sweetening agent, approximately 500 times more sweet than sucrose

**OFFICIAL NAME: SODIUM LAURYL SULFATE**

**INN:** Sodium lauryl sulfate; Natrii laurilsulfas

**Synonyms:** Dodecyl sodium sulfate; sodium dodecyl sulfate

**Chemical Name & CAS Number:** Sulfuric acid monododecyl ester sodium salt (151-21-3)

**Molecular Formula:** C<sub>12</sub>H<sub>25</sub>NaO<sub>4</sub>S

**Structure:**

**Description:** Small, white or light yellow crystals, having a slight, characteristic odor of soap

**Properties:** Solubility 1 g in 10 mL water; 1% solution pH 7.0–9.5; density 1.07 g/cc; moisture content <5%

**Incompatibilities:** Reacts with cationic surface-active agents with loss of activity, even in concentrations too low to cause precipitation; mildly corrosive to steel, copper, brass, and aluminum

**Uses:** As an anionic surfactant

**OFFICIAL NAME: SODIUM METABISULFITE**

**INN:** Sodium metabisulfite; Natrii metabisulfis

**Synonyms:** Disodium disulfite; disodium pyrosulfite; sodium pyrosulfite

**Chemical Name & CAS Number:** Sodium pyrosulfite (7681-57-4)

**Molecular Formula:** Na<sub>2</sub>S<sub>2</sub>O<sub>5</sub>

**Description:** White crystals or white to yellowish crystalline powder with an odor of sulfur dioxide

**Properties:** Solubility 1 g in 2 mL water; slightly soluble in alcohol; freely soluble in glycerin; 5% solution pH 3.5–5.0; melting point 150°C

**Incompatibilities:** Phenylmercuric acetate, possible rubber caps of multi-dose vials

**Uses:** As an antioxidant

**OFFICIAL NAME: SODIUM STARCH GLYCOLATE**

**INN:** Sodium starch glycolate; Carboxymethylamylum natriicum

**Synonyms:** Carboxymethyl starch, sodium salt; SSG, Explotab, Primogel

**Chemical name & CAS Number:** Sodium carboxymethyl starch (9036-38-1)

**Structure:**

**Description:** White to off-white, free flowing, rounded granules that are odorless and tasteless

**Properties:** Particle size range of 20–100µm; moisture content of <10%; insoluble in water, but does swell to 300 times its original volume

**Incompatibilities:** Ascorbic acid

**Use:** As a super disintegrant in tablet and capsule formulations

**OFFICIAL NAME: SODIUM STEARYL FUMARATE**

**INN:** Sodium Stearyl Fumarate

**Synonyms:** Fumaric acid, octadecyl ester, sodium salt; sodium monostearyl fumarate

**Chemical Name & CAS Number:** (E)2-Butenedioic monooctadecyl ester, sodium salt (4070-80-8)

**Molecular Formula:** C<sub>22</sub>H<sub>39</sub>NaO<sub>4</sub>

**Structure:**

**Description:** An odorless, tasteless, fine white powder with agglomerates of flat circular particles

**Properties:** 5% solution pH 8.3; density 0.3-0.5g/cc; melting point 224–245°C; insoluble in water at room temperature

**Incompatibilities:** Chlorhexidine acetate

**Use:** As a tablet and capsule lubricant

**OFFICIAL NAME: SORBIC ACID**

**INN:** Sorbic acid; Acidum sorbicum

**Synonyms:** 2,4-hexadienoic acid; 2-propenylacrylic acid

**Chemical Name & CAS Number:** (E,E)-Hexa-2,4-dienoic acid (22500-92-1)

**Molecular Formula:** C<sub>6</sub>H<sub>8</sub>O<sub>2</sub>

**Structure:**

**Description:** Free-flowing, white, crystalline powder, with a characteristic odor

**Properties:** Solubility 1 g in 400 mL water, 10 mL alcohol or 19 mL propylene glycol; melting point 135°C; density 1.2 g/cc

**Incompatibilities:** Bases, oxidizing agents, and reducing agents. Some functionality is lost in the presence of nonionic surfactants

**Uses:** As a preservative

**OFFICIAL NAME: SORBITAN ESTERS**

**INN:** Sorbitan; Sobritani

**Synonyms:** Spans

**Chemical Name & CAS Number:** Sorbitan esters (monolaurate [1338-39-2]; monooleate [1338-43-8]; monopalmitate [26266-57-9]; monostearate [1338-41-6]; trioleate [26266-58-0]; tristearate [26658-19-5])

**Structure:**

**Description:** Monolaurate: Amber, oily liquid; Monooleate: Amber liquid; Monopalmitate: Tan, granular waxy solid; Monostearate: Cream to tan beads; Trioleate: Amber, oily liquid; viscosity about 200 cps; HLB number 1.8; acid number 15 max; saponification number 170–190; hydroxyl number 55–70. Tristearate: Tan, waxy beads; HLB number 2.1; acid number 12–15; saponification number 176–188; hydroxyl number 66–80

**Properties:** Monolaurate: Soluble in methanol or alcohol; dispersible in distilled water and hard water (200 ppm); insoluble in hard water (20,000 ppm); viscosity 4250 cps; HLB number 8.6; acid number 7.0. Monooleate: Soluble in most

mineral or vegetable oils; slightly soluble in ether; dispersible in water; insoluble in acetone; viscosity approximately 1000 cps; HLB number 4.3 acid number 8.0. Monopalmitate: Dispersible in distilled water or hard water (200 ppm); soluble in ethyl acetate; insoluble in cold distilled water or hard water (20,000 ppm); HLB number 6.7; acid number 7.5. Monostearate: Soluble (above melting point) in vegetable oils or mineral oil; insoluble in water, alcohol, or propylene glycol; HLB number 4.7; acid number 5–10. Trioleate: Soluble in mineral oil, vegetable oils, alcohol, or methanol; insoluble in water; HLB number 1.8; acid number 15; viscosity approximately 200 cps. Tristearate: Soluble in isopropyl alcohol; insoluble in water; HLB number 2.1; acid number 12–15.

**Uses:** As a nonionic surfactant used as emulsifying agents.

### OFFICIAL NAME: SORBITOL

**INN:** Sorbitol; D-Sorbitol; Sorbitolum

**Synonyms:** 1,2,3,4,5,6-hexanhexol; sorbite; D-sorbitol

**Chemical Name & CAS Number:** D-Glucitol (50-70-4)

**Molecular Formula:** C<sub>6</sub>H<sub>14</sub>O<sub>6</sub>

**Structure:**

**Description:** White, hygroscopic powder, granules, or flakes with a sweet taste

**Properties:** Solubility 1 g in about 0.45 mL of water; slightly soluble in alcohol, methanol, or acetic acid; 10% solution pH 4.5–7.0; density 1.507 g/cc; melting point of 96°C

**Incompatibilities:** di- and tri-valent ionic compounds (chelate formation), penicillins, and iron oxide

**Uses:** As a sweetener (chewable tablets); humectant liquid products, plasticizer for gelatin and other polymers; and, in 70% (w/w) solution, a vehicle

### OFFICIAL NAME: STARCH

**INN:** Maize-, Potato-, Rice-, Tapioca-, Wheat- starch; Maydis-, Oryzae-, Solani-, Triticum- amyllum

**Synonyms:** Corn Starch; Wheat Starch; Potato Starch

**Chemical Name & CAS Number:** Starch (9005-25-8)

**Molecular Formula:** (C<sub>6</sub>H<sub>10</sub>O<sub>5</sub>)<sub>n</sub>

**Structure:**

**Description:** Irregular, angular, white masses or fine powder; odorless; slight, characteristic taste

**Properties:** Insoluble in cold water or alcohol; when it is boiled with about 20 times its weight of hot water for a few minutes and then cooled, a translucent, whitish jelly results; aqueous suspension neutral to litmus

**Incompatibilities:** No known incompatibilities

**Uses:** As a filler, binder, and disintegrant for tablets and capsules

**Note:** Under the title **Pregelatinized Starch**, the NF recognizes starch that has been processed chemically or mechanically to rupture all or part of the granules in the presence of water and subsequently dried. This alteration results in a material that is more soluble in cold water and more easily used in manufacturing as a granulating agent/binder. Some

types may be modified to render them compressible and flowable for use in direct compression applications.

### OFFICIAL NAME: STEARIC ACID

**INN:** Stearic acid; Acidum stearicum

**Synonyms:** Stearic acid; cetylacetic acid; stereophanic acid

**Chemical Name & CAS Number:** Octadecanoic acid (57-11-4)

**Molecular Formula:** C<sub>18</sub>H<sub>36</sub>O<sub>2</sub>

**Structure:**

**Description:** Hard, white, or faintly yellowish, somewhat glossy and crystalline solid, or a white or yellowish white powder; an odor and taste suggestive of tallow

**Properties:** Practically insoluble in water; 1 g in about 20 mL alcohol; melting point 55°C; density 0.98g/cc; moisture content 0%

**Incompatibilities:** Insoluble stearates are formed with di- and tri-valent metal ions. Ointment bases made with stearic acid may show evidence of drying out or lumpiness, due to such a reaction when zinc or calcium salts are present.

**Uses:** As a tablet lubricant; ointment base

### OFFICIAL NAME: STEARYL ALCOHOL

**INN:** Stearyl alcohol; Alcohol stearylicus

**Synonyms:** n-octadecanol; octadecyl alcohol; stenol

**Chemical Name & CAS Number:** 1-Octadecanol (112-92-5)

**Molecular Formula:** C<sub>18</sub>H<sub>38</sub>O

**Structure:**

**Description:** White, unctuous flakes or granules having a faint, characteristic odor and a bland taste

**Properties:** Insoluble in water; soluble in alcohol or vegetable oils; melting point range 55–60°C; density 0.884–0.906g/cc

**Incompatibilities:** Strong oxidizing agents

**Uses:** As a stiffening agent for semi-solids

### OFFICIAL NAME: SUCRALOSE

**INN:** Sucralose

**Synonyms:** Splenda; TGS; 1',4',6'-trichlorogalactosucrose

**Chemical Name & CAS Number:** 1,6-Dichloro-1,6-dideoxy-β-D-fructofuranosyl-4-chloro-4-deoxy-α-D-galactopyranoside (56038-13-2)

**Molecular Formula:** C<sub>12</sub>H<sub>19</sub>Cl<sub>3</sub>O<sub>8</sub>

**Structure:**

**Description:** White to off-white free flowing crystalline powder

**Properties:** Freely soluble in both water and ethanol; density 1.63 g/cc; particle size 90% < 12μ; 10% solution pH 5–6

**Incompatibilities:** No known incompatibilities

**Uses:** As a sweetener

### OFFICIAL NAME: SUCROSE

**INN:** Sucrose; Saccharum

**Synonyms:** α-D-glucopyranosyl-β-D-fructofuranoside; Sugar; Cane Sugar; Beet Sugar

**Chemical Name & CAS Number:**  $\beta$ -D-fructofuranosyl-  $\alpha$ -D-glucopyranoside (57-50-1)

**Molecular Formula:**  $C_{12}H_{22}O_{11}$

**Structure:**

**Description:** Occurs as a colorless mass or block, or as a white odorless and sweet tasting crystalline powder

**Properties:** Solubility 1 g in 0.5 mL water, 170 mL alcohol; density 1.6g/cc; hygroscopic capable of absorbing 1% moisture

**Incompatibilities:** Sucrose has no known incompatibilities; however, the naturally occurring trace materials in sucrose could result in issues. These trace materials include heavy metals, which could interfere with some APIs (e.g., ascorbic acid), and sulfite, which could result in discoloration of tablet coatings.

**Uses:** As a sweetener in oral liquids and solids; coating material for tablets; diluent for parenteral products

#### OFFICIAL NAME: TALC

**INN:** Purified talc; Talc; Talcum

**Synonyms:** Powdered talc; purified French chalk; soapstone; steatite

**Chemical Name & CAS Number:** Talc (14807-96-6)

**Molecular Formula:**  $Mg_6(Si_2O_5)_4(OH)_4$

**Description:** Very fine, white, or grayish white, odorless, non-gritty crystalline powder

**Properties:** Insoluble in water, dilute acids and alkali; particle size (grade dependant) 99% < 74 $\mu$  or 99% < 44 $\mu$ ; 20% aqueous dispersion pH 6.5–10

**Incompatibilities:** Quaternary ammonium compounds

**Uses:** As a lubricant or glidant

#### OFFICIAL NAME: TARTARIC ACID

**INN:** Tartaric acid; Acidum tartaricum

**Synonyms:** L-(+)-2,3-dihydroxybutanedioic acid; *d*-tartaric acid; L-(+)-tartaric acid

**Chemical name & CAS Number:** [R-(R\*,R\*)]-2,3-dihydroxybutanedioic acid (87-69-4)

**Molecular Formula:**  $C_4H_6O_6$

**Structure:**

**Description:** Large, colorless, or translucent crystals, or a white crystalline powder; odorless; extremely tart taste; stable in the air; solutions acid to litmus; dextrorotatory

**Properties:** Solubility 1 g in 0.8 mL water or 3 mL alcohol; 1.5% solution pH 2.2; density 1.76g/cc

**Incompatibilities:** Silver salts and reacts with metal carbonates and bicarbonates

**Uses:** As an acidulant; sialogogue and activator for carbonation

#### OFFICIAL NAME: TITANIUM DIOXIDE

**INN:** Titanium dioxide; Titanii dioxidum

**Synonyms:** Anatase titanium dioxide; brookite titanium dioxide

**Chemical Name & CAS Number:** Titanium oxide (13463-67-7)

**Molecular Formula:**  $TiO_2$

**Description:** White, amorphous, odorless, tasteless powder

**Properties:** Particle size < 1 $\mu$ ; density 3.8-4.2g/cc; moisture 0.44%; insoluble in water

**Incompatibilities:** Possesses a catalytic effect in the presence of some actives

**Use:** As an opacifier for coatings and semisolids

#### OFFICIAL NAME: TRAGACANTH

**INN:** Tragacanth; Tragacantha

**Synonyms:** Gum Tragacanth; Gum Dragon; Goat's Thorn; Persian tragacanth

**Chemical Name & CAS Number:** Tragacanth gum (9000-65-1)

**Molecular Formula:** A mixture of water soluble and insoluble polysaccharides derived from dried gum of *Astragalus gummifer*. It's comprised of 60–70% bassorin and 30–40% soluble gum (*tragacanthin*).

**Description:** Flattened, lamellated, frequently curved fragments or straight or spirally twisted linear pieces 0.5-2.5 mm in thickness; white to weak-yellow in color; translucent; horny in texture; odorless; insipid, mucilaginous taste. When powdered, it is white to yellowish white.

**Properties:** 1% dispersion pH 5–6; practically insoluble in water and alcohol; when mixed with water, it does swell to 10 times its original volume creating a viscous dispersion.

**Incompatibilities:** Above pH of 7 tragacanth, reduces activity of benzalkonium chloride

**Use:** As a suspending agent; granulating agent

#### OFFICIAL NAME: TRIACETIN

**INN:** Triacetin; Glycerolum triacetat

**Synonyms:** Glycerol triacetate; glyceryl triacetate; triacetyl glycerin

**Chemical Name & CAS Number:** 1,2,3-Propanetriol triacetate (102-76-1)

**Molecular Formula:**  $C_9H_{14}O_6$

**Structure:**

**Description:** Colorless viscous liquid with a slight fatty odor

**Properties:** Density 1.16 g/cc; solubility 1 in 14 of water, miscible with ethanol; viscosity 17 mPa.s

**Incompatibilities:** Metal ions, oxidizing agents

**Use:** As a humectant, solvent or plasticizer for polymers

#### OFFICIAL NAME: TRIETHANOLAMINE

**INN:** Triethanolamine; Trolaminum; Trolamine

**Synonyms:** Triethylolamine; trihydroxytriethylamine; tris(hydroxyethyl)amine; TEA

**Chemical Name & CAS Number:** 2,2',2''-Nitrilotriethanol (102-71-6)

**Molecular Formula:**  $C_6H_{15}NO_3$

**Structure:**

**Description:** Colorless to pale yellow, clear viscous liquid with a slight odor of ammonia

**Properties:** Miscible with water; 0.1N solution pH 10.5; freezing point 21.6°C

**Incompatibilities:** Higher fatty acids; mineral acids; heavy metal salts; if hydroxyl groups are replaced with halogen, the resultant product is toxic similar to mustard gas

**Use:** As a polymer plasticizer; humectants; emollient

### OFFICIAL NAME: VANILLIN

**INN:** Vanillin; Vanillinum

**Synonyms:** 4-Hydroxy-*m*-anisaldehyde; *p*-hydroxy-*m*-methoxybenzaldehyde; vanillic aldehyde

**Chemical Name & CAS Number:** 4-Hydroxy-3-methoxybenzaldehyde (121-33-5)

**Molecular Formula:** C<sub>8</sub>H<sub>8</sub>O<sub>3</sub>

**Structure:**

**Description:** Fine, white to slightly yellow crystals, usually needle-like, with an odor and taste suggestive of vanilla

**Properties:** Solubility 1 g in about 100 mL water, about 20 mL glycerin, or 20 mL water at 80°C and freely soluble in alcohol; affected by light and air; solutions are acid to litmus; melting point 81–83°C; density is 0.6g/cc

**Incompatibilities:** Combines with glycerin, forming a compound almost insoluble in alcohol; decomposed by alkali; oxidized slowly by the air

**Uses:** As a flavor

### OFFICIAL NAME: WATER

**INN:** Purified Water; Aqua purificata

**Synonyms:** Aqua; hydrogen oxide

**Chemical Name & CAS Number:** Purified Water (7732-18-5)

**Molecular Formula:** H<sub>2</sub>O

**Description:** Clear, colorless, odorless, and tasteless liquid

**Properties:** Boiling point 100°C, freezing point 0°C; miscible with most polar solvents

**Incompatibilities:** With drug subject to hydrolysis; reacts violently with alkali metals

**Use:** Most widely used excipient in pharmaceutical manufacturing; solvent for granulating agents; solvent for syrups, suspensions; vehicle for aqueous solutions; in oral solid and liquid processing; in parenteral processing as water for injection or sterile water for injection; in topical, ocular, otic delivery systems; to clean all processing equipment

**Special Classes of Water:**

**Purified Water:** Obtained by distillation, ion-exchange treatment, reverse osmosis, or any other suitable process; contains no added substance

**Water for Injection:** Purified by distillation or by reverse osmosis under aseptic conditions; not sterilized by filtration or in the final container

**Bacteriostatic Water for Injection:** Sterile water for injection containing one or more suitable antimicrobial agents

### OFFICIAL NAME: XANTHAN GUM

**INN:** Xanthan gum; Xanthani gummi

**Synonyms:** Corn sugar gum; Keltrol

**Chemical Name & CAS Number:** Xanthan Gum (11138-66-2)

**Structure:**

**Description:** White or cream-colored, tasteless, free-flowing powder

**Properties:** Soluble in hot or cold water; 1% solution pH 6–8; 1200–1600 mPa.s for 1% solution at 25°C

**Incompatibilities:** Cationic surfactants, polymers, and preservatives will cause precipitation; exhibits thixotropic gel characteristics at concentrations greater than 1%

**Uses:** As a stabilizing agent; viscosity increasing agent

### OFFICIAL NAME: XYLITOL

**INN:** Xylitol; Xylitolum

**Synonyms:** meso-xylitol

**Chemical Name & CAS Number:** xylo-Pentane-1,2,3,4,5-pentol (87-99-0)

**Molecular Formula:** C<sub>5</sub>H<sub>12</sub>O<sub>5</sub>

**Structure:**

**Description:** White, odorless, yet sweet tasting granular solid, consisting of equi-dimensional particles

**Properties:** 5% solution pH 5.0–7.0; Density 1.52 g/cc; moisture content of up to 3% depending upon environmental conditions; particle size is grade dependant; solubility is 1 in 1.6 of water, 1 in 15 of propylene glycol and 1 in 80 of ethanol

**Incompatibilities:** Oxidizing agents

**Use:** As a non-cariogenic sweetening agent for tablets, syrups, and coatings

**OFFICIAL NAME: ZEIN****INN:** Zein**Chemical Name & CAS Number:** Zein (9010-66-6)**Description:** Straw to pale yellow amorphous powder or flake with a characteristic odor and bland taste**Properties:** Density 1.23 g/cc; practically insoluble in water and ethanol; soluble in glycols**Incompatibilities:** Oxidizing agents**Use:** As a wet binder or tablet coating

# Chapter 37

## Basic Pharmacokinetics and Pharmacodynamics

The goal of pharmacotherapy is to provide optimal drug therapy in the treatment or prevention of disease. A major barrier to the achievement of this goal is the large variability in the pharmacological effect that is observed following drug administration (Fig 37-1).<sup>1</sup> The ability to implement drug therapy in a safe and rational manner necessitates an understanding of the factors that cause this variability. One of the most important factors is the concentration of drug that is achieved at the site of action.

### ANALYTICAL CONSIDERATIONS

Any discussion of pharmacokinetics presumes that the drug concentrations can be determined with a high degree of accuracy and precision. One of the most frequent causes of high variability in pharmacokinetic parameters is poor data resulting from imprecise analytical procedures. Evaluation of pharmacokinetic data in the literature must begin with an assessment of the validity of the assay used under the conditions in which the study was conducted. An assay must be tested for specificity, sensitivity, reproducibility, stability, and accuracy. Because drug metabolites are frequently present in the fluid to be measured and are similar in structure to the parent compound, differentiation of drug from any putative metabolites must be ensured.

### THE CRITICAL NATURE OF THE CONCENTRATION VERSUS EFFECT RELATIONSHIP

The quantitative response to a drug depends highly on the concentration of drug at the site of action. In most situations one cannot quantify drug concentration at the actual site of action. Rather, drug concentrations are measured in an easily accessible site that is believed to be in equilibrium with the site of action (e.g., blood or one of its components). Figure 37-2<sup>2</sup> provides a good illustration of a drug whose pharmacological effect is particularly sensitive to changes in blood concentration. Numerous studies have been published that substantiate the critical nature of the concentration-effect relationship for a wide variety of drugs.

It is recognized now that drug therapy may be optimized by designing regimens that account for the concentration of a drug necessary to achieve a desired pharmacological response.

However, there is often significant difficulty in achieving such target concentrations. In particular, it often is observed that if a fixed dose of a drug is administered to a group of individuals, the drug concentration measured in plasma can vary widely. For example, the peak concentration of 6-mercaptopurine achieved in a group of 20 patients who received a standard 1 mg/m<sup>2</sup> dose is shown in Figure 37-3.<sup>3</sup> The concentrations ranged from 0 to 660 ng/mL. Taken together, this suggests that variability in drug concentration is a major source of variability in drug effect, and there may be a significant degree of variability among individuals in the drug concentrations produced by a given dose of drug.

A basic understanding of the factors that control drug concentration at the site of action is important for the optimal use of drugs. This is the area of study referred to as *pharmacokinetics*, which is the study of the time course of drug absorption, distribution, metabolism, and elimination.

### DRUG CONCENTRATION VERSUS TIME PROFILE

Blood (or its components, plasma or serum) represents the most frequently sampled fluid used to characterize the pharmacokinetics of drugs. Drug concentration in the blood is the sum of several processes (Fig 37-4).<sup>4</sup> Initially visual characterization of the processes controlling the concentration of drug in the blood can be made by constructing a drug concentration versus time profile (i.e., a plot of drug concentration in the blood versus time). As can be seen from Figure 37-5, several useful pieces of information can be derived from such a profile. For example, the time at which the peak concentration occurs can be approximated and the peak concentration quantified. If the minimum concentration needed to maintain a desired effect is known, the onset and duration of effect also can be approximated. While useful information can be drawn casually from a simple graph as depicted in Figure 37-5, a more rigorous description of the pharmacokinetics of a drug is necessary to achieve the accuracy in dosage regimen design required for the safe and effective use of drugs. This higher degree of accuracy necessitates the development of mathematical models for describing the time course of absorption, distribution, metabolism, and elimination.

**Figure 37-1.** Decrease in blood glucose in 97 subjects 30 min after an intravenous dose of 1 g of tolbutamide. Note the large variability observed after the equivalent dose was administered in this group. (Data from Swerdloff RS *et al.* Influence of age on the intravenous tolbutamide response test. *Diabetes* 1967; 16: 161–170.)

**Figure 37-2.** Blood pethidine concentration-response curves for three individual patients, illustrating a typical range in interpatient responses. (From Austin KL, Stapleton JV, Mather LE. Relationship Between Blood Meperidine Concentrations and Analgesic Response: A Preliminary Report. *Anesthesiology* 1980; 53:460–66.)

## PHARMACOKINETIC MODELS

One of the primary objectives of pharmacokinetic models is to develop a quantitative method to describe the relationship of drug concentration, or amount in the body, as a function of time. The complexity of the pharmacokinetic model will vary with the route of administration, the extent and duration of

**Figure 37-3.** Distribution of peak 6-mercaptopurine concentrations achieved in a group of 20 patients receiving an oral dose of 1 mg/m<sup>2</sup>. (Data from Sulh H *et al.* Pharmacokinetic determinants of 6-mercaptopurine myelotoxicity and therapeutic failure in children with acute lymphoblastic leukemia. *Clin Pharmacol Ther* 1986; 40: 604–609.)

distribution into various body fluids and tissues, the processes of elimination, and the intended application of the pharmacokinetic model. Often, numerous potential mathematical models exist for a particular drug. In such cases, the simplest model that will adequately and accurately describe the pharmacokinetics of the drug is the model that should be chosen.

There are a wide variety of potential uses for pharmacokinetic models, which include:

1. Prediction of drug concentration in blood/plasma or tissue.
2. Calculation of a dosage regimen.
3. Quantitative assessment of the effect of disease on drug disposition.
4. Elucidation of the mechanism of disease-induced alterations in drug disposition.
5. Determination of the mechanism for drug-drug interactions.
6. Prediction of drug concentration versus effect relationships.

There are three primary types of pharmacokinetic models: compartmental, noncompartmental, and physiological.

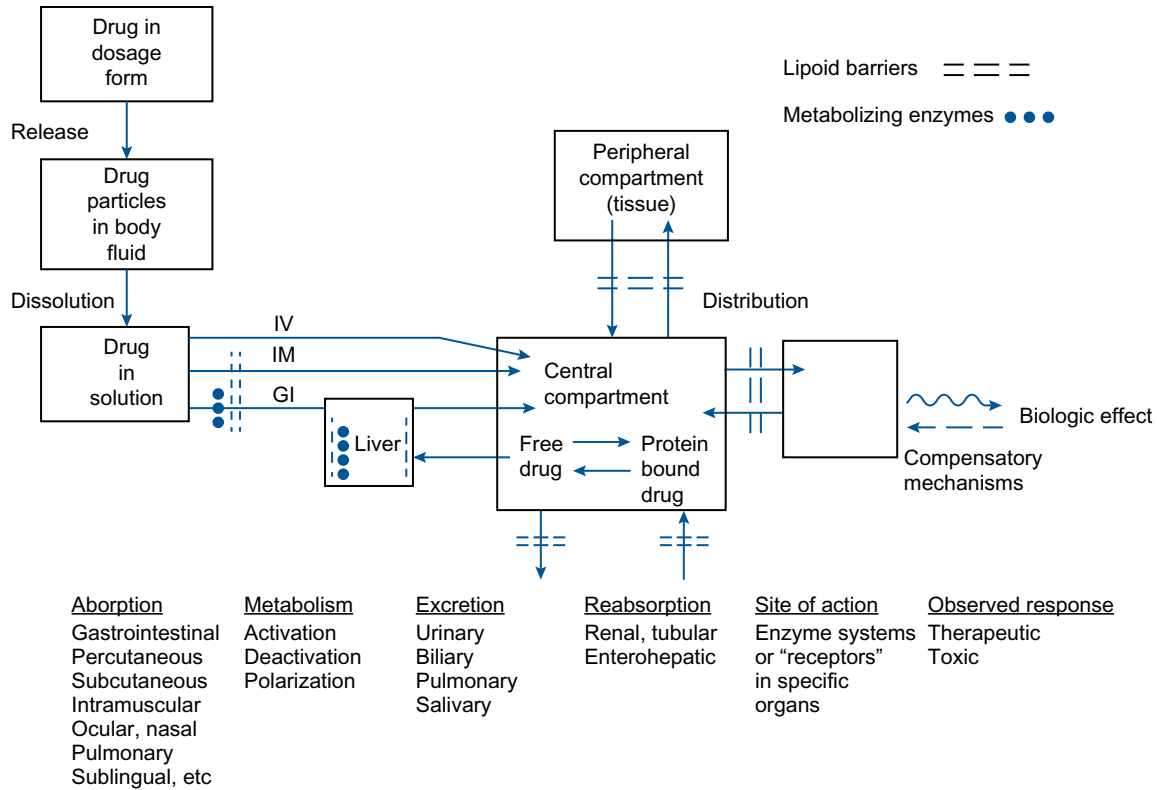

Compartmental models describe the pharmacokinetics of drug disposition by grouping body tissues that are kinetically indistinguishable and describe the transfer of drug between body tissues in terms of rate constants.

Noncompartmental models describe the pharmacokinetics of drug disposition using time- and concentration-averaged parameters.

Physiological models attempt to describe drug disposition in terms of realistic physiological parameters, such as blood flow and tissue-partition coefficients.

## RATES AND ORDERS OF REACTIONS

Many pharmacokinetic models use parameters that are analogous to rate constants in chemical kinetics. For example,

**Figure 37-4.** Diagram illustrating the factors that influence onset, duration, and intensity of drug effects. Note that the drug must dissolve before being absorbed and that it passes across many lipid barriers and some metabolizing systems before reaching the site of action. (From Barr WH. Principles of biopharmaceutics. *Am J Pharm Educ* 1968; 32: 958-959.)

**Figure 37-5.** Hypothetical plot of drug-concentration data after oral administration of a drug.

consider the case of a drug (*D*) that is metabolized to a metabolite (*M*).

This reaction may be described as a function of either the disappearance of the drug or as a function of the appearance of

**Figure 37-6.** Plots illustrating a zero-order and a first-order reaction.

the metabolite. If the *amount* of the drug that is converted to a metabolite is a constant with respect to time, the reaction is said to be *zero-order* and is expressed as

$$\frac{-dD}{dt} = k_0 \tag{1}$$

where  $k_0$  is the zero-order rate constant with units of mass per time (e.g., mg/min). A plot of the time-course of the amount of the drug in the body that is converted to a metabolite by zero-order kinetics is shown in Figure 37-6. Integration of Equation 1 yields an equation for a straight line, which describes the amount of the drug in the body at any time (*t*):

$$\text{Amount}_t = -k_0t + \text{Amount}_{t=0} = -k_0t + \text{Dose} \tag{2}$$

Zero-order rate processes typically are found when an enzyme or transport system becomes saturated and the rate process becomes constant and cannot be increased by increases in

the concentration of substrate. Zero-order rate processes are typical of constant-rate intravenous infusions and prolonged-release dosage forms.

If the amount of the drug in the body is converted to a metabolite at a rate that is a constant fraction of the amount of the drug in the body, the conversion of  $D$  to  $M$  is said to be a first-order reaction described by:

$$\frac{dD}{dt} = -kD \quad (3)$$

where  $k$  is the first-order rate constant expressed in units of reciprocal time (e.g.,  $\text{min}^{-1}$ ). Rearrangement of Equation 3 leads to:

$$\frac{dD}{D} = -kdt \quad (4)$$

and integration of this expression yields:

$$\int_0^t \frac{dD}{D} \Rightarrow \ln D = -kt + \ln D_0 \quad (5)$$

where  $\ln$  is the natural logarithm. This equation also can be expressed in the exponential form:

$$D_t = D_0 e^{-kt} \quad (6)$$

Graphically, the integrated form usually is expressed in terms of  $\log_{10}$  rather than in natural logarithms (see Fig 37-6):

$$\log D = \frac{-kt}{2.303} + \log D_0 \quad (7)$$

### INSTANTANEOUS INPUT WITH INSTANTANEOUS DISTRIBUTION

The disposition of a drug from its site of administration and its distribution and elimination from the body occurs via the vascular system. Most drugs are low-molecular-weight compounds of sufficient lipophilicity that they are able to distribute readily into the intra- and extracellular fluid compartments in the body. The transfer of drug from the circulation to these fluid compartments and then into tissues is called distribution. The pharmacokinetic parameter *volume of distribution* is a proportionality constant that relates drug concentration in a reference fluid, typically plasma, to the amount of drug distributed throughout the body.

$$\text{Volume of distribution}(V_D) = \frac{\text{Amount of drug in body}(D_B)}{\text{Drug concentration}(CP)} \quad (8)$$

Drugs that distribute widely to tissues will have large volumes of distribution and low plasma concentrations relative to the dose administered, whereas drugs that are highly bound to plasma proteins (e.g., warfarin, phenylbutazone) or do not readily enter cells (e.g., amikacin) will have low volumes of distribution and high plasma concentrations relative to the administered dose.

Oie and Tozer<sup>5</sup> have developed a physiological model for expression of the apparent volume of distribution, which takes into account the extracellular water, including plasma- and protein-binding of the drug in both plasma and tissue. For an average 70-kg male, total body water is about 42 L, of which 3 L is plasma and 12 L is extracellular fluid space. Moreover, 55–60% of the albumin in the extracellular space is found outside of plasma. Thus, for drugs that are largely bound to albumin, the apparent volume of distribution can be expressed as:

$$V_D = 7 + 8f_u + V_T \left[ \frac{f_u}{f_{uT}} \right] \quad (9)$$

where  $f_u$  is the fraction of the drug in plasma that is unbound (often referred to as the *free fraction*),  $f_{uT}$  is the *free fraction* of

drug in tissue, and  $V_T$  is the volume of intracellular tissue water. Equation 9 can be simplified further to:

$$V_D = 7 + 8f_u + 27 \left[ \frac{f_u}{f_{uT}} \right] \quad (10)$$

This model has been extremely useful in predicting the magnitude of changes in the apparent volume of distribution due to alterations in (1) plasma protein binding, (2) tissue protein binding, and (3) the volume of extracellular and intracellular fluid. For example, if a drug distributes into extracellular fluid but not intracellular fluid, the apparent volume of distribution can be expressed as:

$$V_D = 7 + 8f_u \quad (11)$$

and will vary between 7 and 15 L, depending upon the extent of plasma protein binding to albumin. For such a compound, with a relatively small volume of distribution, alterations in the plasma protein binding will not produce proportional changes in the apparent volume of distribution. Indeed, as reported by Williams *et al.*,<sup>6</sup> the free fraction of tolbutamide in plasma increases in patients with cirrhosis by 28%, from 0.068 to 0.087, yet the apparent volume of distribution increases less than 10%, from 0.15 to 0.164 L/kg. Conversely, drugs with a volume of distribution greater than total body water indicate drug distribution and binding to tissue proteins and other cellular components. Such compounds also may be bound highly to plasma proteins. With drugs having a large volume of distribution ( $\geq 50$ –100 L), the contribution of plasma and extracellular water space can be ignored, and Equation 3 simplifies to:

$$V_D = 27 \left[ \frac{f_u}{f_{uT}} \right] \quad (12)$$

Changes in the plasma or plasma-free fraction will produce proportional changes in the apparent volume of distribution. For example, a two-fold increase in the free fraction of drug in tissue,  $f_{uT}$ , will decrease the apparent volume of distribution by two-fold. Less drug will be distributed to tissue, reflected by an increase in plasma concentrations. The volume necessary to account for the total amount of drug in the body will appear to have been decreased.

Once a drug is in the vascular system, it is transported by the blood to tissues where it can be eliminated from the circulation by distribution into tissue, metabolism by the tissue, or excretion from the tissue (see Fig 37-4). All of these processes lower the plasma concentration of drug. Each separate process may be described by a first-order rate constant, and the overall change in the plasma concentration is the net effect of all of these parallel, competing, first-order processes.

Intravenous injection of a drug that has nearly instantaneous distribution and first-order elimination can be described by an open one-compartment model (Fig 37-7). The body behaves as if it were a homogeneous compartment. In the one-compartment model, distribution is very rapid and can be considered instantaneous and is, therefore, ignored. After intravenous administration the plasma concentration declines exponentially according to:

$$C = C_0 e^{-\lambda t} \quad (13)$$

where  $C_0$  is the initial concentration and  $\lambda$  is the overall elimination rate constant. Such an exponential elimination of theophylline, given intravenously, is shown in Figure 37-8.<sup>7</sup> According to Equation 13, if the data of Figure 37-8 are plotted on semilog paper, a straight line should result, and such a plot is shown in Figure 37-9. Several derived data can be obtained from a plot of  $\log$  concentration versus time. Extrapolation to zero time (i.e., the y-intercept) gives an estimated theoretical concentration in plasma at time zero, from which the apparent volume of distribution ( $V_D$ ) can be estimated by simply dividing the dose by  $C_0$ .

**Figure 37-7.** The open one-compartment pharmacokinetic model. The amount of the drug dose ( $D$ ) that enters the body is  $D_B$ ; in the case of intravenous injection, this is the entire dose, whereas in the case of extravascular administration, some fraction of the dose ( $F$ ) is absorbed with a rate constant of  $k_a$ . The compartment has an apparent volume of distribution ( $V_d$ ), into which drug distributes instantaneously to achieve a concentration of  $C_p$ . Drug is eliminated from the compartment with a rate constant  $k_{el}$ .  $D_u$  is the amount excreted into urine, feces, bile, expired air, sweat, milk, etc;  $D_m$  is the amount of drug metabolized.

It is a theoretical concentration because neither the injection nor the distribution is actually instantaneous.

The *half-life* of a drug is the time required to reduce the amount of drug in the body or the plasma concentration by 50%. For a first-order process, the half-life is constant and is independent of the starting value of the amount of drug in the body (or plasma concentration). The plasma half-life,  $t_{1/2}$ , can be determined directly from the graph or from the elimination rate constant,  $\lambda$  or  $k_{el}$ , by means of the relationship:

$$t_{1/2} = \frac{0.693}{\lambda} = \frac{0.693}{k_{el}} \quad (14)$$

As shown, the half-life is related inversely to the elimination rate constant. When the elimination rate constant,  $k_{el}$ , is determined from the slope of the concentration versus time plot, one must keep in mind that the data need to be plotted on a semilog scale. From Figure 37-9, the  $k_{el}$  is determined to be  $0.22 \text{ hr}^{-1}$ . This is the instantaneous rate constant and indicates that 22% of the theophylline in the body is lost per hour. The rate constant

**Figure 37-8.** Elimination curve of average blood levels of theophylline in 11 human subjects after intravenous administration of 0.5 g aminophylline per 70 kg to each. (Data from Truitt Jnr EB *et al.* Theophylline blood levels after oral, rectal, and intravenous administration, and correlation with diuretic action. *J Pharmacol Exp Ther* 1950; 100: 309–315.)

**Figure 37-9.** Semilog plot of the elimination curve in Figure 37-8. Note the log scale of the ordinate.

for elimination (see Fig 37-7) is shown without reference to the route of elimination. It must be recognized that  $k_{el}$  represents the overall elimination by all competing, parallel pathways and is equal to the sum of the rate constants that define the various simultaneous (i.e., parallel) contributory processes (e.g., metabolism, renal excretion, or biliary secretion). Thus, the overall rate constant,  $k_{el} = k_1 + k_2 + k_3 + \dots + k_N$ , where  $k_1 + k_2 + k_3 + \dots + k_N$  are the rate constants of the separate contributory processes.

Half-life is a clinically useful pharmacokinetic parameter in that it indicates when the next dose of a drug needs to be administered and is therefore helpful in designing an optimal dosing regimen. The half-life also is useful in determining:

1. The fluctuation of plasma concentrations between doses;
2. The time required to reach steady-state equilibrium after beginning continuous drug administration; and
3. The persistence of drug in the system once drug administration has ceased.

Under some conditions, it is not possible to obtain plasma concentration data over sufficient time to obtain accurate estimates of the half-life for designing dosage regimens. The elimination rate constant, and hence the half-life, may be estimated from the excretion rate of unchanged drug. Because the first-order elimination rate constant is independent of the amount of drug in the body, the instantaneous excretion rate,  $dD_u/dt$ , is directly proportional to the total amount of drug in the body.

$$\frac{dD_u}{dt} = k_u D_B \quad (15)$$

where  $D_B$  and  $D_u$  are the amount of drug in the body at time zero and the amount of drug excreted in the urine, respectively, and  $k_u$  is the urinary excretion rate constant. A plot of  $\log dD_u/dt$  versus time yields a straight line with slope of  $-k_e/2.303$ . One also may estimate the half-life from urinary excretion data using the cumulative amount of drug excreted (sigma-minus) method. Using this approach:

$$D_u \infty = D_B \frac{k_u}{k_{el}} (1 - e^{-k_{el}t}) \quad (16)$$

$k_u/k_{el}$  represents the fraction of the drug in the body that eventually is excreted in urine as unchanged drug and  $D_u^\infty$  represents the total amount of unchanged drug excreted in urine. A plot of the log of the amount of drug remaining to be excreted ( $D_u^\infty - D_u$ ) versus time yields a slope equal to  $-k_e/2.303$ . This method requires collecting urine for at least six to eight half-lives to achieve an accurate measure of  $D_u^\infty$ .

For a drug eliminated by first-order kinetics, the elimination rate constant,  $k_{el}$ , can be expressed as the fraction of the volume of distribution that is presented to an eliminating organ and cleared of drug per unit time (clearance) relative to the total volume of distribution,  $V_D$ . Thus,  $k_{el}$  represents the fractional removal rate of drug from the system, and the elimination rate constant can be expressed in terms of clearance and volume of distribution:

$$\frac{\text{Clearance}}{V_D} = \text{Elimination-rate constant}(k_{el}) \quad (17)$$

As written in Equation 17, the elimination rate constant (and hence, plasma half-life) is a dependent parameter that, by itself, is not always the most reliable indicator of drug removal from the body. Disease or altered physiology (e.g., aging, pregnancy) can alter protein binding, thereby affecting the apparent volume of distribution, or alter organ function, thereby affecting clearance, but these changes may not be reflected by changes in the half-life. For example, the volume of distribution may be altered due to changes in tissue or plasma protein binding, independent of specific organ function (clearance). In this instance, the half-life of a drug may be changed, but clearance could remain constant. Although a useful parameter, one must always bear in mind that half-life is a dependent or derived parameter that does not reliably reflect irreversible removal of drug from the body. A more accurate way to express half-life (Equation 14), therefore, is:

$$t_{1/2} = 0.693 \frac{V_D}{CL} \quad (18)$$

Clearance is the most useful pharmacokinetic indicator of irreversible loss of drug from the body and refers to a volume of fluid from which the drug appears to be removed in a given amount of time. Clearance also can be expressed as the quotient of overall rate of elimination of a drug relative to the drug concentration at a particular organ of elimination,

$$\text{Clearance} = \frac{\text{Rate of elimination}}{\text{Concentration}} \quad (19)$$

and, if time-averaged over the time course of plasma concentrations, drug clearance can be expressed as:

$$\text{Clearance} = \frac{\text{Amount of drug removed}}{AUC} \quad (20)$$

where  $AUC$  is the area under the concentration-versus-time curve. Total body clearance,  $CL_T$ , also can be estimated as the quotient of dose and area under the concentration-versus-time curve from zero to infinity.

$$CL_T = \frac{\text{Dose}_{IV}}{AUC_0^\infty} \quad (21)$$

Total body clearance is the sum of all the separate clearances that contribute to drug elimination:

$$CL_T = CL_{RENAL} + CL_{HEPATIC} + CL_{OTHER} \quad (22)$$

## INSTANTANEOUS INPUT WITH NONINSTANTANEOUS DISTRIBUTION

The one-compartment model adequately describes the pharmacokinetics of drugs with instantaneous distribution.

However, for some compounds, distribution requires some finite time to reach equilibrium. During this time, the drug undergoes distribution and elimination, and drug concentrations decrease rapidly. When distribution equilibrium is established, the loss of drug from the body is due to elimination, and plasma concentrations decline more slowly. This biexponential time-course of plasma concentrations can be described by a two-compartment model. In this model, the body appears to behave as if it is comprised of two compartments, a central compartment and a peripheral compartment. By convention, drug absorption (or injection) and drug elimination occur from the central compartment, and the peripheral compartment is closed and communicates with the environment only through the central compartment (Fig 37-10). The movement of drug between compartments, following rapid intravenous injection with elimination from the central compartment, can be described by:

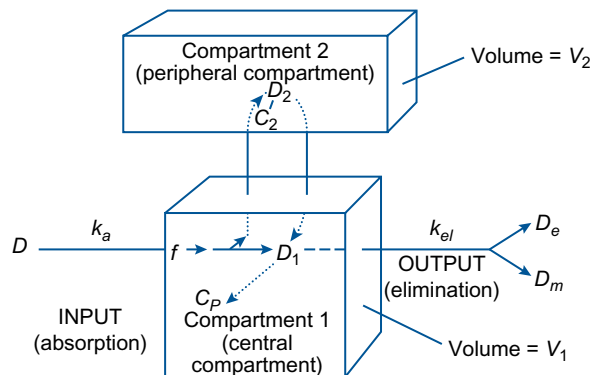

$$\frac{dD_1}{dt} = k_{21}D_2 - k_{12}D_1 - k_{10}D_1 \quad (23)$$

and

$$\frac{dD_2}{dt} = k_{12}D_1 - k_{21}D_2$$

where  $D_2$  is the amount of drug in the peripheral or tissue compartment,  $D_1$  is the amount of drug in the central compartment,  $k_{21}$  and  $k_{12}$  are the apparent first-order intercompartmental distribution rate constants, and  $k_{10}$  or  $k_{el}$  is the apparent first-order elimination rate constant from Compartment 1.

After intravenous injection of a drug that obeys two-compartment pharmacokinetics, the plasma concentration declines in a complex biexponential fashion. When plotted on semilog graph paper, the separate processes of distribution and elimination can be identified by the method of residuals (Fig 37-11).<sup>8</sup>

**Figure 37-10.** Diagram of open two-compartment pharmacokinetic model. The amount of dose that enters the body for an intravenous injection is the entire dose, and administration is instantaneous. The amount of dose absorbed from an extravascular dose is  $f d$ , where  $f$  is the fraction of dose absorbed with a rate constant,  $k_a$ . Some of the absorbed drug enters Compartment 2 with a first-order rate constant of  $k_{12}$  and is returned to Compartment 1 with a first-order rate constant of  $k_{21}$ .  $D_1$  is the amount of drug in Compartment 1, and  $D_2$  in Compartment 2;  $C_1$  and  $C_2$  are the respective concentrations in Compartments 1 and 2 ( $C_1 = C_p$ ). Drug is eliminated from Compartment 1 with a first-order rate constant,  $k_{el}$ , which, however, is obscured by the lag in transfer of drug from Compartment 2 to Compartment 1.  $D_u$  is the amount excreted into urine, feces, expired air, sweat, milk, etc;  $D_m$  is the amount of drug metabolized. The relative volumes  $V_1$  and  $V_2$  may vary greatly,  $V_1$  sometimes being the larger and other times the smaller.

Figure 37-11 shows such a resolution of the biexponential decay into the two components of distribution and elimination. From the slopes and intercepts of the residuals, the plasma concentration,  $C$ , at any time,  $t$ , can be described as the sum of two exponentials, namely:

$$C = C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} \quad (24)$$

where

$$C_1 = \frac{\text{Dose}(\lambda_1 - k_{21})}{V_1(\lambda_1 - \lambda_2)} \quad (25)$$

and

$$C_2 = \frac{\text{Dose}(k_{21} - \lambda_2)}{V_1(\lambda_1 - \lambda_2)} \quad (26)$$

Distribution is more rapid than elimination, such that at some point, the first term in Equation 24,  $C_1 e^{-\lambda_1 t}$  approaches zero, and the biological half-life can be determined from the slope of the terminal phase:

$$t_{1/2} = \frac{0.693}{\lambda_2} \quad (27)$$

$C_1$ ,  $C_2$ ,  $\lambda_1$ , and  $\lambda_2$  are hybrid constants, representing the intercepts,  $C_1$ ,  $C_2$ , and slopes,  $\lambda_1$ ,  $\lambda_2$ , of the two exponential phases, which can be obtained by computer-fitting the biexponential data. The zero-time intercept and the volume of the central compartment,  $V_1$ , and the actual pharmacokinetic parameters  $k_{12}$ ,  $k_{21}$ , and  $k_{el}$  can be derived from the hybrid rate constants, using the following relationships. At time  $t = 0$

$$C_0 = C_1 + C_2; V_1 = \frac{\text{Dose}}{C_1 + C_2} \quad (28)$$

**Figure 37-11.** Resolution of the plasma concentration curve for pralidoxime into its distribution and elimination components after intravenous administration. Note that plasma concentration is plotted on a logarithmic scale. The time constant for the elimination phase is determined from the slope,  $-0.434 \lambda_2$ ; it is a hybrid constant and  $\lambda_2$  is not the same as  $k_{el}$  (see text). Likewise, the time constant for distribution,  $\lambda_1$ , is obtained from the slope,  $-0.434 \lambda_1$ , of the distribution line;  $\lambda_1$  is also a hybrid constant. (From Gibaldi M, Perrier D. *Pharmacokinetics*, 2nd edn. New York: Dekker, 1982.)

The hybrid rate constants,  $\lambda_1$  and  $\lambda_2$ , can be defined using the following two equations:

$$\lambda_1 \lambda_2 = k_{21} k_{el} \quad (29)$$

$$\lambda_1 + \lambda_2 = k_{12} + k_{21} + k_{el} \quad (30)$$

Thus,

$$k_{el} = \frac{\lambda_1 \lambda_2}{k_{21}} \quad (31)$$

$$k_{21} = \frac{C_1 \lambda_2 + C_2 \lambda_1}{\lambda_1 - \lambda_2} \quad (32)$$

$$k_{12} = \lambda_1 + \lambda_2 - k_{21} - k_{el} \quad (33)$$

The reader is referred to Gibaldi and Perrier (see *Bibliography*) for a more in-depth derivation of these expressions. The slope of the final phase of biexponential disposition,  $\lambda_2$ , can be related to the elimination-rate constant,  $k_{el}$ , by:

$$\lambda_2 = f_C k_{el} \quad (34)$$

where  $f_C$  is the fraction of the drug that is in the central compartment after distribution equilibrium has been achieved. After distribution, the fraction of the drug in the central compartment is a constant.

$$f_C = \frac{k_{21} - \lambda_2}{k_{21} + k_{12} - \lambda_2} \quad (35)$$

The terminal disposition constant,  $\lambda_2$ , reflects disposition from the entire body and is a function of distribution and elimination. The rate constant,  $k_{el}$ , represents only elimination from the theoretical central compartment.

The volume of distribution,  $V_D$ , can be determined in a two-compartment system; however, the estimation is complicated by the noninstantaneous nature of the distribution phase between the two compartments and results in the apparent volume of distribution being time-dependent. From Equation 18, it can be seen that the volume of distribution of the central compartment,  $V_1$ , can be obtained following administration of an intravenous dose,  $D_{IV}$ , of drug from:

$$V_1 = \frac{D_{IV}}{C_1 + C_2} \quad (36)$$

Clearance can be calculated from the product of  $k_{el}$  and  $V_1$ , and the volume of the central compartment can be expressed as:

$$V_1 = \frac{D_{IV}}{k_{10} [AUC]_{0 \rightarrow \infty}} \quad (37)$$

The most accurate method of estimating the volume of distribution is to estimate the steady-state volume of distribution. The volume of distribution at the steady state,  $V_{SS}$ , represents the steady state with respect to distribution of the drug from the central compartment to the tissue compartments and is not altered by changes in drug elimination or clearance. The total amount of the drug in the body at the steady state is the sum of the amounts in all compartments, thus:

$$V_{SS} = V_1 + \frac{k_{12}}{k_{21}} V_1 \quad (38)$$

Notice that  $V_{SS}$  is independent of the elimination rate constant,  $k_{el}$ , and  $\lambda_2$ .

The volume of distribution by area,  $V$ , is an alternate method of estimating the apparent volume of distribution and relies on the assumption that the plasma and the amount of drug in the body decline in parallel during the postdistributive phase.

$$V_{\beta} = \frac{V_1 k_{el}}{\lambda_2} \quad (39)$$

The least accurate method of estimating the volume of distribution for a drug that follows biexponential elimination kinetics is by extrapolation,  $V_{EXTRAP}$ , because changes in distribution can alter the estimation of the hybrid intercept,  $C_2$ .

$$V_{EXTRAP} = \frac{D_{IV}}{C_2} \quad (40)$$

Distribution to various tissues depends upon both blood flow to that tissue and the rate of uptake (effective partition coefficient) into a particular tissue and its cells. The overall pattern of drug distribution is governed by both tissue perfusion and diffusion of drug within tissues. Tissues with the highest blood flow, such as liver, kidney, and brain, equilibrate more rapidly than tissues that are perfused less well, such as skin and fat. Once in the tissue vasculature, drug distribution into tissue is controlled largely by diffusional barriers of cell membranes. Rowland and Tozer (see *Bibliography*) present a useful expression for the first-order rate constant for distribution of drug into tissue.

$$k_{TISSUE} = \frac{(Q/V_{TISSUE})}{k_{PARTITION}} \quad (41)$$

where  $k_{PARTITION}$  is the equilibrium distribution ratio of tissue and venous drug concentration,  $Q$  is tissue blood flow,  $V_{TISSUE}$  is the tissue volume, and the quotient of  $Q$  and  $V_{TISSUE}$  is the tissue perfusion rate. The time to reach tissue equilibrium is the reciprocal of Equation 41. For a poorly perfused tissue such as fat, the  $k_{PARTITION}$  may be quite high and the  $Q/V_{TISSUE}$  low, resulting in a long time to reach tissue equilibrium. Even for highly perfused tissues, such as the brain, the distribution of some drugs may be quite variable and will depend upon diffusion across cell membranes. In this case, distribution is said to be diffusion-rate-limited and will depend upon both the oil-to-water partition coefficient and the degree of ionization at physiological pH.

For most drugs, distribution usually occurs more rapidly than elimination, resulting in complete distribution before most of the drug has been eliminated. For some drugs, once injected, distribution is so rapid that the overall plasma-concentration time-course represents elimination (see Fig 37-7). Thus, both administration and distribution appear to be instantaneous, and the pharmacokinetics can be modeled by the simplest one-compartment model (see Fig 37-7). For such a drug, the volume of distribution can be calculated as the quotient of the intravenous dose and the extrapolated plasma concentration at time zero,  $C_0$ .

## CONTINUOUS INPUT

It is sometimes desirable to administer a drug continuously to maintain constant plasma concentration. This is often the case for drugs with very rapid elimination or for those that have a low therapeutic index. Continuous input commonly is thought of in terms of intravenous infusion; however, sustained-release oral dosage forms and delivery of drugs through the skin from patches also are examples of continuous input, and the pharmacokinetics of drug administration is similar for all systems with continuous input.

With constant intravenous infusion, the plasma concentration rises in a logarithmic fashion and eventually reaches a plateau (Fig 37-12).<sup>8</sup> The time to reach the plateau or steady-state concentration is determined by the elimination rate constant.

**Figure 37-12.** Semilogarithmic plot of plasma concentration during and after cessation of a constant intravenous infusion of a drug in a one-compartment system. Whether infusion is stopped prior to the attainment of a plateau or after, the plasma concentration will fall logarithmically with a slope of  $-0.434k_{el}$ . In the figure,  $K$  is  $k_{el}$  and  $1/2.303 = 0.434$ .  $C_{ss}$  is the steady-state concentration,  $C_p^{ss}$ . (From Gibaldi M, Perrier D. *Pharmacokinetics*, 2nd edn. New York: Dekker, 1982.)

The rate of change of drug in the body ( $D_B$ ) during a constant rate infusion ( $R_0$ ) is the difference between the zero-order infusion rate and the first-order elimination rate.

$$\frac{dD_B}{dt} = R_0 - (k_{el} \cdot D_B) \quad (42)$$

The plasma concentration ( $C$ ) at any time during the constant infusion is:

$$C = \frac{R_0}{CL_T} (1 - e^{-k_{el} t_{inf}}) \quad (43)$$

where  $t_{inf}$  equals the time of the infusion. As the time of the infusion increases, the exponential expression approaches zero, and the concentration approaches steady state. At steady state the rate of infusion is equal to the rate of elimination, and the simplified expression can be expressed as:

$$C_{ss} = \frac{R_0}{CL_T} \quad (44)$$

The fraction of the steady state that is achieved in some time,  $t_{inf}$ , after the start of the infusion can be calculated as:

$$\frac{C}{C_{ss}} = (1 - e^{-k_{el} t_{inf}}) \quad (45)$$

and can be expressed in terms of half-lives as:

$$\frac{C}{C_{ss}} = (1 - 2^{-n}) \quad (46)$$

where  $n$  is the ratio of infusion time and half-life. For example, when the infusion time equals three half-lives ( $n = 3$ ), the concentration is at 87.5% of the steady state, and when the infusion has lasted for four half-lives ( $n = 4$ ), the concentration has achieved 93.75% of the steady state. Theoretically, one never reaches steady-state conditions because this is an exponential process; however, for clinical purposes one can assume, with little error, that steady-state concentrations are achieved within four to five half-lives.

If a drug has a relatively long half-life and the therapeutic situation demands rapid attainment of therapeutic plasma concentrations, it is sometimes desirable to give a loading dose at the beginning of the constant-rate infusion. The loading dose should approximate the amount of drug in the body at steady state. If the apparent volume of distribution and target concentration is known, the loading dose can be calculated simply as:

$$\text{Dose}_{\text{LOADING}} = (\text{Target concentration})(V_D) \quad (47)$$

The plasma concentration is the sum of the contributions from the loading dose and the infusion and can be estimated at any time after the loading dose has been given and infusion started from:

$$C = \frac{\text{Dose}_{\text{LOADING}}}{V_D} (e^{-k_{el}t}) + \frac{R_0}{CL_T} (1 - e^{-k_{el}t}) \quad (48)$$

and if the half-life of the drug is known, the loading dose can be estimated from the quotient of infusion rate,  $R_0$ , and elimination rate constant,  $k_{el}$ . For some drugs, such as lidocaine, the entire loading dose cannot be given in a single bolus injection because there is a significant distribution phase. In such a case, fractional loading-dose schemes can be used in which the loading dose is divided into several smaller bolus doses and given during the beginning of the infusion.

Finally, it should be noted that whether or not a loading dose is given, the attainment of steady state is determined by the elimination half-life and not by the rate of the infusion or the use of bolus loading doses to achieve concentrations rapidly.

## MULTIPLE-DOSE ADMINISTRATION

Continuous administration of a drug is often impractical, and multiple-dose regimens are used to maintain the concentration of a drug within an acceptable range that minimizes the development of toxicity and avoids loss of efficacy. Usually, the dose of a drug is administered with a constant dose interval, referred to as  $\tau$ . Some features of a multiple dosage scheme are shown in Figure 37-13. The drug is administered at a fixed dose and a

fixed interval. Each successive dose is administered before the previous dose has been eliminated entirely, and thus drug accumulation occurs. As with the constant intravenous infusion, the time to reach a steady-state fluctuation depends upon the elimination half-life and not on the size of the dose or the dosing interval. In Figure 37-13, the dose,  $D$ , is administered at a dosing interval equal to the half-life. After the first dose is given, the amount of drug in the body is equal to that dose. When the next dose is given, the amount of drug in the body is equal to  $D + 0.5D$ . At the end of each dose interval, the total amount of drug in the body is half of the postinjection peak and is the sum of the amount remaining from all of the previous doses. The maximum,  $C_{\text{MAX,SS}}$ , and minimum,  $C_{\text{MIN,SS}}$ , concentrations at steady state are described by:

$$C_{\text{MAX,SS}} = \frac{\text{Dose}/V_D}{(1 - e^{-k_{el}\tau})} \quad (49)$$

and

$$C_{\text{MIN,SS}} = C_{\text{MAX,SS}} e^{-k_{el}\tau} \quad (50)$$

The concentration at the midpoint of a dosing interval at the steady state is a time-averaged concentration,  $C_{\text{AV}}$ , over the entire dosing interval and is described by:

$$C_{\text{AV}} = \frac{D_{\text{IV}}}{V_D k_{el} \tau} = \frac{1.44 t_{1/2} D_{\text{IV}}}{V_D \tau} \quad (51)$$

## NONCOMPARTMENTAL ANALYSIS FOLLOWING INSTANTANEOUS INPUT

There are numerous disadvantages associated with viewing drug disposition from a compartmental perspective, not the least of which is the lack of physiological relevance of such models. Noncompartmental models have been developed and are generally the preferred method for assessing overall drug disposition, in part because parameters such as volume of distribution and clearance can be calculated directly from the

**Figure 37-13.** The accumulation of drug in the body during a regimen of multiple dosing. Dose,  $D$ , is administered intravenously at intervals,  $\tau$ , equal to the half-life,  $t_{1/2}$ . Thus, after each dose, the amount in the body,  $D_B$ , has decreased to half the previous peak amount at the time each dose is administered. When the cumulated amount in the body after injection reaches  $2D$ , the body content will fluctuate from  $2D$  to  $1D$  during each dose interval thereafter. Approximately five half-lives are required before this leveling off (plateau) of the body content occurs. The stippled area is the area under the elimination curve of a single injection if no second dose had been given. The cross-hatched area is the area under the curve during a single-dose interval at steady state. The two areas are equal.

data, without computer fitting. Moreover, parameters estimated by these methods generally are less sensitive to variability in the data. Noncompartmental methods characterize drug disposition using time- and concentration-averaged parameters and have been described by Jusko.<sup>9</sup> This analysis also is known as nonparametric analysis and assumes that all processes are first-order and that the parameters of the model reflect steady-state behavior. A primary tool used in this methodology is that of statistical moments.<sup>10</sup>

### STATISTICAL MOMENTS

The use of statistical moments in the analysis of the time-course of drug concentrations is especially useful because it frees the investigator from the use of such models as the compartmental, which often are derived empirically and do not represent physiological events.

The time-course of drug concentration in blood generally can be viewed as a statistical distribution curve and described in a similar manner as any other array of data. A moment is simply a mathematical description of a discrete distribution of data. In the field of statistics, for example, the sample size ( $n$ ), mean, and variance are the zero ( $M_0$ ), first ( $M_1$ ) and second ( $M_2$ ) moments, respectively, for an array of data. In physics, for example, weight, center of mass, and moment of inertia represent  $M_0$ ,  $M_1$ , and  $M_2$ , respectively.

In statistics, the mean of a population is estimated by the sample mean. Similarly, in pharmacokinetics one may calculate estimates of the true function that describes the drug concentration versus time using statistical moments. Assume the existence of a theoretical relationship for  $C(t)$  as a function of time. The non normalized moments,  $S_r$ , where  $r = 0, 1, 2, \dots, m^{\text{th}}$  moment, about the origin are calculated as:

$$S_r = \int_0^{\infty} t^r C(t) dt \quad (r = 0, 1, 2, \dots, m) \quad (52)$$

Hence,

$$S_0 = \int_0^{\infty} C(t) dt = AUC \quad (53)$$

$$S_1 = \int_0^{\infty} tC(t) dt = AUMC \quad (54)$$

where  $AUMC$  is the area under the  $C$ - $t$  versus time curve, whereas  $S_0$  and  $S_1$  are the zero and first nonnormalized moments, respectively. These two parameters,  $AUC$  and  $AUMC$ , are derived from the drug concentration versus time data and are used to calculate the pharmacokinetic parameters of interest.

The use of noncompartmental methods requires a means of determining the  $AUC$ . While several methods are available for such determinations, the simplest is the use of the trapezoidal rule.<sup>11</sup> This permits calculation of the  $AUC$  or the  $AUMC$  from zero to the time of the last sample ( $t_n$ ). However, it generally is necessary to determine the area from zero to infinity. If one assumes that there is log-linear decline from  $t_n$  to infinity, then

$$AUC_{t_n}^{\infty} = \int_{t_n}^{\infty} C dt = \frac{C^n}{\lambda_z} \quad (55)$$

where  $\lambda_z$  is the slope of the terminal exponential. Thus, the  $AUC$  from zero to infinity can be calculated as

$$AUC_0^{\infty} = AUC_0^{t_n} + \frac{C^n}{\lambda_z} \quad (56)$$

For the  $AUMC$ ,

$$AUMC_{t_n}^{\infty} = \frac{C^n}{(\lambda_z)^2} + \frac{t^n C^n}{\lambda_z} \quad (57)$$

and

$$AUMC_0^{\infty} = AUMC_0^{t_n} + \frac{C^n}{(\lambda_z)^2} + \frac{t^n C^n}{\lambda_z} \quad (58)$$

### PHARMACOKINETIC PARAMETERS DERIVED FROM STATISTICAL MOMENTS

There are four parameters of primary interest that are derived using statistical moments, the most important of which is clearance. A conceptual consideration of clearance is provided by considering an organ through which blood containing a drug flows.

where  $Q_{IN}$ ,  $Q_{OUT}$ ,  $C_A$ , and  $C_V$  are the blood flow in and out and the concentration of the drug in arterial and venous blood, respectively. If  $C_V < C_A$ , the organ is capable of elimination and is referred to as a clearing organ, or an organ of elimination. The elimination of a drug can be described using mass balance considerations:

$$\text{Rate of the drug entering the organ} = QC_A \quad (59)$$

$$\text{Rate of the drug leaving the organ} = QC_V \quad (60)$$

Rate of elimination of the drug:

$$\text{Rate of elimination of the drug} = QC_A - QC_V = Q(C_A - C_V) \quad (61)$$

The ratio of the rate of drug elimination and the rate at which the drug enters the organ is defined as the extraction ratio,  $E$ .

$$E = \frac{\text{Rate of elimination}}{\text{Rate of entry}} = \frac{Q(C_A - C_V)}{QC_A} = \frac{(C_A - C_V)}{C_A} \quad (62)$$

The extraction ratio is a measure of the efficiency with which an organ eliminates a drug. From this parameter, the organ clearance of a drug can be described as:

$$CL_T = QE = \frac{Q(C_A - C_V)}{C_A} \quad (63)$$

Recall that clearance is defined as the volume of blood from which all of the drug would appear to be removed per unit time. By analogy to the definition of organ clearance, one can define the total or systemic clearance as the ratio of overall elimination rate,  $dX/dt$ , to drug concentration in blood,  $C$ :

$$CL_T = \frac{dX/dt}{C} \quad (64)$$

Integrating from zero to infinity yields:

$$CL_T = \frac{\int_0^{\infty} dX/dt}{\int_0^{\infty} C dt} \quad (65)$$

where the numerator is the total amount of the drug ultimately eliminated (the IV dose) and the denominator is the  $AUC$  from zero to infinity. Thus, the total clearance is the quotient of intravenous dose and the  $AUC$  from zero to infinity.

$$CL_T = \frac{\text{Dose}_{IV}}{AUC_0^{\infty}} \quad (66)$$

The volume of distribution at the steady-state,  $V_{ss}$ , most reliably measured during a steady-state infusion, now can be determined using data from single-dose experiments and employing statistical moment analysis.<sup>12</sup>

$$V_{ss} = \frac{(\text{Dose}_{IV})(AUMC)}{(AUC)^2} \quad (67)$$

Equation 67 assumes that:

1. All processes involved in drug disposition (e.g., distribution, elimination) are linear.
2. The drug is administered to and eliminated via the sampling site.
3. There is instantaneous input.

If the drug is administered via a short infusion, the volume of distribution at the steady state can be estimated from:

$$V_{ss} = \frac{(R_0 T)(AUMC)}{(AUC)^2} - \frac{R_0 T^2}{2(AUC)} \quad (68)$$

Where  $R_0$  is the rate of infusion and  $T$  is the duration of the infusion.

Another important pharmacokinetic parameter that can be determined using statistical moment analysis is the *systemic availability*,  $F$ , which is a measure of the fraction of the administered dose that reaches the systemic circulation following oral administration. This parameter can be calculated as:

$$F = \frac{AUC_{PO} Dose_{IV}}{AUC_{IV} Dose_{PO}} \quad (69)$$

where  $AUC_{PO}$  and  $Dose_{PO}$  are the oral area under the concentration-versus-time curve and oral dose, respectively.

When administering a drug, the amount administered in terms of gross weight (e.g., mg, g, or  $\mu$ g) often is considered. It is, however, probably more appropriate to focus on *molecules* when considering pharmacokinetic and pharmacodynamic events. Even the administration of a relatively small dose of drug may represent a large number of molecules. Consider the administration of 1 mg of a drug with a molecular weight of 300 daltons. The number of molecules in this dose is approximately  $2 \times 10^{18}$ . Instantaneous administration of the entire dose will result in drug molecules spending various amounts of time in the body. After the intravenous injection of a drug, one can imagine that some of the drug molecules are eliminated immediately, whereas some of the molecules require a longer time to be eliminated, and some molecules even require a very long time to be eliminated. The time spent in the body, for a given molecule, is its residence time. The *mean residence time*,  $MRT$ , is the sum of all the residence times divided by the number of molecules. A conceptual understanding of this can be gained from the following example.

Assume a child receives 20 dimes for his birthday and immediately places them in his piggy bank. Over the next month, he periodically removes one or more dimes from the piggy bank to purchase candy. Specifically, 3 days after placing the coins in his bank, he removes 5 dimes, on day 10 he removes 4 dimes, on day 21 he removes 6 dimes, and on day 30 he removes 5 dimes. At the 30<sup>th</sup> day after placing the coins in his bank, all of the coins have been removed. Hence, the *elimination* of dimes from the bank is complete. The  $MRT$  of dimes in the piggy bank is simply the sum of the times that coins spend in the bank divided by the number of dimes placed in the bank:

$$MRT = \frac{3+3+3+3+10+10+10+10+21+21+21+21+21+30+30+30+30}{20}$$

$$MRT = \frac{3 \times 5 + 10 \times 4 + 21 \times 6 + 30 \times 5}{20}$$

$$MRT = 16.55 \text{ days}$$

This provides a relationship with which one can determine the  $MRT$  for any given number of drug molecules,  $A_i$ , which spend a given amount of time in the body of,  $t_i$ , thus:

$$MRT = \frac{\sum_{i=1}^n A_i t_i}{A_{TOTAL}} \quad (70)$$

where  $n$  equals the total number of residence times. The mean rate of drug leaving the body relative to the total amount eliminated also can be expressed in terms of concentration.

$$MRT = \frac{\int_0^{\infty} tC(t)dt}{C(t)dt} = \frac{AUMC}{AUC} \quad (71)$$

Equation 71 is not a definition of  $MRT$ , rather, it is the derived expression from which one can calculate  $MRT$  when clearance is constant. The mean residence time assumes instantaneous administration, and therefore, it is technically incorrect to calculate the mean residence time following an oral dose using the quotient of  $AUMC_{PO}$  and  $AUC_{PO}$ . When calculated in this manner, it often is stated that the  $MRT$  is a function of the route of administration. Actually,  $MRT$  is *independent* of the route of administration because the mean time that molecules reside in the body is not influenced by the route of administration.<sup>13</sup> However, the interpretation of the ratio of  $AUMC$  and  $AUC$  does change as a function of administration because this ratio only yields the  $MRT$  when the input is instantaneous.

A better way to express the route dependence of the  $AUMC/AUC$  is to refer to this ratio as the *mean transit time*,  $MTT$ . The  $MTT$  is the average time required for drug molecules to leave a kinetic system after administration. Thus, because an IV bolus assumes instant input,

$$AUMC_{IV} / AUC_{IV} = MRT = MTT_{IV} \quad (72)$$

whereas,

$$\begin{aligned} AUMC_{PO} / AUC_{PO} &= MTT_{PO} = MTT_{IV} + MAT \\ &= MRT + MAT \end{aligned} \quad (73)$$

where  $MAT$  is the mean absorption time. Thus, for oral absorption, the  $AUMC/AUC$  provides an  $MTT$  in the kinetic system that is composed of the gastrointestinal (GI) tract and the body. The  $MRT$  also can be calculated as the quotient of the  $V_{SS}$  and clearance. Finally, one can relate the  $MRT$  to the elimination half-life by considering the situation in which a drug displays monoexponential decline. The  $MRT$  can be written as:

$$MRT = \frac{AUMC}{AUC} = \frac{C_0 / \lambda^2}{C_0 / \lambda} = \frac{1}{\lambda} \quad (74)$$

and represents the time required for 63.2% of an intravenous dose to be eliminated from the body.

## ABSORPTION

If a drug is administered intravenously in a single, rapid injection, the process of absorption is bypassed. The time for this injection is typically so short compared with other pharmacokinetic processes that it is ignored. As previously described for a one-compartment model, peak plasma concentration and distribution equilibrium are achieved instantaneously. This is depicted in Figure 37-14A.<sup>14</sup> In the model for the figure, there is no elimination, and the concentration remains constant following administration. With a constant intravenous infusion ( $B$ ), the concentration rises rectilinearly so long as the infusion is maintained at a constant, zero-order rate. With other routes of administration, there are delays in the appearance of drug in the vascular system because the drug must be absorbed from the site of administration (oral, intramuscular, subcutaneous, and rectal). Drug absorption depends upon both the physicochemical properties of the drug ( $pK_a$ , dosage form, partition coefficient) and the physiology of the site of absorption (surface area, blood flow). Most drugs are absorbed by simple diffusion, and the kinetics are first-order. Zero-order absorption occurs for some processes that are saturable and for sustained-release dosage forms. Absorption and elimination of a drug are a sequential process, and the rate of change of drug in the body is the difference between the rate of uptake (absorption) and rate of efflux (elimination). For a drug that is absorbed by a first-order process and eliminated by a first-order process, with

**Figure 37-14.** Time-concentration curves for injection (A), infusion (B), and extravenous (C) administration of drug in the one-compartment model. The volume of the compartment is 100 L ( $V_d$  100 L); the amount of drug administered in each instance is 1000 mg. Drug elimination has been set to zero so that the time-concentration curve for each model of administration can be examined without the complication of simultaneous elimination. (Adapted from Bigger JT. Pharmacologic and clinical control of antiarrhythmic drugs. *Am J Med* 1975; 58: 479-488.)

instantaneous distribution, the rate of change of the amount of drug in the body can be expressed as:

$$\frac{dD_B}{dt} = \text{RATE}_{IN} - \text{RATE}_{OUT} \quad (75)$$

For a drug that is absorbed from the GI tract, the rate of change of the amount of drug in the body is

$$\frac{dD_B}{dt} = Fk_a D_{GI} - kD_{BODY} \quad (76)$$

The time-course of absorption and elimination is shown in Figure 37-15.<sup>7</sup> The plasma concentration at any time  $t$  is equal to:

$$C = \frac{k_a D_0 F}{V_D (k_a - k_{el})} (e^{-k_{el}t} - e^{-k_a t}) \quad (77)$$

where  $F$  is the fraction of the dose,  $D_0$ , that is absorbed from the GI tract and  $k_{el}$  and  $k_a$  are the first-order rate constants for elimination and absorption, respectively. The time to reach the maximum concentration,  $t_{MAX}$ , can be determined from:

$$t_{MAX} = \frac{2.3 \log(k_a / k)}{k_a - k} \quad (78)$$

and this time substituted into Equation 77 will determine the maximum concentration,  $C_{MAX}$ . The rising phase of the plot (see Fig 37-15) is not log-linear because absorption and elimination are occurring simultaneously. At  $C_{MAX}$ , the absorption rate is equal to the elimination rate, and after absorption is complete, the plot declines in a log-linear manner. This log-linear line described by the elimination phase, when extrapolated to zero time, yields a theoretical zero-time concentration. The absorption rate constant,  $k_a$ , can be obtained from the difference between the empirical curve and the extrapolated line using the *method of residuals*. This is a commonly used technique in pharmacokinetics to separate a curve into its component parts and is often referred to as *feathering*, *stripping*, or *peeling* the curve. The reader is referred to Gibaldi and Perrier (see *Bibliography*) for a more comprehensive discussion with examples of the application of this technique.

That the peak concentration should vary with the dose is self-evident from Equations 77 and 78 and from Figure 37-16. The time of the peak concentration is the same for all doses. The time to peak concentration can be affected by both the absorption rate and the elimination rate. In Figure 37-17, the effect of altering the absorption rate on the time to peak concentration is shown. With faster absorption, the time to peak concentration occurs earlier and is higher than with slower absorption. Figure 37-18 shows the effect of altering the elimination rate constant on the  $t_{MAX}$ . With a rapid elimination rate (shorter

half-life), the peak concentration occurs sooner and is lower than with slower elimination (longer half-life).

The maximum concentration at the steady state for an oral regimen is given by:

$$C_{MAX,SS} = \frac{FDose}{V_D} \left( \frac{1}{1 - e^{-k\tau}} \right) e^{-k t_{PEAK}} \quad (79)$$

The minimum concentration at the steady state is:

$$C_{MIN,SS} = \frac{k_a FD}{V(k_a - k)} \left( \frac{1}{1 - e^{-k\tau}} \right) e^{-k\tau} \quad (80)$$

To design multiple oral dosing regimens, the equations that describe the maximum and minimum concentrations at the

**Figure 37-17.** The effect of differences in the rate of absorption of drugs on the peak concentration, time of peak concentration, and sojourn in the body. The rate of elimination is the same for all curves. The dotted line ( $k_a = \infty$ ) is approximately what the concentration curve would be, had the drug been given intravenously. The data were calculated from a one-compartment model.

steady state are somewhat unwieldy. In clinical practice, values for  $k_a$  are not always readily available, and in such instances the equations for the maximum and minimum concentrations at the steady state following intravenous administration will generally suffice as long as one recalls that because absorption is not instantaneous, the peak concentration and time to peak concentration will not occur immediately.

## ORGAN-SPECIFIC CLEARANCE

The total clearance of a drug from the body almost always involves more than one organ of elimination. The anatomy of the human body is such that the clearance from the composite clearing organs occurs in parallel and is, therefore, additive. For example, if a drug is eliminated solely by hepatic and renal elimination, the total clearance,  $CL_T$ , of the drug is given as

$$CL_T = CL_H + CL_R \quad (81)$$

where  $CL_H$  and  $CL_R$  are the hepatic and renal clearance, respectively. Measurement of the total amount of drug excreted unchanged in urine,  $D_U$ , after an intravenous dose,  $D_{IV}$ , allows the calculation of the fraction of the drug eliminated renally,  $F_r$ , where

$$F_r = \frac{D_U}{D_{IV}} \quad (82)$$

The renal clearance,  $CL_R$ , may be determined as the product of total clearance and the fraction of the drug eliminated by the kidney. If the liver is the only other eliminating organ, the hepatic clearance is given by

$$CL_H = CL_T - CL_R \rightarrow (1 - F_r)CL_T \quad (83)$$

One exception to the principle of the additivity of organ clearances is pulmonary drug elimination. This exception is because the lung is in circulatory series with the rest of the body organs such that 100% of cardiac output passes through the lungs. Few drugs exhibit significant elimination by the lungs so that this exception is rarely of concern in the overall assessment of drug elimination.

## HEPATIC CLEARANCE

It was shown previously that the ratio of the rate of drug elimination and the rate at which drug enters the organ of elimination is defined as the extraction ratio,  $E$ , and is a measure of the efficiency with which an organ eliminates a given drug. One can define the organ clearance of a drug as the product of blood flow to the organ,  $Q$ , and the extraction ratio, and for hepatic clearance the equation becomes:

$$CL_H = Q_H E \quad (84)$$

where  $Q_H$  is the hepatic blood flow. While an initial examination of this simplistic model for hepatic clearance would suggest that  $CL_H$  is directly proportional to  $Q_H$ , this conclusion is not correct because  $E$  varies inversely with  $Q_H$ . Specifically, as  $Q_H$  increases,  $E$  decreases. This observation indicates that a more complex model of hepatic clearance is necessary if quantitative and qualitative predictions of hepatic drug clearance are to be made. In particular, this parameter must be described in terms that are physiologically independent.

Numerous models have been proposed and tested to describe the hepatic clearance of drugs. While a discussion of the advantages and disadvantages of the various models proposed is beyond the scope of this chapter, the *venous equilibrium* model of hepatic clearance has shown substantial utility in the prediction of both pathophysiological and drug-induced changes in hepatic clearance. For a good discussion of the various models of hepatic clearance, see the review by Morgan and Smallwood.<sup>15</sup> In the venous equilibrium model, the hepatic extraction is described by:

$$E = \frac{f_{ub} CL_{u,int}}{Q_H + f_{ub} CL_{u,int}} \quad (85)$$

where  $f_{ub}$  and  $CL_{u,int}$  are the unbound fraction in blood and the unbound intrinsic hepatic clearance, respectively. The unbound intrinsic clearance reflects the ability of the liver to remove drug from blood in the absence of other confounding factors, such as  $Q_H$  and  $f_{ub}$ . Since it has already been shown that hepatic clearance is the product of  $Q_H$  and  $E$ ,

$$CL_H = \frac{(Q_H)(f_{ub} CL_{u,int})}{Q_H + f_{ub} CL_{u,int}} \quad (86)$$

This model for hepatic clearance provides a powerful tool for predicting changes in drug clearance and, subsequently, steady-state drug concentrations, when certain limiting conditions are met. In particular,

when  $Q_H \gg f_{ub} CL_{u,int}$ ,  $CL_H$  can be approximated by  $f_{ub} CL_{u,int}$  (87)

When  $Q_H \ll f_{ub} CL_{u,int}$ ,  $CL_H$  can be approximated by  $Q_H$  (88)

Compounds with a high  $f_{ub} CL_{u,int}$  are said to exhibit perfusion rate-limited elimination; that is, their elimination rate will be rate-limited by hepatic blood flow. Compounds with a low  $f_{ub} CL_{u,int}$  are said to be perfusion rate-independent. These limiting conditions allow us to place many drugs into classifications that exhibit similar pharmacokinetics. For example, agents with an  $f_{ub} CL_{u,int} < 0.2$  L/min can be classified as low intrinsic clearance drugs, whereas those with an  $f_{ub} CL_{u,int} > 5$  L/min are defined as exhibiting a high intrinsic clearance (Table 37-1).

The venous equilibrium model also serves as a useful tool in the assessment of the impact of changes in protein binding on hepatic clearance. Recall in Equation 87 that for a drug exhibiting a low intrinsic clearance, changes in protein binding will result in proportional changes in hepatic clearance. This type of drug is said to exhibit *restrictive clearance*; that is, only the free (or unbound) drug is available for clearance by the liver. High intrinsic clearance drugs, on the other hand, are said to exhibit *nonrestrictive clearance*.

These relationships provide important insight into the effect of changes in protein-binding on the steady-state concentration of drugs. Consider the case of a drug being administered as a constant-rate intravenous infusion. As described previously:

$$C_{ss} = R_0 / CL_T \rightarrow R_0 / CL_H \quad (89)$$

for a drug solely eliminated by the liver. In the case of a drug with a low intrinsic clearance, Equation 89 can be simplified to:

$$C_{ss} = R_0 / (f_{ub} CL_{u,int}) \quad (90)$$

If  $f_{ub}$  were to be increased, for example, by displacement from protein-binding sites, the steady-state concentration would decrease. This may lead one to the conclusion that the infusion rate needs to be increased to maintain the original steady-state concentration. However, one needs to examine the effects of altered physiology on the free or unbound drug concentration,  $C_{u,ss}$ :

$$C_{u,ss} = f_{ub} C_{ss} \rightarrow C_{ss} = C_{u,ss} / f_{ub} \quad (91)$$

substituting for  $C_{ss}$  in Equation 90 and solving for  $C_{u,ss}$  yields

$$C_{u,ss} = R_0 / CL_{u,int} \quad (92)$$

It can be seen that the steady-state concentration of unbound (active) drug is independent of changes in the free fraction, and no dosage adjustment would be necessary. This conclusion also is valid following the oral administration of a drug with a low intrinsic clearance.

In contrast, for a drug with a high intrinsic clearance, a change in  $f_{ub}$  will result in a proportional change in the steady-state unbound drug concentration during a constant-rate infusion.

**Table 37-1. Examples of Drugs with Low and High Intrinsic Clearances that are Eliminated Largely by Hepatic Metabolism**

Low intrinsic clearance	High intrinsic clearance
Antipyrine	Chlorpromazine
Barbiturates	Encainide
Diazepam	Meperidine
Digitoxin	Metoprolol
Isoniazid	Organonitrates
Phenytoin	Propafenone
Theophylline	Propranolol
Tolbutamide	Tricyclic antidepressants
Warfarin	Verapamil

An additional consideration, which must be accounted for with high intrinsic clearance drugs, is the impact of the first-pass effect. When a drug is absorbed from the stomach and small intestine, the venous blood from the sites of absorption enters into the portal venous flow. This results in all the absorbed drug passing through the liver prior to entry into the systemic circulation. For drugs that exhibit a high intrinsic clearance, the consequence of presystemic hepatic metabolism is a substantial reduction in the systemic availability of the drug when administered orally. This phenomenon explains the marked discrepancy between an oral and an intravenous dose of a given drug required to achieve identical plasma concentrations. For example, the therapeutic dose of propranolol ranges between 1 and 6 mg intravenously, whereas the oral doses necessary to achieve therapeutic effect range from 40 to 200 mg.

The systemic availability,  $F$ , of a drug that is absorbed completely from the GI tract after oral administration is the fraction of the absorbed dose that escapes extraction and is given as:

$$F = 1 - E \quad (93)$$

Rearranging Equation 85 and substituting for  $E$  in Equation 93 yields

$$F = \frac{Q_H}{Q_H + f_{ub} CL_{u,int}} \quad (94)$$

Similar to the limiting conditions described for  $CL_H$ , one can define two limiting conditions for systemic availability,  $F$ . Specifically, when  $Q_H \ll f_{ub} CL_{u,int}$ ,  $F$  approaches 1.0, whereas when  $Q_H \gg f_{ub} CL_{u,int}$ ,  $F$  approaches zero. These limiting conditions indicate that a drug with a high  $f_{ub} CL_{u,int}$  will exhibit low systemic availability after oral administration because of extensive first-pass metabolism. On the other hand, drugs with a low  $f_{ub} CL_{u,int}$  will not be subject to significant first-pass metabolism.

Generally, the parameter most commonly determined to assess overall drug availability after oral administration is the area under the drug concentration-versus-time curve,  $AUC$ . Recall from Equation 67 that the total clearance is equal to the quotient of intravenous dose and  $AUC$  from zero to infinity. If the drug is eliminated entirely by metabolism, the hepatic clearance is defined as:

$$CL_H = \frac{Dose_{IV}}{AUC_{IV}} = \frac{FDose_{PO}}{AUC_{PO}} \quad (95)$$

Substituting Equation 86 for  $CL_H$  and Equation 94 for  $F$  yields:

$$\frac{(Q_H)(f_{ub} CL_{u,int})}{Q_H + f_{ub} CL_{u,int}} = \left( \frac{Dose_{PO}}{AUC_{PO}} \right) \left( \frac{Q_H}{Q_H + f_{ub} CL_{u,int}} \right) \quad (96)$$

Simplifying,

$$f_{ub} CL_{u,int} = Dose_{PO} / AUC_{PO} \quad (97)$$

Thus, for a high intrinsic hepatic clearance drug, the  $AUC_{PO}$  is independent of  $Q_H$ . Additionally, the steady-state  $AUC$  for unbound drug is independent of the free fraction. For a more in-depth discussion of these concepts on hepatic clearance, see the paper by Wilkinson and Shand.<sup>16</sup>

## RENAL CLEARANCE

Physiologists studied the renal clearance of endogenous and exogenous substances long before the use of clearance concepts became popular in pharmacokinetics. Indeed, the basis for the understanding of drug clearance in pharmacokinetics has its roots in the decades of work by renal physiologists. Moreover, there are significant differences in the complexity of processes involved in hepatic and renal handling of drugs. In the kidney there are three primary processes (and one minor process) responsible for the renal elimination of drugs, namely filtration, secretion, and reabsorption (and metabolism), respectively. Each of the major processes is affected by common, yet unique, determinants.

The rate of filtration in the kidney for a drug is given as:

$$\text{Rate of filtration} = (GFR)(C_u) \quad (98)$$

where  $GFR$  is the glomerular filtration rate and  $C_u$  is the previously defined free-drug concentration. The clearance by filtration is the quotient of the rate of filtration at a given concentration; therefore, the renal clearance,  $CL_R$ , of a drug due to filtration is:

$$CL_R = (GFR)(f_u) \quad (99)$$

The renal clearance of a drug that is eliminated only by filtration can be estimated if the glomerular filtration rate and the free fraction of drug are known. There are two substances commonly used to estimate the  $GFR$ , namely creatinine, an endogenous by-product of muscle metabolism, and inulin, a polysaccharide. Both are essentially 100% eliminated in the urine by filtration and, thus, the  $CL_T$  of these two substances can be used as reasonable estimates for the  $GFR$ .

Another primary process involved in the renal elimination of drugs is active tubular secretion,  $ATS$ . There are several active-transport systems in the proximal renal tubule that are capable of excreting drugs from the blood into the urine. There appears to be a multiplicity of systems for the  $ATS$  of cations and anions. Whenever the renal clearance is greater than the product of the  $GFR$  and the free fraction, there must be net tubular secretion in addition to clearance by filtration. The renal clearance due to  $ATS$ , which is  $CL_{ATS}$ , is given as:

$$CT_{ATS} = \frac{(Q_{RP})(f_u CL_{u,s,int})}{Q_{RP} + f_u CL_{u,s,int}} \quad (100)$$

where  $Q_{RP}$  and  $CL_{u,s,int}$  represent effective renal plasma flow and unbound intrinsic secretory clearance, respectively. Similar to the situation described for hepatic clearance, drugs may exhibit a high or low intrinsic secretory clearance. The impact of changes in plasma protein-binding on renal clearance would substantially differ between these two situations.

For drugs that undergo both filtration and  $ATS$ , the renal clearance is simply the sum of the clearance due to filtration and the clearance due to secretion,

$$CL_R = (f_u)(GFR) + CL_{ATS} \quad (101)$$

In addition to these two processes, some drugs undergo tubular reabsorption, whereby some fraction of the drug excreted into the urine by filtration and secretion is reabsorbed into the body. Therefore, the full expression for renal clearance, taking into account all three processes, is given by:

$$CL_R = (f_u)(GFR) + CL_{ATS} - F_{TR}((f_u)(GFR) + CL_{ATS})$$

$$\text{or } CL_R = (1 - F_{TR})((f_u)(GFR) + CL_{ATS}) \quad (102)$$

where  $F_{TR}$  is the fraction undergoing tubular reabsorption. These relationships provide the basis for determining the primary mechanisms involved in the renal handling of a given drug. Specifically, determination of the ratio of renal clearance and that of inulin provides a clinically useful means to determine the processes that are primarily responsible for renal excretion. If the ratio is equal to 1, the drug would appear to be filtered exclusively by the kidney. Both  $ATS$  and  $TR$  also could be occurring, but at equal rates (an unlikely occurrence). If the ratio of renal clearance to inulin clearance is greater than 1, it is clear that the drug is undergoing net tubular secretion as well as filtration. Similarly, if the ratio is less than 1, the drug must be undergoing net tubular reabsorption.

Assessment of the mechanisms for the renal excretion of specific drugs is important because different factors will alter  $CL_R$ . For example, if a drug undergoes net tubular secretion, other drugs secreted by the same transport processes may compete for secretory sites, resulting in an overall decrease in the renal excretion of the drug. Alternatively, if a drug undergoes tubular re-absorption and is a weak acid (e.g., salicylate) or a weak

base (e.g., amphetamine), the renal clearance may be altered by manipulation of the urine pH or urine flow. See the review by Tucker<sup>17</sup> for a description of the methods for calculation of  $CL_R$ .

## PROTEIN-BINDING

Drugs circulating in the blood may bind reversibly to a number of components, including plasma proteins. This reversible binding may be described by simple mass-law relationships,

where  $[D_{unbound}]$ ,  $[P]$ , and  $[D - P]$  are the molar concentrations of the free drug, the protein to which the drug binds, and the drug-protein complex, respectively. It is obvious from this relationship that the amount of drug-protein complex formed is a function both of the concentration of the drug and protein and the affinity between the protein and the drug. Thus, changes in the protein concentration may alter binding, as may changes in the total drug concentration. For most drugs and their respective binding proteins, the concentration of protein far exceeds the concentration of drug, such that the fraction of drug that is bound to protein is independent of drug concentration in plasma or blood.

Because plasma proteins often have a molecular size that restricts their passage across cell membranes and capillary walls, drugs that are bound to plasma proteins are restricted similarly. Thus, plasma protein-binding can have a marked effect on the distribution and elimination of drugs. It is a basic tenet of pharmacology that only the unbound (free) drug is pharmacologically active, because it is assumed that the unbound drug is able to traverse biological membranes and reach the site of drug action. While there have been few direct tests of this hypothesis, those investigations that have been conducted support the assumption that the free drug is the principal pharmacologically active species.

There are several methods by which drug protein-binding may be described quantitatively, though the most frequent and useful is the free fraction,  $f_u$ . The  $f_u$  can be determined as:

$$f_u = \frac{C_u}{C_u + C_B} = \frac{C_u}{C_T} \quad (104)$$

where  $C_u$  is the concentration of unbound or free drug,  $C_B$  is the concentration of drug bound to protein, and  $C_T$  is the concentration of total drug (bound plus free). Obviously,  $f_u$  can range from 0 to 1. This relationship provides a means by which free drug *in vivo* can be calculated if the total concentration and the free fraction are known.

$$C_u = (C_T)(f_u) \quad (105)$$

Recognizing changes in protein-binding is important because it may substantially alter the pharmacokinetics of a drug. The previous section described the impact of protein-binding on clearance, referenced to total drug concentration. Protein-binding changes also may result in alterations in other pharmacokinetic parameters. The volume of distribution at the steady state can be expressed as:

$$V_{SS} = V_{blood} + V_{TW} \frac{f_u}{f_{uT}} \quad (106)$$

where  $V_{TW}$  is the volume of tissue water and  $f_{uT}$  is the free fraction of drug in tissue. From the relationship in Equation 106 (which is analogous to Equation 12, for drugs with a volume of distribution >50 L), it is clear that a decrease in protein-binding (i.e., an increase in  $f_u$ ) will result in an increase in the  $V_{SS}$ . The impact of changes in  $f_u$  on the half-life of a drug with a large volume of distribution can be assessed from Equation 18 and either Equations 87 or 88. The impact resulting from a change in protein-binding of a drug depends upon the magnitude of such binding alterations on both  $V_{SS}$  and  $CL_T$ .

The two major drug-binding proteins in plasma are albumin and  $\alpha_1$ -acid glycoprotein (AAG). Albumin is the major protein

both in plasma and in the extracellular space outside of plasma and is present in concentrations ranging from 3.5 to 5.5 g/dL in normal, healthy individuals. Albumin is the primary binding protein for acidic drugs, such as salicylate, tolbutamide, or warfarin. Numerous diseases can result in marked reductions in the concentration of albumin, including nephrotic syndrome, severe burns, liver disease, malnutrition, and some chronic inflammatory conditions.<sup>18</sup> Thus, disease is most likely to produce an increase in  $f_u$  for those drugs highly bound to albumin.

The substance AAG belongs to the family of *acute-phase reactants*, endogenous substances that are markedly increased in concentration secondary to some type of stress. While normal AAG concentrations range from 80 to 120 mg/dL, concentrations may increase above 300 mg/dL in patients experiencing major stress, such as surgery, trauma, or burns. More moderate elevations of AAG have been observed in patients following a myocardial infarction or in inflammatory diseases, such as Crohn disease. The increase in AAG concentration results in a decrease in  $f_u$ , and AAG is the major binding protein for many basic lipophilic drugs.

A major source of drug interactions is competition for protein-binding sites. Each albumin molecule contains at least four different drug-binding sites, two of which are the sites where most drugs that bind to albumin interact with the other molecule. If two drugs bind to the same site on a protein, they may compete with each other for binding. Thus, the addition of a drug to the existing therapeutic regimen of a patient may result in displacement of existing bound drug molecules from their protein-binding sites. However, as described in the *Hepatic Clearance* section of this chapter, these types of interactions rarely are clinically significant (i.e., these interactions do not significantly alter the free-drug concentration). Hence, while protein-binding interactions are probably the most widely reported drug interaction, they rarely necessitate alterations in drug therapy.<sup>19</sup>

### ROLE OF TRANSPORTERS IN ALTERING PHARMACOKINETICS

As previously discussed, tissue (cellular) distribution of drugs is a function of tissue perfusion, drug permeability and plasma and tissue protein binding. Influx and efflux drug transporters are also now acknowledged to be major determinants controlling cellular drug accumulation. For a number of chemically diverse drugs (atorvastatin, methotrexate, enalapril, and valsartan) hepatic uptake by a specific transporter (i.e., OATP1B1 or organic anion transporter protein) is a prerequisite to hepatic biotransformation. In the case of atorvastatin (and other statin drugs), the liver is both a distribution tissue and an organ of elimination. A decrease in hepatic OATP activity, either by concomitant administration of a transporter inhibitor, such as rifampin or cyclosporine, or by the presence of transporter gene polymorphism, can produce a decrease in both volume of distribution and drug clearance.<sup>20</sup>

### DOSE-AND TIME-DEPENDENT PHARMACOKINETICS

Up to this point, the processes for drug absorption, distribution, metabolism, and elimination have been assumed to be characterized by first-order rate constants, and the general concepts and equations presented are applicable to a wide variety of drugs, with modification. Moreover, with any of the pharmacokinetic models (compartmental, noncompartmental, or physiological), a number of basic assumptions apply, in particular, the principle of superposition holds. In other words, measurements of the concentration of drug plasma, urinary excretion of unchanged drug, or amount of metabolite recovered in bile increase proportionally with increases in dose. When these measurements or other observations are corrected for dose, the values are identical or superimposable. Thus, the

pharmacokinetic parameters  $V_D$ ,  $CL_T$ , and  $F$  remain constant with respect to time and with dose or concentration.

But the processes controlling the disposition of drugs are biological and therefore involve processes that are mediated by specialized carriers or enzymes. Under some conditions these processes can become saturated, and changes in dose may produce nonproportional changes (e.g., in concentration, amount of metabolite(s) produced, etc.) Table 37-2 delineates some of the various causes of nonlinear pharmacokinetic behavior.

Nonlinearity is a term applied to all situations in which a semilogarithmic plot of plasma concentration versus time data cannot be resolved completely into log-linear components (i.e., first-order processes). There are a wide variety of causes for nonlinearity, such as capacity-limited metabolism, capacity-limited absorption, saturable first-pass metabolism, changes in blood supply to the site of absorption and/or the organ of elimination, low or erratic dissolution or release rates from dosage forms, low solubility of the drug, or drug-induced changes in organ function or body temperature. Nonlinear drug disposition primarily has been determined by measuring the pharmacokinetics at several dosage levels. When a capacity-limited enzyme metabolism is the source of the nonlinearity, the Henri Michaelis-Menten equation,

$$\text{Velocity} = \frac{V_{\text{MAX}}C_{\text{SS}}}{K_M + C_{\text{SS}}} \quad (107)$$

can be applied to assess the velocity versus substrate (drug) concentration relationship. There are several techniques for the determination of the direct cause of nonlinearity in drug kinetics, including direct calculation of  $CL_T$ ,  $CL_{\text{ORAL}}$ ,  $F$ ,  $V_{\text{SS}}$ , and  $V_1$ . Most commonly, lack of superposition (disproportionate increase in  $AUC$  with increasing dose) is an indication of nonlinearity in the system.

**Table 37-2. Examples of Mechanisms for Dose- and Time-Dependent Pharmacokinetics (Nonlinear Drug Disposition)**

Kinetic Process and Mechanism	Examples
<b>Gastrointestinal absorption</b>	
Saturable transport	Riboflavin, penicillins
Intestinal metabolism	Salicylamide
<b>Biotransformation</b>	
Saturable metabolism	Phenytoin, salicylate
Product inhibition	Phenytoin (rat)
Cosubstrate depletion	Acetaminophen
Plasma protein-binding	Prednisolone, disopyramide
<b>Renal excretion</b>	
Glomerular filtration/ protein-binding	Naproxen
Tubular secretion	<i>p</i> -Aminohippuric acid, mezlocillin
Tubular reabsorption	Riboflavin, cephapirin
<b>Biliary excretion</b>	
Biliary secretion	Iodipamide, BSP
Enterohepatic cycling	Cimetidine, isotretinoin
<b>Tissue distribution</b>	
Plasma protein-binding	Prednisolone, ceftriaxone
Hepatic uptake	Indocyanine green, warfarin (rat)
CSF transport	Benzylpenicillins
Cellular uptake	Methicillin (rabbit)
Tissue-binding	Cyclosporine, dideoxyinosine (rat)

## PROTEIN-BINDING

When the amount of drug bound to plasma proteins approaches saturation, the percentage of the drug that is unbound may vary considerably with increasing dose. Under the conditions of saturation, for example, after a salicylate overdose, the  $f_u$  may vary considerably with the total amount of drug in the body, and hence, certain pharmacokinetic parameters, such as apparent volume of distribution, will be influenced.

## TIME-DEPENDENT KINETICS

Carbamazepine is a drug with low-to-intermediate intrinsic clearance, which also induces an increase in the activity of the biotransforming enzyme system by which it is metabolized. This increase will increase total clearance and decrease half-life. Because such autoinduction of metabolism does not occur until several dose-intervals of repetitive dosing, the pharmacokinetics vary with time and are called time-dependent. *Allosteric* (feedback) inhibition by accumulated metabolites of a drug, or an effect of a drug to impair its route of elimination, also will cause dose-and time-dependent changes in pharmacokinetics. Drugs that cause the depletion of some slowly replaceable intermediary factor, such as the depletion of norepinephrine by reserpine or the depletion of inorganic sulfate by acetaminophen, will manifest time-dependent effects.

## DOSE DEPENDENT KINETICS

When the elimination route is saturated by either capacity-limited metabolism or capacity-limited renal excretion, it is evident that the total clearance of a drug will decrease and the half-life will increase with increases in doses. Examples of important drugs that demonstrate dose-dependent kinetics are salicylic acid, phenylbutazone, probenecid, levodopa, phenytoin, heparin, and dicumarol. Ethanol obeys essentially zero-order elimination kinetics at blood concentrations above 0.02 to 0.04%, which is a fact of considerable social and legal importance.

Salicylic acid is one of the most interesting examples of dose-dependent kinetics from multiple sources. Salicylic acid is eliminated from the body by at least five parallel, competing processes.<sup>21</sup> Two of these are saturable processes for the formation of salicyluric acid (the glycine conjugate of salicylic acid) and salicylphenol glucuronide. The other three processes of elimination, excretion of unchanged salicylic acid in urine and formation of gentisic acid and salicyl glucuronide, are first-order processes. The half-life of salicylic acid increases from about 3 hours to over 20 hours as the dose is increased upward from 300 mg to 10 g. At low doses, the half-life is about 3 hours, the apparent volume of distribution is approximately 9L, and a total clearance can be estimated to be 2 L/hr. The binding of salicylic acid to albumin also is capacity-limited (saturable), and saturation occurs even at therapeutic (low) doses of the drug. Therefore, as the amount of salicylic acid in the body increases, the  $CL_{u,int}$  decreases, whereas the  $f_u$  increases. These two effects tend to oppose each other, such that the total clearance of salicylic acid remains relatively unchanged within the anti-inflammatory range of unbound concentrations (between 10 and 60 mg/L; Fig 37-19).<sup>22</sup> Finally, the renal excretion of salicylic acid ( $pK_a = 3.5$ ) can be increased by increasing urinary pH, resulting in a decrease in renal tubular reabsorption (data not shown). The toxicological consequences of a salicylic acid overdose are well known, but it is not always appreciated that as the concentration of salicylic acid increases, the total amount of drug in the body increases out of proportion to the total plasma concentration.

## STEREOCHEMICAL CONSIDERATIONS

Chiral drugs constitute approximately 60% of the drugs that are currently commercially available. Most of these are marketed as racemic mixtures. These facts obviously indicate the importance of understanding the impact of stereochemistry on both

**Figure 37-19.** The clearance of unbound drug ( $\bullet$ ), determined under steady-state conditions, and the fraction unbound in plasma ( $\circ$ ) vary inversely with each other as the salicylic acid concentration is increased. The corresponding total plasma salicylic acid concentrations are superimposed on the linear scale of the concentration of unbound drug; 1 mg/L = 7.2 micromolar. (Redrawn from Furst DE *et al.* Salicylate clearance, the resultant of protein binding and metabolism. *Clin Pharmacol Ther* 1979; 26: 380–389).

pharmacokinetics and pharmacodynamics. While it has long been appreciated that optical isomers often differ in the potency of pharmacological or toxic effect, it is only recently that significant attention has been paid to the influence of chirality on pharmacokinetic processes involved in absorption, distribution, and elimination. This is primarily due to the previous lack of analytical methodology required to separate drug enantiomers. The recent development of reasonably inexpensive methods for the separation of stereoisomers has led to a more comprehensive assessment of the pharmacokinetics of drugs that are administered as racemic mixtures.

Enantiomers possess identical physical and chemical properties, despite significant differences in spatial configuration. Thus, biological processes that are passive in nature (and thereby depend only upon physical and chemical characteristics of the molecule) do not display selectivity for one isomer over another. In contrast, biological processes that require the interaction of a drug molecule with a macromolecule (such as protein-binding or metabolism) may exhibit stereoselectivity. This knowledge permits some generalizations about when pharmacokinetic processes may differ between enantiomers.

## ABSORPTION

Since most drugs are absorbed by passive diffusion, most will not exhibit stereoselective alterations in absorption. Drugs that are absorbed by a carrier-mediated or active process may display such stereoselectivity. Indeed, demonstration of stereoselective absorption would be strong evidence that a drug is absorbed via a carrier-mediated process.

## PROTEIN-BINDING

Drug association with plasma proteins requires interaction of a small molecule with a macromolecule, which depends upon the spatial configuration of both components. It should not be surprising, therefore, that plasma protein-binding has been found to exhibit stereoselectivity for some drugs, including disopyramide, ibuprofen, mexilitene, propranolol, and verapamil.

## METABOLISM

Biotransformation requires the interaction of a drug with an enzyme, an interaction in which spatial arrangement is critical.

Many drugs that undergo metabolism exhibit stereoselective hepatic clearance. For example, the oral clearance of verapamil (a high intrinsic clearance drug) displays profound stereoselectivity such that the oral clearance ratio of the *R* to *S* isomers is approximately.<sup>4</sup>

### RENAL EXCRETION

Filtration in the kidney is a passive process; however, if a drug exhibits stereoselective protein-binding, one might anticipate that the drug enantiomers would exhibit differential filtration rates. Active tubular secretion, being an active process, also may demonstrate stereoselectivity for some drugs. Indeed, numerous drugs, including chloroquine, disopyramide, and terbutaline, have been found to be secreted stereoselectively by the kidney. While passive tubular reabsorption would not be expected to show stereoselective effects, active reabsorption may demonstrate these effects, as has been shown for certain endogenous substances such as glucose and amino acids.

### KINETICS OF PHARMACOLOGIC EFFECT

In addition to considering the relationship between drug concentration and time, proper design of therapeutic regimens often necessitates an understanding of the relationship between concentration and response. These two relationships can be combined to produce a time course of pharmacologic response, and this is referred to as pharmacodynamics. This area of investigation provides important quantitative information regarding the onset, duration, and intensity of pharmacologic effect, often in relation to drug concentration. Full characterization of these elements can involve the development of pharmacokinetic/pharmacodynamic models. Modeling the kinetics of effect requires an understanding of the mechanism of pharmacologic action, of which there are many. These include receptor stimulation (e.g.,  $\beta_2$ -adrenoceptor agonists), receptor antagonism (e.g.,  $H_1$ -histamine receptor antagonists), transporter inhibition (probenecid, diuretics), enzyme inhibitors (e.g., angiotensin converting enzyme), substrate replacement (e.g., thyroxine, testosterone), non-receptor-mediated drug action (e.g., chelation) and chemotherapy (e.g., antibiotics).

Clinically useful information can often be derived from relatively simplistic models. The relationship between drug response and concentration is usually graded, that is, the rise in concentration results in a progressively increasing magnitude of effect (Fig 37-20). There is essentially always a ceiling, or maximum, to the intensity of effect, such that further increases in drug concentration will not result in additional increases in the intensity of pharmacologic response. In practice, plasma concentrations rarely, if ever, reach the maximum effect because toxicities often develop. Thus, only the linear portion of the concentration-effect curve may be observed. The placement of the curve along the *x*-axis may vary among compounds, resulting in differences in the potency the drugs. Moreover, the steepness of the curve (the rate at which the intensity of the effect changes as a function of concentration) will vary among drug responses. For some drugs, such as narcotic agonists, a small change in the drug concentration can result in marked changes in drug effect (see Fig 37-20).

There are certain agents that appear to exhibit an all-or-none response. Rather than the typical graded increase in effect as concentration increases, these compounds exhibit a threshold of response that, once reached, result in the detection in the response. While a given individual's response to the drug is identified by the presence or absence of the effect, the fraction of subjects in a sample population responding will increase as the concentration of drug is increased. A good example of this is seen in the conversion to normal sinus rhythm in patients with atrial fibrillation treated with an antiarrhythmic agent (Fig 37-21). In this instance, there is variation within the patient population in the concentration that must be achieved to convert a specific patient from atrial fibrillation to normal sinus rhythm.

**Figure 37-20.** A graded pharmacologic response to a drug, showing a progressive increase in the intensity of effect as concentration increases until the maximal effect is achieved, when effect is plotted as a function of the log concentration. (Redrawn from Nies AS, Spielberg SP, Principles of Therapeutics, In: Hardman JG et al. eds. *Goodman and Gilman's The Pharmacologic Basis of Therapeutics*, 9th edn San Francisco: McGraw Hill, 1996.)

Thus, the higher the concentration achieved in a patient, the more likely he or she is to exhibit the pharmacologic effect.

Although visual inspection of concentration-response graphs can yield much useful information, rigorous comparisons between agents require a more quantitative analysis of concentration response data. The models that are used for such analyses are highly dependent upon the mechanism of action of the drug. In general, the mechanisms of pharmacologic agents can be divided into three categories: direct acting reversible agents, indirect acting reversible agents, and irreversibly acting agents.

**Figure 37-21.** Cumulative frequency of conversion to normal sinus rhythm (expressed as percent of patients) as a function of quinidine concentration in a group of subjects with atrial fibrillation treated with the antiarrhythmic quinidine. (Redrawn from Gibaldi M. *Biopharmaceutics and Clinical Pharmacokinetics*, 4th edn, Philadelphia: Lippincott Williams & Wilkins, 1991.)

### INTENSITY OF EFFECT—THE INTENSITY (OR MAGNITUDE) OF PHARMACOLOGIC EFFECT IS GIVEN AS

$$\text{Intensity of Effect} = \frac{E_{\max} C^\gamma}{EC_{50}^\gamma + C^\gamma} \quad (108)$$

where  $E_{\max}$  = maximum effect,  $EC_{50}$  = concentration necessary to achieve 50%  $E_{\max}$ ,  $C$  = concentration of drug, and  $\gamma$  = Hill coefficient

This equation is similar to that which describes the binding of oxygen to hemoglobin. One significant difference is that when used to quantify pharmacologic effect, the Hill coefficient has no physical or mechanistic meaning. However, the larger the value of the Hill coefficient, the steeper will be the concentration versus response relationship. For some measured pharmacologic responses, there is a baseline physiological value that must be taken into consideration when modeling the pharmacologic effect. For example, there are a number of therapeutic agents that induce methemoglobinemia after ingestion. There is, however, a low level of methemoglobin (1-2%) in drug-naïve subjects that needs to be accounted for in modeling the intensity of effect of agents that induce methemoglobinemia. Equation 108 can be adjusted to account for baseline effect:

$$\text{Intensity of Effect} = E_0 \frac{E_{\max} \cdot C^\gamma}{EC_{50}^\gamma + C^\gamma} \quad (109)$$

where  $E_0$  = baseline effect.

Such a quantitative approach permits comparison of the intensity of drug effect between various agents. For example, while the antimicrobial agent dapsone is widely reported to cause methemoglobinemia in patients treated with the drug, the antimicrobial agent sulfamethoxazole is rarely associated with methemoglobinemia, despite the fact that both form a reactive hydroxylamine metabolite and that sulfamethoxazole is administered at much higher doses than dapsone. It was unclear whether this difference was due to differences in the potency of their respective hydroxylamine metabolite or due to differences in the pharmacokinetics of the drugs and/or metabolites. This question was addressed by comparing the ability of the two hydroxylamine metabolites for forming methemoglobin when incubated with human erythrocytes *in vitro* and modeling the effects using Equation 109.<sup>23</sup> As shown in Table 37-3, the maximal effect of the two metabolites studied were similar, but the potency ( $EC_{50}$ ) of dapsone hydroxylamine was 20-fold greater than that of sulfamethoxazole hydroxylamine.

### DURATION OF EFFECT

A measurable pharmacologic effect will be observable as soon as drug concentration reaches the minimal effect concentration (MEC). The duration of effect is determined by how long the concentration remains above the MEC, which is influenced by the dose administered and the rate of elimination of the drug. Consider the linear range of the log concentration-effect curve, such that  $0.2E_{\max} < E < 0.8E_{\max}$ . The effect within this boundary may be expressed as:

$$E = m \log C + r \quad (110)$$

where  $m$  = slope of  $E$  versus  $\log C$  plot and  $r$  = constant. This equation can be rearranged, such that:

$$\log C = \frac{E - r}{m} \quad (111)$$

Recall that for a drug exhibiting instantaneous distribution, following instantaneous administration:

$$\log C = \log C_0 - \frac{\lambda}{2.303} t \quad (112)$$

The maximal effect elicited by this dose,  $E_m$ , will occur when  $C = C_0$ . Thus,

$$\log C_0 = \frac{E_m - r}{m} \quad (113)$$

Substituting the equivalents in Eq. 111 and 113 into Eq. 112 yields

$$E = E_m - \frac{m\lambda}{2.303} t \quad (114)$$

Thus, the intensity of effect should decline at a constant rate that is a function of the elimination rate constant and the slope of the response versus log concentration curve. It should be noted that though the decrease in concentration is first-order, the decrease in effect is zero-order. But how can we quantify the actual duration of action following a given dose of a drug? Recall from Equation 13 that

$$C = \frac{D_{iv}}{V_d} e^{-\lambda t} \quad (115)$$

The duration time ( $t_d$ ) is that time at which the plasma concentration drops just below the MEC, such that:

$$MEC = \frac{D_{iv}}{V_d} e^{-\lambda t} \quad (116)$$

Solving to duration time:

$$t_d = \frac{1}{\lambda} [\log D_{iv} - \log(MEC)V_d] \quad (117)$$

### DIRECT ACTING, REVERSIBLE AGENTS

It could be argued that few, if any, drugs are truly “direct acting.” Most drugs interact with a receptor that produces the effect. Sometimes this interaction results in a cascade of events that ultimately produce the measured pharmacologic response. Thus, it might be appropriate to designate a category of drugs as *rapid acting, reversible agents*. The drug-receptor interaction is easily reversible, the pharmacological effect is easily reversible, and the time course of the effect is not delayed with respect to the time course of the drug-receptor interaction. For example, the  $\beta_1$ -adrenoceptor antagonists (metoprolol) and the suppression of exercise-induced heart rate. There is a reversible (i.e., non-covalent) interaction with a cellular macromolecule, which, as a consequence of the binding of the drug, stimulates a cellular response. This can be expressed as:

where  $C$  = concentration in plasma,  $C_R$  = concentration at receptor site,  $R$  = receptor,  $C_R - R$  = drug receptor complex.

The intensity and duration of response can be readily quantified by measuring the “response” at several different concentrations.

### INDIRECT ACTING, REVERSIBLE AGENTS

For many drugs, the response measured clinically is several steps removed from the initial biochemical effect of the drug. The time course of the effect, therefore, lags behind the time

**Table 37-3. Pharmacodynamics of Dapsone Hydroxylamine (DNOH) and Sulfamethoxazole Hydroxylamine (SNOH) Induced Methemoglobin Formation in Human Erythrocytes**

	DNOH	SNOH
$E_{\max}$ (%)	26 (5)	463 (105)
$EC_{50}$ (0M)	89 (4)	84 (5)

Data from Reilly TP *et al.* Methemoglobin formation by hydroxylamine metabolism of sulfamethoxazole and dapsone: implications for differences in adverse drug reactions. *J Pharmacol Exp Ther* 199; 288: 951–959.

course of concentrations. In these circumstances there may appear to be no direct association or relationship between the concentration of the drug in blood or plasma and the pharmacologic response.

and “ $\Rightarrow$ ” represents a “transduction” of the response that may depend on several factors, including the rate of turnover and trafficking of endogenous substrates or other mediators of drug effect. In this instance the drug-receptor interaction may not easily be reversible, and the pharmacologic effect is prolonged, such as the acetylation by aspirin of the serine moiety at the active site of cyclooxygenase. For some drugs with an indirect pharmacologic response, the drug-receptor interaction is easily reversible, but the pharmacologic effect is prolonged. An example might be corticosteroids, which bind with nuclear receptor proteins, resulting in RNA transcription and protein synthesis.

A classic example of an indirect pharmacologic response is the oral anticoagulant warfarin (Fig. 37-22). In this instance, the dissociation between the pharmacologic effect and the concentration is readily understood by a consideration of the mechanism action.

Warfarin inhibits the synthesis of the vitamin K-dependent factors that determine the prothrombin time. However, there is a time lag for this effect to be observed since circulating clotting factors must be degraded by the normal metabolic processes before an anticoagulant effect is observed. Thus, the turnover rate of the clotting factors, and not the time course of warfarin concentrations, becomes key determinant for the onset, duration, and offset of effect. This was accounted for by models that incorporated the endogenous degradation and synthesis rates of the clotting factors, thereby providing a good relationship between the concentration and “true” pharmacologic effect.<sup>24</sup>

**Figure 37-22.** Time course of plasma warfarin concentration (top panel) and pharmacologic response, measured as percent decrease in normal prothrombin activity (bottom panel). Open circles represent warfarin concentration, while closed circles represent prothrombin activity. Note that the pharmacologic effect does not become evident until the concentration has reduced substantially from its maximal value. (Redrawn from Nagashima R *et al.* Kinetics of pharmacologic effects in man: the anticoagulant effect of warfarin. *Clin Pharmacol Ther* 1969; 10: 22–35).

**Figure 37-23.** A counterclockwise hysteresis is observed following administration of a drug that exhibits noninstantaneous distribution and for which the site of action is in the slowly equilibrating tissues. Open circles represent a single effect measurement at a given concentration, and numbers indicate time (in hours) that measurements were made.

If distribution of a drug to its site of action is delayed, a counterclockwise hysteresis curve can be observed when plotting the effect versus plasma concentration after a dose of the drug, particularly when administered via a slow infusion (Fig 37-23). Thus, the intensity of effect observed for a given concentration shortly after administration (while concentrations are rising) is less than the intensity observed at that same concentration during the decline in concentration. This is due to the fact that during the distribution phase most of the drug is in the rapidly equilibrating tissues (i.e., the central compartment), while in the latter time periods the larger fraction of the drug is in the slowly equilibrating tissues (i.e., the peripheral compartment). Hence, the relationship between effect and *plasma* concentration for such a drug will be time dependent. This type of hysteresis can also be observed if the response is due to an active metabolite rather than the parent drug. A clockwise hysteresis is observed when tolerance occurs.

Sheiner *et al*<sup>25</sup> and Sheiner and Holford<sup>26</sup> originally modeled the time delay in pharmacological response with a hypothetical “effect compartment.” Using regression analysis to estimate the rate constants for the “effect compartment,” the hysteresis loop was collapsed, thereby making it possible to model indirect effects. Jusko and colleagues<sup>27,28</sup> have developed a series of comprehensive physiologic indirect response models that incorporate an understanding of the mechanism(s) producing a particular pharmacologic effect. These indirect response models envision a given pharmacologic response that is based on the inhibition or stimulation of the input or the output factors controlling the pharmacologic effect. These complex models have increased our understanding of a variety of pharmacologic effects, such as induction of protein synthesis, cell trafficking, and altered hormone secretion.

### IRREVERSIBLE ACTING AGENTS

Modeling the pharmacodynamics of irreversible acting agents is considerably more complex but has been successfully accomplished. The most intensely studied agents are those used in the treatment of cancer or infections. Modeling the ability of such agents to kill tumor or bacterial cells necessitates incorporation of cell-cycle kinetics. Such models have been useful in determining whether agents are best administered infrequently at high doses or in continuous exposure regimens.

DRUG ACTION AND EFFECT 727

DEFINITIONS AND CONCEPTS 727

DOSE-EFFECT RELATIONSHIPS 728

DRUG RECEPTORS AND RECEPTOR THEORY 732

OCCUPATION AND OTHER THEORIES 732

MECHANISMS OF DRUG ACTION 734

TYPES OF TARGETS FOR DRUG ACTION 734

RECEPTOR BINDING 735

RECEPTOR STRUCTURE AND FUNCTION 735

A drug is an agent intended for use in the diagnosis, mitigation, treatment, cure, or prevention of disease in humans or other animals. One of the most remarkable qualities of drugs is the great diversity of their actions and effects on the body, which enables their selective use in the treatment of a wide range of conditions involving virtually every body organ, tissue, and cell. Some drugs selectively stimulate or depress the cardiac muscle, the central nervous system (CNS), or the gastrointestinal tract. Mydriatic drugs dilate the pupil of the eye, whereas miotic drugs constrict or decrease pupillary size. Some drugs can induce vomiting, whereas others prevent vomiting. Diuretic drugs increase the flow of urine, whereas other drugs decrease it. Laxatives evacuate the bowel; other drugs cause constipation. The diverse effects of drugs in the body include the treatment of infections, cancer, cardiovascular disease, asthma, glaucoma, Alzheimer disease, and many others. Drugs can aid in diagnosis, treatment, replenishment, prevention, as well as many other applications.

Drug discovery and development is a complex phenomenon that involves the collective contributions of many scientific specialists. After a new potential drug substance has undergone definitive chemical and physical characterization, the basic pharmacology, or the nature and mechanism of action of the drug on the biologic system, must be determined. The drug's effects, or multiple effects, as well as its selectivity, dose, potency and efficacy, dose-effect relationships, dose-intensity of effect relationships, dose-frequency of response relationships, and variations in response and responsiveness must be ascertained. Additional studies on how the new drug works investigate drug receptors and receptor theory, occupation and other theories, mechanisms of drug action, types of targets for drug action, receptor binding, receptor structure and function, voltage-sensitive channels, ligand-activated ion channels, G protein-coupled receptors, tyrosine kinase-linked receptors, intracellular receptors that control DNA transcription, enzyme inhibition, and receptor regulation.

### DRUG ACTION AND EFFECT

The word *drug* imposes an action-effect context within which the properties of a substance are described. The description must include the pertinent properties of the recipient of the drug. Thus, when a drug is defined as an analgesic, it is implied that the recipient reacts to a noxious stimulus in a certain way, called *pain*. (Studies indicate that pain is not simply the *perception* of a certain kind of stimulus but rather, a *reaction* to the perception of a variety of kinds of stimuli or stimulus patterns.) Both because the pertinent properties are locked into the complex and somewhat imprecise biological context and because the types of possible response are many, descriptions of the properties of drugs tend to emphasize the qualitative features of the effects they elicit. Thus, a drug may be described as having analgesic,

vasodepressor, convulsant, antibacterial, or other properties. The specific effect (or use) categories into which many drugs may be placed are covered in the section Pharmaceutical and Medicinal Agents and are not elaborated upon in this chapter. However, the description of a drug does not end with the enumeration of the responses it may elicit. Certain intrinsic properties of the drug-recipient system can be described in quantitative terms and are essential to the full description of the drug and to the validation of the drug for specific uses. In the following section, Definitions and Concepts, certain general terms are defined in qualitative language; the subsequent section, Dose-Effect Relationships, lays the foundation for an appreciation of some of the quantitative aspects of pharmacodynamics.

### DEFINITIONS AND CONCEPTS

The vocabulary that is unique to the field of pharmacology is relatively small; the general vocabulary is that of the biological sciences and chemistry. Nevertheless, there are a few definitions that are important to the proper understanding of pharmacology. It is necessary to differentiate among *action*, *effect*, *selectivity*, *dose*, *potency*, and *efficacy*.

### ACTION VERSUS EFFECT

The *effect* of a drug is an alteration of function of the structure or process upon which the drug acts. It is common to use the term *action* as a synonym for *effect*. However, action precedes effect. *Action* is the alteration of condition that brings about the effect.

The final effect of a drug may be far removed from its site of action. For example, the diuresis subsequent to the ingestion of ethanol does not result from an action on the kidney but, rather, from a depression of activity in the region of the hypothalamus, which regulates the release of antidiuretic hormone from the posterior pituitary gland. The alteration of hypothalamic function is, of course, also an effect of the drug, as is each subsequent change in the chain of events leading to diuresis. The action of ethanol was exerted only at the initial step, with each subsequent effect becoming then the action to a following step.

### MULTIPLE EFFECTS

No known drug is capable of exerting a single effect, although a number are known that appear to have a single mechanism of action. Multiple effects may derive from a single mechanism of action. For example, the inhibition of acetylcholinesterase by physostigmine will elicit an effect at every site where acetylcholine is produced, is potentially active, and is hydrolyzed by cholinesterase. Thus, physostigmine elicits a constellation of effects.

A drug also can cause multiple effects at several different sites by a single action at only one site, providing that the

function initially altered at the site of action ramifies to control other functions at distant sites. Thus, a drug that suppresses steroid synthesis in the liver not only may lower serum cholesterol, impair nerve myelination and function, and alter the condition of the skin (as a consequence of cholesterol deficiency), but also may affect digestive functions (because of a deficiency in bile acids) and alter adrenocortical and sexual hormonal balance.

Although a single action can give rise to multiple effects, most drugs exert multiple actions. The various actions may be related, as for example, the sympathomimetic effects of phenylephrine that accrue to its structural similarity to norepinephrine and its ability to exert sympathetic responses, or the actions may be unrelated, as with the actions of morphine to interfere with the release of acetylcholine from certain autonomic nerves, block some actions of 5-hydroxytryptamine (serotonin), and release histamine. Many drugs bring about immunological (i.e., allergic or hypersensitivity) responses that bear no relation to the other pharmacodynamic actions of the drug.

### SELECTIVITY

Although most drugs have the potential to elicit multiple effects, one effect is generally more readily elicitable than another. This differential responsiveness is called *selectivity*. It usually is considered to be a property of the drug, but it is also a property of the constitution and biodynamics of the recipient subject or patient.

Selectivity may come about in any of several ways. The subcellular structure (receptor) with which a drug combines to initiate one response may have a higher affinity for the drug than that for some other action. Atropine, for example, has a much higher affinity for muscarinic receptors that subserve the function of sweating than it does for the nicotinic receptors that subserve voluntary neuromuscular transmission, so that suppression of sweating can be achieved with only a tiny fraction of the dose necessary to cause paralysis of the skeletal muscles. A drug may be distributed unevenly, so that it reaches a higher concentration at one site than throughout the tissues generally; for example, chloroquine is much more effective against hepatic than intestinal (colonic) amebiasis because it reaches a much higher concentration in the liver than in the wall of the colon. An affected function may be much more critical to, or have less reserve in, one organ than in another, so that a drug will be predisposed to elicit an effect at the more critical site. Some inhibitors of dopa decarboxylase (also known as 5-hydroxytryptophan decarboxylase) depress the synthesis of histamine more than that of either norepinephrine or 5-hydroxytryptamine (serotonin), even though histidine decarboxylase is less sensitive to the drug, simply because histidine decarboxylase is the only step and, hence, is rate-limiting in the biosynthesis of histamine. Dopa decarboxylase does not become rate limiting in the synthesis of either norepinephrine or 5-hydroxytryptamine until the enzyme is nearly completely inhibited. Another example of the determination of selectivity by the critical balance of the affected function is that of the mercurial diuretic drugs. An inhibition of only 1% in the tubular resorption of glomerular filtrate usually will double urine flow, because 99% of the glomerular filtrate normally is resorbed. Aside from the question of the possible concentration of diuretics in the urine, a drug-induced reduction of 1% in sulfhydryl enzyme activity in tissues other than the kidney usually is not accompanied by an observable change in function. Selectivity also can be determined by the pattern of distribution of inactivating or activating enzymes among the tissues and by other factors.

### DOSE

Even the uninitiated person knows that the dose of a drug is the amount administered. However, the appropriate dose of a drug is not some unvarying quantity, a fact sometimes overlooked by pharmacists, official committees, and physicians. The practice

of pharmacy is entrapped in a system of fixed-dose formulations, so that fine adjustments in dosage often are difficult to achieve. Fortunately, a rather wide latitude in dosages usually is allowable. It is obvious that the size of the recipient individual should have a bearing upon the dose, and the physician may elect to administer the drug on a body-weight or surface-area basis rather than as a fixed dose. Usually, however, a fixed dose is given to all adults, unless the adult is exceptionally large or small. The dose for infants and children often is determined by one of several formulas that take into account age or weight, depending on the age group of the child and the type of action exerted by the drug. Infants are relatively more sensitive to many drugs, often because systems involved in the inactivation and elimination of the drugs may not be developed fully in the infant.

The patient's nutritional status, his or her mental outlook, the presence of pain or discomfort, the severity of the condition being treated, the presence of secondary disease or pathology, and genetic factors as well as many other factors affect the dose of a drug necessary to achieve a given therapeutic response or to cause an untoward effect. Even two apparently well-matched normal persons may require widely different doses for the same intensity of effect. Furthermore, a drug is not always employed for the same effect and, therefore, is not always given in the same dose. For example, the dose of a progestin necessary for an oral contraceptive effect is considerably different from that necessary to prevent spontaneous abortion, and the dose of an estrogen used for the treatment of menopausal symptoms is much lower than that used for the treatment of prostatic carcinoma.

The wise physician knows that the dose of a drug is not a rigid quantity, but, rather, that which is necessary and can be tolerated, and he or she individualizes the regimen accordingly. The wise pharmacist also recognizes that official or manufacturer's recommended doses sometimes are quite narrowly defined and should serve only as a useful guide rather than as an absolute.

### POTENCY AND EFFICACY

The *potency* of a drug is the reciprocal of dose. Thus, it will have the units of persons/unit weight of drug or body weight/unit weight of drug, for example. Potency generally has little utility other than to provide a means of comparing the relative activities of drugs in a series; *relative potency*, relative to some prototypic member of the series, is a parameter commonly used among pharmacologists and in the pharmaceutical industry.

Whether a given drug is more potent than another has little bearing on its clinical usefulness, as long as the potency is not so low that the size of the dose is physically unmanageable or the cost of treatment is higher than with an equivalent drug. A drug that is less potent but more selective is the one to be preferred. Promotional arguments in favor of a more potent drug, therefore, are irrelevant to the important considerations that should govern the choice of a drug. However, drugs of the same class sometimes differ in the maximum intensity of effect; that is, some drugs of the class may be less efficacious than others, regardless of how large a dose is used.

*Efficacy* connotes the property of a drug to achieve the desired response, and *maximum efficacy* denotes the maximum achievable effect. Even huge doses of codeine often cannot achieve the relief from severe pain that relatively small doses of morphine can; thus, codeine is said to have a lower maximum efficacy than morphine. Efficacy is one of the primary determinants of which drug is chosen.

### DOSE-EFFECT RELATIONSHIPS

It is crucial to know how changes in the intensity of response to a drug vary with the dose. Both the physician, who prescribes or administers a drug, and the manufacturer, who must package the drug in appropriate dose sizes, must translate such

knowledge into everyday practice. Theoretical or molecular pharmacologists also study such relationships in inquiries into mechanism of action and receptor theory. It is necessary to define two types of relationships: (1) dose-intensity relationship, i.e., the manner in which the intensity of effect in the individual recipient relates to dose; and (2) dose-frequency relationship, i.e., the manner in which the number of responders among a population of recipients relates to dose.

### DOSE-INTENSITY OF EFFECT RELATIONSHIPS

Whether the intensity of effect is determined *in vivo* (e.g., the blood-pressure response to epinephrine in the human patient) or *in vitro* (e.g., the response of the isolated guinea pig ileum to histamine), the dose-intensity of effect (often called dose-effect) curve usually has a characteristic shape, one that closely resembles one quadrant of a rectangular hyperbola.

In the dose-intensity curve depicted in Figure 38-1, the curve appears to intercept the  $x$  axis at 0 only because the lower doses are quite small on the scale of the abscissa, the smallest dose being  $1.5 \times 10^{-3}$  micrograms. Actually, the  $x$  intercept has a positive value, because a finite dose of drug is required to bring about a response, this lowest effective dose being known as the *threshold dose*. Statistics and chemical kinetics predict that the curve should approach the  $y$  axis asymptotically. However, if the intensity of the measured variable does not start from zero, the curve may have a positive  $y$  intercept (or negative  $x$  intercept), especially if the ongoing basal activity before the drug is given is closely related to that induced by the drug.

In practice, instead of an asymptote to the  $y$  axis, dose-intensity curves nearly always show an upward concave foot at the origin of the curve, so that the curve has a lopsided sigmoid shape. At high doses, the curve approaches an asymptote that is parallel to the  $x$  axis, and the value of the asymptote establishes the maximum possible response to the drug, or *maximum efficacy*. However, experimental data in the regions of the asymptotes generally are too erratic to permit an exact definition of the curve at very low and very high doses. The example shown in Figure 38-1 represents an unusually good set of data.

Because the dose range may be 100- or 1000-fold from the lowest to the highest dose, it has become the practice to plot

**Figure 38-1.** Relationship of the intensity of the blood pressure response of the cat to the intravenous dose of norepinephrine.

dose-intensity curves on a logarithmic scale of abscissa (i.e., to plot the log of dose versus the intensity of effect). Figure 38-2 is such a semilogarithmic plot of the same data used in Figure 38-1. In the figure, the intensity of effect is plotted both in absolute units (at the left) or in relative units, as percentages (at the right).

Although no new information is created by a semilogarithmic representation, the curve is stretched in such a way as to facilitate the inspection of the data; the comparison of results from multiple observations and the testing of different drugs also is rendered easier. In Figure 38-2, the curve is essentially what is called a *sigmoid curve* and is nearly symmetrical about the point that represents an intensity equal to 50% of the maximal effect (i.e., about the midpoint). The symmetry follows from the rectangular hyperbolic character of the previous Cartesian plot (see Figure 38-1). The semilogarithmic plot better reveals the dose-effect relationships in the low-dose range, which are lost in the steep slope of the Cartesian plot. Furthermore, the data about the midpoint form almost a straight line; the nearly linear portion covers approximately 50% of the curve. The slope of the linear portion of the curve or, more correctly, the slope at the point of inflection, has theoretical significance (see Drug Receptors and Receptor Theory, later in this chapter).

The upper portion of the curve approaches an asymptote, which is the same as that in the Cartesian plot. If the response system is completely at rest before the drug is administered, the lower portion of the curve should be asymptotic to the  $x$  axis. Both asymptotes and the symmetry derive from the law of mass action.

Dose-intensity curves often deviate from the ideal configuration illustrated and discussed earlier. Usually, the deviate curve remains sigmoid but not extended symmetrically about the mid-point of the linear segment. Occasionally, other shapes occur. Deviations may derive from multiple actions that converge upon the same final effector system, from varying degrees of metabolic alteration of the drug at different doses, from modulation of the response by feedback systems, from nonlinearity in the relationship between action and effect, or from other causes.

It often is necessary to identify which dose elicits a given intensity of effect. The intensity of effect generally designated is 50% of maximum intensity. The corresponding dose is called the *50% effective dose*, or *individual ED50* (see Figure 38-2). The use of the adjective *individual* distinguishes the ED50 based on intensity of effect from the median effective dose, also abbreviated ED50, determined from frequency of response data in a population (see Dose-Frequency Relationships in this chapter).

Drugs that elicit the same quality of effect may be compared graphically. In Figure 38-3, five hypothetical drugs are

**Figure 38-2.** Relationship of the intensity of the blood pressure response of the cat to the log of the intravenous dose of norepinephrine.

**Figure 38-3.** Log dose–intensity of effect curves of five different hypothetical drugs (see text for explanation).

compared. Drugs A, B, C, and E can achieve the same maximum effect, which suggests that the same effector system may be common to all. D may be working through the same effector system, but there are no *a priori* reasons to think this is so. Only A and B have parallel curves and common slopes. Common slopes are consistent with, but in no way prove, the idea that A and B not only act through the same effector system but also by the same mechanism. Although drug-receptor theory (see Drug Receptors and Receptor Theory, later in this chapter) requires that the curves of identical mechanism have equal slopes, exceptions do exist. Furthermore, mass-law statistics require that all simple drug-receptor interactions generate the same slope; only when slopes depart from this universal slope in accordance with distinctive characteristics of the response system do they provide evidence of specific mechanisms.

The relative potency of any drug may be obtained by dividing the ED<sub>50</sub> of the standard, or prototypic, drug by that of the drug in question. Any level of effect other than 50% may be used, but it should be recognized that when the slopes are not parallel, the relative potency depends on the intensity of effect chosen. Thus, the potency of A relative to C (see Figure 38-3) calculated from the ED<sub>50</sub> will be smaller than that calculated from the ED<sub>25</sub>.

The low maximum intensity inducible by D poses even more complications in the determination of relative potency than do the unequal slopes of the other drugs. If its dose-intensity curve is plotted in terms of percentage of its own maximum effect, its relative inefficacy is obscured, and the limitations of relative potency at the ED<sub>50</sub> level will not be evident. This dilemma underscores the fact that drugs can be compared better from their entire dose-intensity curves than from a single derived number such as ED<sub>50</sub> or relative potency.

Drugs that elicit multiple effects will generate a dose-intensity curve for each effect. Even though the various effects may be qualitatively different, the several curves may be plotted together on a common scale of abscissa, and the intensity may be expressed in terms of percentage of maximum effect; thus, all curves can share a common scale of ordinates in addition to a common abscissa. Separate scales of ordinates could be employed, but this would make it harder to compare data.

The selectivity of a drug can be determined by noting what percentage of maximum of one effect can be achieved before a second effect occurs. As with relative potency, selectivity may be expressed in terms of the ratio between the ED<sub>50</sub> for one effect and that for another effect, or a ratio at some other intensity of effect. As with relative potency, difficulties follow from nonparallelism. In such instances, selectivity expressed in dose ratios varies from one intensity level to another.

When the dose-intensity curves for a number of subjects are compared, they are found to vary considerably from individual to individual in many respects, e.g., threshold dose, mid-point, maximum intensity, and sometimes even slope. An average dose-intensity curve can be constructed by averaging the intensities of the effect at each dose.

Average dose-intensity curves have limited application in comparing drugs. A single line expressing an average response

has little value in predicting individual responses unless it is accompanied by some expression of the range of the effect at the various doses. This may be done by indicating the standard error of the response at each dose. Occasionally, a simple scatter diagram is plotted in lieu of an average curve and statistical parameters. An average dose-intensity curve also may be constructed from a population in which different individuals receive different doses; if sufficiently large populations are employed, the average curves determined by the two methods will approximate each other.

The determination of such average curves from a population large enough to be statistically meaningful requires a great deal of work. Retrospective clinical data occasionally are treated in this way, but prospective studies rarely are designed in advance to yield average curves. The usual practice in comparing drugs is to employ a quantal (i.e., all-or-none) endpoint and plot the frequency or cumulative frequency of response over the dose range, as discussed in the following section.

## DOSE-FREQUENCY OF RESPONSE RELATIONSHIPS

When an endpoint is truly all-or-none, such as death, it is easy to plot the number of responding individuals (e.g., dead subjects) at each dose of drug or intoxicant. Many other responses that vary in intensity can be treated as all-or-none if simply the presence or absence of a response (e.g., cough or no cough, convulsion or no convulsion) is recorded, without regard to the intensity of the response when it occurs. When the response changes from the basal or control state in a less abrupt manner (e.g., tachycardia, miosis, rate of gastric secretion), it may be necessary to designate arbitrarily some particular intensity of effect as the end point. If the end point is taken as an increase in heart rate of 20 beats/min, all individuals whose tachycardia is less than 20 beats/min would be recorded as nonresponders, whereas all those with 20 or above would be recorded as responders. When the percentage of responders in the population is plotted against the dose, a characteristic dose-response curve, more properly called a *dose-cumulative frequency* or *dose-percentage* curve, is generated. Such a curve is, in fact, a cumulative frequency distribution curve, with the percentage of responders at a given dose being the frequency of response.

Dose-cumulative frequency curves usually are of the same geometric shape as dose-intensity curves (i.e., sigmoid) when frequency is plotted against log dose (Figure 38-4). The tendency of the cumulated frequency of response (i.e., percentage) to be linearly proportional to the log of the dose in the middle of the dose range is called the *Weber-Fechner law*, although it is not invariable, as a true natural law should be. In many instances, the cumulative frequency is simply proportional to dose rather than log dose. The Weber-Fechner law applies to either dose-intensity or dose-cumulative frequency data. The similarity between dose-frequency and dose-intensity curves may be more than fortuitous—the intensity of response usually has an approximately linear relationship to the percentage of responding *units* (e.g., smooth muscle cells, nerve fibers) and, hence, also is a type of cumulative frequency of response. These are the same kind of statistics that govern the law of mass action.

If only the increase in the number of responders with each new dose is plotted, rather than the cumulative percentage of responders, a bell-shaped curve is obtained. This curve is the first derivative of the dose-cumulative frequency curve and is a *frequency distribution* curve. The distribution will be symmetrical—i.e., *normal* or Gaussian (see Chapter 10)—only if the dose-cumulative frequency curve is symmetrically hyperbolic. Because most dose-cumulative frequency curves are more nearly symmetrical when plotted semilogarithmically (i.e., as log dose), dose-cumulative frequency curves usually are *log-normal*.

Because the dose-intensity and dose-cumulative frequency curves are similar in shape, it follows that the curves have similar defining characteristics, such as ED<sub>50</sub>, maximum effect

**Figure 38-4.** The relationship of the number of responders in a population of mice to the dose of pentylenetetrazole.

(maximum efficacy), and slope. In dose-cumulative frequency data, the ED50 (*median effective dose*) is the dose to which 50% of the population responds (see Figure 38-4). If the frequency distribution is normal, the ED50 is both the arithmetic mean and the median dose and is represented by the midpoint on the curve; if the distribution is log-normal, the ED50 is the median dose but not the arithmetic mean dose. The efficacy is the cumulative frequency summed over all doses; it is usually, but not always, 100 percent. The slope is characteristic of both the drug and the test population. Even two drugs of identical mechanism may give rise to different slopes in dose-percentage curves, whereas in dose-intensity curves the slopes are the same.

Dose-cumulative frequency relationships are characterized by statistical parameters such as standard deviation, in addition to ED50, maximum cumulative frequency (efficacy) and slope (see Chapter 10).

Several formulations are available for dose-cumulative frequency curves, some of which are employed only to define the linear segment of a curve and to determine the statistical parameters of this segment. For the statistical treatment of dose-frequency data, see Chapter 10. One simple mathematical expression of the entire log-symmetrical sigmoid curve is:

$$\log \text{dose} = K + f \log \left( \frac{\% \text{ response}}{100\% - \text{response}} \right) \quad (1)$$

where percentage response may be either the percentage of maximum intensity or the percentage of a population responding. The equation is thus basically the same for both log normal dose-intensity and log normal dose-percentage relationships.  $K$  is a constant that is characteristic of the midpoint of the curve, or ED50, and  $1/f$  is characteristically related to the slope of the linear segment, which, in turn, is closely related to the standard deviation of the derivative log-normal frequency-distribution curve.

The comparison of dose-percentage relationships among drugs is subject to the pitfalls indicated for dose-intensity comparisons, namely, that when the slopes of the curves are not the same (i.e., the dose-percentage curves are not parallel), it is

necessary to state at which level of response a potency ratio is calculated. As with dose-intensity data, potencies generally are calculated from the ED50, but potency ratios may be calculated for any arbitrary percentage response. The expression of selectivity is, likewise, subject to similar qualifications, inasmuch as the dose-percentage curves for the several effects usually are nonparallel.

The term *therapeutic index* is used to designate a quantitative statement of the selectivity of a drug when a therapeutic effect is being compared with an undesired effect. If the untoward effect is designated  $T$  (for toxic) and the therapeutic effect is designated  $E$ , the therapeutic index may be defined as  $TD_{50}/ED_{50}$  or a similar ratio at some other arbitrary levels of response. The TD and the ED are not required to express the same percentage of response; some clinicians use the ratio  $TD_{1}/ED_{99}$  or  $TD_{5}/ED_{95}$ , based on the rationale that if the untoward effect is serious, it is important to use a most-severe therapeutic index in passing judgment upon the drug. Unfortunately, therapeutic indices are known in humans for only a few drugs.

Each untoward effect that a drug may elicit will have a different therapeutic index, and, if there is more than one therapeutic effect, it will have a family of therapeutic indices for each therapeutic effect. However, in clinical practice, it is customary to distinguish among the various toxicities by indicating the percentage incidence of a given side-effect.

#### VARIATIONS IN RESPONSE AND RESPONSIVENESS

The preceding discussion of dose-frequency relationships and information presented in Chapter 10 show that in a normal population, there may be quite a large difference between the dose required to elicit a given response in the least-responsive member of the population and that needed to elicit the response in the most-responsive member. The difference ordinarily will be a function of the slope of the dose-percentage curve or, in statistical terms, of the standard deviation. If the standard deviation is large, the extremes of responsiveness of responders are likewise large.

In a normal population, 95.46% of the population responds to doses within two standard deviations from the ED50 and 99.73% within three standard deviations. In log-normal populations, the same distribution applies when standard deviation is expressed as log dose.

In the population represented in Figure 38-4, 2.25 percent of the population (two standard deviations from the median) would require a dose more than 1.4 times the ED50; an equally small percentage would respond to 0.7 of the ED50. The physician who is unfamiliar with statistics is apt to consider the 2.25 percent of patients at either extreme to be abnormal reactors. The statistician will argue that these 4.5 percent are within the normal population and that only those who respond well outside the normal population, at least three standard deviations from the median, deserve to be called abnormal.

Regardless of whether physician's or statistician's criteria of abnormality obtain, the term *hyporeactive* applies to those individuals who require abnormally high doses, and *hyperreactive* applies to those who require abnormally low doses. The terms *hyporesponsive* and *hyperresponsive* also may be used. It is incorrect to use the terms *hyposensitive* and *hypersensitive* in this context; *hypersensitivity* denotes an allergic response to a drug and should not be used to refer to hyperreactivity. The term *supersensitivity* correctly applies to hyperreactivity that results from denervation of the effector organ; it often is more definitively called *denervation supersensitivity*. Sometimes hyporeactivity is the result of an immunochemical deactivation of the drug, or *immunity*. Hyporeactivity should be distinguished from an increased dose requirement that results from a severe pathological condition. Severe pain requires large doses of analgesics, but the patient is not a hyporeactor; what has changed is the baseline from which the endpoint quantum is measured. The responsiveness of a patient to certain drugs

sometimes may be determined by his or her history of previous exposure to appropriate drugs.

*Tolerance* is a diminution in responsiveness as use of the drug continues, which results in an increase in the dose requirement. It may be due to an increase in the rate of elimination of drug (as discussed elsewhere in this chapter), to reflex or other compensatory homeostatic adjustments, to a decrease in the number of receptors or in the number of enzyme molecules or other coupling proteins in the effector sequence, to exhaustion of the effector system or depletion of mediators, to the development of immunity, or to other mechanisms. Tolerance may be gradual, requiring many doses and days to months to develop, or acute, requiring only the first or a few doses and only minutes to hours to develop. Acute tolerance is called *tachyphylaxis*.

*Drug resistance* is the decrease in responsiveness of microorganisms, neoplasms, or pests to chemotherapeutic agents, anti-neoplastics, or pesticides, respectively. It is not tolerance in the sense that the sensitivity of the individual microorganism or cancer cell decreases; rather, it is the survival of normally unresponsive cells, which then pass the genetic factors of resistance on to their progeny.

Patients who fail to respond to a drug are called *refractory*. Refractoriness may result from tolerance or resistance, but it also may result from the progression of pathological states that negate the response or render the response incapable of surmounting an overwhelming pathology. Rarely, it may result from a poorly developed receptor or response system.

Sometimes a drug evokes an unusual response that is *qualitatively* different from the expected response. Such an unexpected response is called a *meta-reaction*. A not uncommon meta-reaction is seen when phenobarbital acts as a CNS stimulant rather than depressant, an effect seen especially in women. Pain and certain pathological states sometimes favor meta-reactivity. Responses that are different in infants or the aged from those in young and middle-aged people are not meta-reactions if the response is usual in the age group. The term *idiosyncrasy* also denotes meta-reactivity, but the word has been so abused that it is recommended that it be dropped. Although hypersensitivity may cause unusual effects, it is not included in the category "meta-reactivity."

## DRUG RECEPTORS AND RECEPTOR THEORY

Most drugs act by combining with some key substance in the biological milieu that has an important regulatory function in the target organ or tissue. This biological partner of the drug goes by the name *receptive substance* or *drug receptor*. The receptive substance is considered to be mainly a cellular constituent, although in a few instances it may be extracellular, as the cholinesterases are, in part. The receptive substance is thought of as having a special chemical affinity and structural requirements for the drug. Drugs such as emollients, which have a physical rather than chemical basis for their action, obviously do not act upon receptors. Drugs such as demulcents and astringents, which act in a nonselective or nonspecific chemical way, also are not considered to act upon receptors, since the candidate receptors have neither sharp chemical nor biological definition. Even antacids, which react with the extremely well-defined hydronium ion, cannot be said to have a receptor, because the reactive proton has no permanent biological residence.

Because of early preoccupation with physical theories of action and the classical and illogical dichotomy of chemical and physical molecular interaction, there is a reluctance to admit receptors for drugs such as general anesthetics or certain electrolytes, for example, which usually are not considered to combine selectively with distinct cellular or organelle membrane constituents. The word *receptor* often is used inconsistently and intuitively. However, the term is a legitimate symbol for that biological structure with which a drug interacts to initiate a response. Ignorance of the identities of many receptors does

not detract from, but rather increases, the importance of the term and general concept.

Once a receptor is identified, it commonly is no longer thought of as a receptor, although such identification may afford the basis of profound advances in receptor theory. Because the effects of anticholinesterases are derived only indirectly from inhibition of cholinesterase, and no drugs are known that stimulate the enzyme, it may be argued that it is not a receptor. Nevertheless, a number of drugs ultimately act indirectly through the inhibition of such modulator enzymes, and it is important for the theoretician to develop models based on such indirect interrelations.

Enzymes, of course, readily suggest themselves as candidates for receptors. However, there is more to cellular function than enzymes. Receptors may be membrane or intracellular constituents that govern the spatial orientation of enzymes, gene expression, compartmentalization of the cytoplasm, contractile or compliant properties of subcellular structures, or permeability and electrical properties of membranes. For nearly every cellular constituent there can be imagined a possible way for a drug to affect its function; therefore, few cellular constituents can be dismissed *a priori* as possible receptors. All the receptors for neurotransmitters and autonomic agonists are membrane proteins with agonist-binding groups projecting into the extracellular space. The transducing apparatus, whereby an occupied receptor elicits a response, is called a *coupling system*. Excitatory neurotransmitters in the CNS, and acetylcholine receptors elsewhere, are coupled to ion channels that, when opened, permit rapid ingress, especially of sodium ions. Each ion channel is composed of five subunits, and each subunit has four transmembrane, spanning regions.  $\gamma$ -Aminobutyric acid (GABA) and glycine are coupled to inhibitory chloride channels. Each of these receptors is composed of pentameric proteins, each of which has two to four different types of subunits. Benzodiazepine receptors are coupled to the GABA receptor. Beta-adrenergic receptors, histamine ( $H_2$ ) receptors, and a number of receptors for polypeptide hormones interact with a stimulatory guanosine diphosphate (GDP)/guanosine triphosphate (GTP) binding protein (G-protein) that can activate the enzyme adenylate cyclase. The cyclase then produces cAMP, which, in turn, activates protein kinases. Other receptors interact with inhibitory G-proteins. Some receptors couple to guanylate cyclase.

Alpha-adrenergic  $\alpha_1$ -receptors, some muscarinic ( $M_1$  and  $M_3$ ) receptors, and various other receptors couple to the membrane enzyme phospholipase C, which cleaves inositol phosphates from phosphoinositides. The cleavage product, 1,4,5-inositol triphosphate ( $IP_3$ ), then causes an increase in intracellular calcium, whereas the product diacylglycerol (DAG) activates kinase C. There are a number of other less ubiquitous coupling systems as well. Substances such as cAMP, cyclic guanosine-3',5'-monophosphate (cGMP),  $IP_3$ , and DAG are called *second messengers*.

There may be several different receptors for a given agonist. Differences may be shown not only in the types of coupling systems and effects but also by differential binding of agonists and antagonists, desensitization kinetics, physical and chemical properties, genes, and amino acid sequences. The differentiation among receptor subtypes is called *receptor classification*. Receptor subtypes are designated by Greek or Arabic alphabetical prefixes and/or numerical subscripts. There are at least two each of beta-adrenergic, histaminergic, serotonergic, GABAergic, and benzodiazepine receptors; three each of muscarinic and alpha-adrenergic receptors; and five opioid receptor subtypes.

## OCCUPATION AND OTHER THEORIES

Drug-receptor interactions are governed by the law of mass action. However, most chemical applications of mass law are concerned with the rate at which reagents disappear or products

are formed, whereas receptor theory usually concerns itself with the fraction of the receptors combined with a drug. The usual concept is that only when the receptor actually is occupied by the drug is its function transformed in such a way as to elicit a response. This concept has become known as the *occupation theory*. The earliest clear statement of its assumptions and formulations is often credited to Clark in 1926<sup>1</sup>, but both Langley and Hill also made important contributions to the theory in the first two decades of the 20th century.

In all receptor theories, the terms agonist, partial agonist, and antagonist are employed. An *agonist* is a drug that combines with a receptor to initiate a response.

In the classical occupation theory, two attributes of the drug are required: (1) *affinity*, a measure of the equilibrium constant of the drug-receptor interaction; and (2) *intrinsic activity*, or *intrinsic efficacy* (not to be confused with efficacy as intensity of effect), a measure of the ability of the drug to induce a positive change in the function of the receptor.

A *partial agonist* is a drug that can elicit some but not a maximal effect and that antagonizes an agonist. In the occupation theory it would be a drug with a favorable affinity but a low intrinsic activity.

A *competitive antagonist* is a drug that occupies a significant proportion of the receptors and thereby preempts them from reacting maximally with an agonist. In the occupation theory, the prerequisite property is affinity without intrinsic activity.

A *noncompetitive antagonist* may react with the receptor in such a way as not to prevent agonist-receptor combination but to prevent the combination from initiating a response, or it may act to inhibit some subsequent event in the chain of action-effect-action-effect that leads to the final overt response.

The mathematical formulation of the receptor theories derives directly from the law of mass action and chemical kinetics. Certain assumptions are required to simplify calculations. The key assumption is that the intensity of effect is a direct linear function of the proportion of receptors occupied. The correctness of this assumption is most improbable on the basis of theoretical considerations, but empirically it appears to be a close enough approximation to be useful. A second assumption upon which formulations are based is that the drug-receptor interaction is at equilibrium. Another common assumption is that the number of molecules of receptor is negligibly small compared with that of the drug. This assumption is undoubtedly true in most instances, and departures from this situation greatly complicate the mathematical expression of drug receptor interactions.

The first clearly stated mathematical formulation of drug-receptor kinetics was that of Clark,<sup>1</sup> in his equation:

$$Kx^n = \frac{y}{100 - y} \quad (2)$$

where  $K$  is the affinity constant,  $x$  is the concentration of drug,  $n$  is the molecularity of the reaction, and  $y$  is the percentage of maximum response. Clark assumed that  $y$  was a linear function of the percentage of receptors occupied by the drug, so  $y$  could also symbolize the percentage of receptors occupied. When the equation is rearranged to solve for  $y$ , we get:

$$y = \frac{100Kx^n}{1 + Kx^n} \quad (3)$$

A Cartesian plot of this equation is identical in form to that shown in Figure 38-1. When  $y$  is plotted against  $\log x$  instead of  $x$ , the usual sigmoid curve is obtained. Thus, it can be seen that the dose-intensity curve derives from mass action equilibrium kinetics, which, in turn, derive from the statistical nature of molecular interaction. The fact that dose-intensity and dose-percentage curves have the same shape shows that they involve similar statistics.

If Equation 2 is put into log form,

$$\log K + n \log x = \log \frac{y}{100 - y} \quad (4)$$

a plot of  $\log y/100 - y$  against  $\log x$  then will yield a straight line with a slope of  $n$ ;  $n$  is theoretically the number of molecules of drug that react with each molecule of receptor. Currently, there are no known examples in which more than one molecule of agonist combines with a single receptor, hence,  $n$  should equal 1, universally. Nevertheless,  $n$  often deviates from 1. Deviations occur because of cooperative interactions among receptors (*cooperativity*), spare receptors (see below), amplifications in the response system (i.e., *cascades*), receptor coupling to more than one sequence (e.g., to both adenylate cyclase and calcium channels), and other reasons. In these departures from  $n = 1$ , the slope becomes a characteristic of the mechanism of action and response system.

The probability that a molecule of drug will react with a receptor is a function of the concentration of both drug and receptor. Unlike the concentration of a drug, the concentration of receptor molecules cannot be manipulated. However, as each molecule of drug combines with a receptor, the population of free receptors is diminished accordingly. If the drug is a competitive antagonist, it will diminish the probability of an agonist-receptor combination in direct proportion to the percentage of receptor molecules preempted by the antagonist. Consequently, the intensity of effect will be diminished. However, the probability of agonist-receptor interaction can be increased by increasing the concentration of agonist, and the intensity of effect can be restored by appropriately larger doses of agonist. Addition of more antagonist will, again, diminish the response, which can, again, be overcome or surmounted by more agonist.

Clark<sup>1</sup> showed empirically and by theory that as long as the ratio of antagonist to agonist was constant, the concentration of the competitive drugs could be varied over an enormous range without changing the magnitude of the response (Figure 38-5). Because the presence of competitive antagonist only diminishes the probability of agonist-receptor combination at a given concentration of agonist and does not alter the molecularity of the reaction, it also follows that the effect of the competitive antagonist is to shift the dose-intensity curve to the right in proportion to the amount of antagonist present; neither the shape nor the slope of the curve is changed (Figure 38-6).

Many refinements of the Clark formula have been made, but they are not discussed in this chapter; details and citations of relevant literature can be found in various works on receptors cited in the Bibliography. Several refinements have been introduced to facilitate studies of competitive inhibition. The introduction of the concepts of intrinsic activity<sup>2</sup> and efficacy<sup>3</sup> required appropriate changes in mathematical treatment.

**Figure 38-5.** Direct proportionality of the dose of agonist (acetylcholine) to the dose of antagonist (atropine) necessary to cause a constant degree of inhibition (50%) of the response of the frog heart. (Adapted from Clark AJ. The antagonism of acetylcholine by atropine. *J Physiol [London]* 1926; 61: 547-556.)

**Figure 38-6.** Effect of an antagonist to shift the log dose-intensity curve to the right without altering the slope. The effector is the isolated heart. I, no atropine; II, atropine,  $10^{-8}$  M; III,  $10^{-7}$  M; IV,  $10^{-6}$  M; V,  $10^{-5}$  M; VI,  $10^{-4}$  M; VII,  $10^{-3}$  M; Y: % of maximum intensity of response. The function  $\log y/(100 - y)$  converts the log dose-intensity relationship to a straight line. (Adapted from Clark AJ. The antagonism of acetylcholine by atropine. *J Physiol [London]* 1926; 61: 547–556.)

Another important concept has been added to the occupation theory, that of *spare receptors*. Clark assumed that the maximal response occurred only when the receptors were completely occupied, which does not account for the possibility that the maximum response might be limited by some step in the action-effect sequence subsequent to receptor occupation. Work with isotopically labeled agonists and antagonists and with dose-effect kinetics has shown that the maximal effect sometimes is achieved when only a small fraction of the receptors are occupied. The mathematical treatment of this phenomenon has enabled theorists to explain several puzzling observations that previously appeared to contradict occupation theory.

The classical occupation theory fails to explain several phenomena satisfactorily, and it is unable to generate a realistic model of intrinsic activity and partial agonism. A rate theory, in which the intensity of response is proportional to the rate of drug-receptor interaction instead of occupation, was proposed to explain some of the phenomena that occupation theory could not, but the rate theory was unable to provide a realistic mechanistic model of response generation, and it had other serious limitations as well.

The phenomena that neither the classical occupation nor the rate theory could explain can be explained by various theories in which the receptor can exist in at least two conformational states, one of which is the active one; the drug can react with one or more conformers. In a *two-state model*,<sup>4</sup>

where R is the inactive and  $R^*$  is the active conformer. The agonist combines mainly with  $R^*$ , the partial agonist can combine with both R and  $R^*$ , and the antagonist can combine with R, with the equilibrium being shifted according to the extent of occupation of R and  $R^*$ . Other variations of occupation theory treat the receptor as an aggregate of subunits that interact cooperatively.<sup>5</sup>

## MECHANISMS OF DRUG ACTION

Drugs are distributed to many or all parts of the body by the circulation. However, they do not act everywhere; they would

have extremely limited usefulness if they did. Clinically useful drugs act only on certain existing biological systems. Although drugs cannot create new systems, some drugs can temporarily or permanently damage existing functional systems that are susceptible to them, thereby producing toxic effects. Almost all drugs act more or less selectively on large specific proteins, glycoproteins, or lipoproteins located on the cell membrane or in the cell cytoplasm, nuclei, or other intracellular organelles. These specific proteins are referred to as *receptors*. Although they often are regarded as drug receptors, they are in reality receptors for endogenous substances that mediate normal biological and physiological regulatory processes.

Virtually all cells of the body have multiple receptors, since they are regulated by a variety of endogenous substances that act continuously, intermittently, or only occasionally. Similarly, cells theoretically can be influenced by a variety of drugs that act on the different receptors that the cells contain. The chemical nature of many of the endogenous substances that activate receptors is known, but new ones continue to be identified and sought. For example, the former mystery of why animals have receptors for morphine, which is produced by some species of poppy plants, was solved when endogenous opioid peptides were identified in the brain and some peripheral tissues in the mid-1970s.

Drugs that selectively activate receptors and produce the same effects normally produced by a respective endogenous substance are called *agonists*. Drugs that selectively block receptors are called *antagonists* because they antagonize, or block, the normal effects of the respective endogenous substance. Pure antagonists do not activate their receptors. Some experimental drugs stimulate or activate certain enzymes, but none are useful therapeutic agents, because their effects are too widespread. Forskolin is one such example; it directly stimulates the enzyme adenylyl cyclase to synthesize cAMP, which is a second messenger in many cellular systems throughout the body.

On the other hand, many very useful therapeutic drugs are *enzyme inhibitors*, which selectively inhibit the normal activity of only one type of enzyme, thereby reducing the ability of the enzyme to act on its normal biochemical substrate. In this context, the enzymes are the drug receptors. Although the chemical nature of receptors and enzymes and their interactions with drugs often was vaguely understood in the past, the application of new techniques in molecular biology, biochemistry, and pharmacology since the mid-1980s has made unprecedented progress in defining the structures of receptors and enzymes and the consequences of drug-receptor interactions.

## TYPES OF TARGETS FOR DRUG ACTION

Drug *effects* are the result of drug *actions*. Drug action may be defined as the drug-receptor interaction, whereas drug effects are the consequences of that action. For example, the interaction of epinephrine with  $\beta$ -receptors in the heart sets into motion a cascade of intracellular events (actions) that lead to increases in heart rate and strength of contraction (effects). The interaction of epinephrine with  $\alpha$ -receptors in the vasculature sets into motion a cascade of intracellular events (actions) that lead to vasoconstriction and increased blood pressure (effects).

Typical responses that involve drug-receptor interactions are those that involve agonist or antagonist interactions at a receptor. Agonists also can act through various transduction mechanisms to produce a variety of intracellular changes that alter cellular activity. (Transduction mechanisms are considered in more detail near the end of this section.) Agonist actions may be direct, as with acetylcholine acting on the nicotinic receptors at the neuromuscular junction to briefly open sodium channels. This produces rapid depolarization of skeletal muscle, leading to muscle contraction. Drugs also can act directly on ion channels to block their activity. For example, lidocaine and other local anesthetics block sodium channels in nerve fibers (i.e.,

axons) so that the conduction of action potentials is blocked, and the area served by those nerve fibers is anesthetized. Drugs also can act directly on ion channels to modulate their activity. The benzodiazepines, characterized by diazepam, produce multiple effects (e.g., sedation, hypnosis, anticonvulsant and antianxiety activity, and muscle relaxation) by modifying the actions of GABA on its receptors in the CNS. GABA is the predominant inhibitory neurotransmitter in the CNS, and it acts on GABA<sub>A</sub> receptor complexes by opening chloride channels on neurons to hyperpolarize them and render them less excitable. The benzodiazepines act on a different receptor on the GABA<sub>A</sub> receptor complex to enhance the actions of GABA on its receptors, thereby rendering target neurons even less excitable.

Many drugs act by inhibiting enzymes so that they cannot perform their normal functions as efficiently. One such drug, omeprazole, reduces the ability of parietal cells in the stomach to produce hydrochloric acid by inhibiting the enzyme, or proton pump, H<sup>+</sup>, K<sup>+</sup>-ATPase, which is found only in these parietal cells. It is used to facilitate healing of peptic ulcers and control esophageal reflux (heartburn). The body's normal enzymes also can convert false substrates into active drugs. For example,  $\alpha$ -methyl dopa is converted into  $\alpha$ -methyl norepinephrine by the enzymes that normally synthesize dopamine and norepinephrine from dopa.  $\alpha$ -Methyl norepinephrine acts on brain receptors to reduce sympathetic activity to blood vessels, thereby reducing blood pressure in hypertensive patients. Antimetabolites used to treat cancer also are false substrates, which are similar in structure to endogenous metabolites involved in cell-cycle reactions but function abnormally to interfere with synthesis of essential metabolites. Some drugs are, or have been, designed to be inactive until they are converted, usually by liver drug-metabolizing enzymes such as cytochrome P450, to active drug; the inactive drug is called a *prodrug*.

Various carriers are used by cells to take up neurotransmitters that have been released. The actions of dopamine released from dopamine nerve terminals in the brain are terminated by reuptake into the nerve terminals by a dopamine carrier. The dopamine then is reused for neurotransmission. If the carrier is blocked by a reuptake blocker such as cocaine, dopamine concentrations between the nerve terminals and the dopamine receptors build up for a time and produce greater effects.

Finally, antibiotics and antiviral, antifungal, and antiparasitic drugs owe their selectivities to selective actions on certain biochemical processes that are essential to the offending organism but are not shared by the mammalian host. The penicillins and related antibiotics interfere with the synthesis of rigid cell walls by growing bacteria, but mammalian cells are contained only by plasma membranes and, therefore, are not affected by penicillins. Antiparasitic drugs target enzymes found only in parasites, enzymes that are indispensable only in parasites, or biochemical functions with different pharmacological properties in the parasite and the host.

## RECEPTOR BINDING

Drugs that bind to certain receptors selectively at pharmacological concentrations are known as *receptor ligands*; they can be agonists or antagonists. Many drugs also bind nonselectively to nonreceptor proteins throughout the body where they exert no pharmacological actions or effects. Many drugs bind to plasma proteins, especially albumin. Albumin-bound drug can act as a reservoir for free drug, with which it is in equilibrium, and competition among drugs for plasma protein binding can lead to increased free drug levels and drug interactions as they displace one another.

Drugs and endogenous ligands or substrates bind selectively to certain receptors because of both a chemical attraction and a proper fit to the protein. The lock-and-key analogy provides a useful concept of proper fit. Carried a step further, an agonist fits the lock and turns it, but an antagonist only fits the lock but cannot turn it; yet, it does block entry of the agonist

key. Generally, a number of drugs with both characteristics can combine with the same receptor. The study of structure-activity relationships among similar drugs and their receptors always has been an important and fruitful approach of both pharmacology and medicinal chemistry. Highly selective drugs tend to bind to only one or several closely related receptors. However, some drugs can combine with and activate or inactivate a number of different receptors that have similar structures, thereby diminishing selectivity and magnifying side effects.

The types of chemical bonds by which drugs bind to their receptors are as follows, in decreasing order of bond strength: covalent, ionic, hydrogen, hydrophobic, and van der Waals bonds. Relatively few drugs form covalent bonds with their receptors. Covalent bonds are irreversible and very long-lasting; new receptors or enzymes must be synthesized to restore function, and this process takes a week or two. Most drugs rely on combinations of the other, weaker bonds to bind tightly but reversibly to receptors. For example, the binding of acetylcholine, a relatively simple molecule, to nicotinic receptors at the neuromuscular junction involves ionic, hydrogen, and van der Waals bonds, with the ionic and hydrogen bonds being the most important. It is no accident that receptor-binding drugs are partially ionized at body pH, because receptor proteins also are partially ionized. Drugs and proteins contain positively charged nitrogen groups and negatively charged carboxyl groups that strongly attract one another and usually provide the initial drug-receptor bonds. Hydrogen bonds, formed between bound hydrogen atoms and oxygen, nitrogen, fluoride, or sulfur atoms, further orient the drug molecule to its receptor to enhance the proper fit. One or several hydrogen bonds can be involved. Hydrophobic bonds form among nonpolar ring structures (e.g., benzene) or chains of methylene groups to stabilize orientation further. Finally, the very weak van der Waals forces provide some additional, electrostatic bonding over very short distances.

Drug molecules that contain asymmetrical carbon atoms can exist as stereoisomers, only one of which is oriented to bond well with its receptors. For example, the side chain of epinephrine contains an asymmetrical carbon atom in the alpha position of the side chain, with a hydroxyl group attached, permitting epinephrine to exist in D- and L- forms (mirror images). The endogenous L-form is about 1000 times more potent than the synthesized D-form, because the L-form has a much greater binding affinity for its receptors because of its preferred configuration. In the past, drugs synthesized as mixtures of stereoisomers were formulated as racemic mixtures, but improved chemical separation techniques now often allow isolation of the more active isomer for formulation.

## RECEPTOR STRUCTURE AND FUNCTION

The number of receptors and their subtypes continues to grow at a rapid pace as a result of the identification of new endogenous ligands and application of newly developed techniques to study them. Despite this large number, most receptors can be classified structurally and functionally into only a few basic types, which are described in this section. No attempt is made to provide detailed descriptions of individual receptors within each category. Rather, one or two examples will suffice for each, with brief reference to some prominent types that are therapeutically relevant.

### VOLTAGE-SENSITIVE CHANNELS

While not generally classified as receptors, voltage-sensitive channels contain receptors that are acted upon by drugs or toxins to block or modify their normal function. The voltage-sensitive sodium channels in axons allow initiation and conduction of action potentials in response to a voltage change in the plasma membrane. When sodium channels open, sodium ions rush into the cytoplasm, thereby causing depolarization and propagation of the action potential. The crucial component

of the sodium channel is a single protein composed of a chain of about 2000 amino acids and called the  $\alpha$  subunit. Several  $\beta$  subunits with minor roles also are associated with the  $\alpha$  subunit. The  $\alpha$  subunit has four repeating domains composed of about 250 amino acids each, and each domain contains six,  $\alpha$ -helical, 22- to 25-amino acid, transmembrane, spanning segments. Each domain forms one of four clusters of the six membrane-spanning regions to encircle the sodium channel so formed. On end, the channel resembles 24 cylinders neatly arranged around the sodium channel that, at rest, is charged positively due to positive charges on the four transmembrane helices that surround the channel. Upon activation, these particular helices are thought to rotate upward, thereby moving the positive charges away from the channel and allowing the positive sodium ions to rush through. The channel remains open for only about 1 msec because the voltage changes attract a protein loop of the channel in the cytoplasm to shut the channel like a tetherball. Local anesthetics block the sodium channel from the cytoplasmic side by binding to receptors inside the channel. Several neurotoxins block from the outside.

Axons are repolarized by brief ( $\sim 1$  msec) opening of voltage-activated potassium channels that are constructed similarly to sodium channels but are composed of four identical subunits of peptide that associate in the membrane to form the potassium channel. Each subunit spans the membrane six times. It probably functions much like the sodium channel, including inactivation by a tetherball segment of cytoplasmic peptide. Quinidine, an antiarrhythmic drug, will block this potassium channel in the heart.

Voltage-activated calcium channels of the L-type are composed of five similar protein subunits that assemble across heart muscle and vascular smooth muscle membranes to form the calcium channel. Its arrangement in the membrane is similar to that of the sodium and potassium channels. Calcium channel blockers such as verapamil and nifedipine are used to treat several cardiovascular conditions by virtue of their ability to block calcium channels in the heart and blood vessels.

### LIGAND-ACTIVATED ION CHANNELS

The best-characterized ligand-activated ion channel is the nicotinic receptor complex at the neuromuscular junction. As the name implies, these channels are activated by receptor ligands—in this case, acetylcholine. The nicotinic receptor complex is composed of five subunit proteins with similar structures that associate across the plasma membrane to form a sodium channel. The receptor complex is formed from two  $\alpha$  and one each of  $\beta$ ,  $\gamma$ , and  $\delta$  subunits (Fig 38-7). In contrast to the voltage-activated ion channels, each of the five proteins

Figure 38-7. Nicotinic receptor complex. ACh, acetylcholine.

crosses the membrane only four times. The two  $\alpha$  subunits contain the nicotinic receptors, which acetylcholine activates, and both must be activated to open the sodium channel to 6.5 Å for about 4 msec. The receptors can be blocked by neuromuscular blocking agents such as curare. The nicotinic receptors on autonomic ganglia are similar in structure but are composed of a different set of subunits, which accounts for the long-known differences in selective antagonists at the two sites.

Other ligand-activated ion channels – GABA<sub>A</sub>, glycine, and glutamate – have structures similar to that of the nicotinic receptor complex. GABA and glycine channels are chloride channels, which permit chloride influx into neurons to produce hyperpolarization and decreased neuronal excitability. Glutamate channels are primarily sodium channels, and they also contain modifying receptors for glycine and polyamines. The GABA<sub>A</sub> receptor complex contains not only receptors for GABA but also separate receptors for benzodiazepines (e.g., diazepam), barbiturates, and steroids, which modify the actions of GABA on the chloride channel. The convulsant activity of strychnine is due solely to its ability to block glycine receptors, primarily in the brainstem and spinal cord.

### G PROTEIN-COUPLED RECEPTORS

The G protein-coupled receptors make up a very large family of receptors that are activated by monoamines (e.g., epinephrine, norepinephrine, dopamine, serotonin), acetylcholine (muscarinic receptors), opioids, and a host of active peptides, including a number of hormones. Structurally, these receptors are single proteins, most of which are composed of chains of 350 to 550 amino acids and cross the plasma membrane seven times in a serpentine arrangement (Fig 38-8). Each of the seven transmembrane domains is composed of 22 to 30 amino acids configured into an  $\alpha$ -helix. The third of three intracellular (cytoplasmic) loops is much longer than the other two and is responsible for coupling with the G proteins. Rather than residing at the extracellular surface of the receptor, the actual receptor-binding sites often lie *within* the membrane between the seven transmembrane domains. For example, the  $\beta$ -adrenergic receptor lies 11 Å below the extracellular surface, or about one-third of the distance through the membrane. The positively charged nitrogen on the side chain of the epinephrine molecule forms an ionic bond with the negatively charged carboxyl group on an

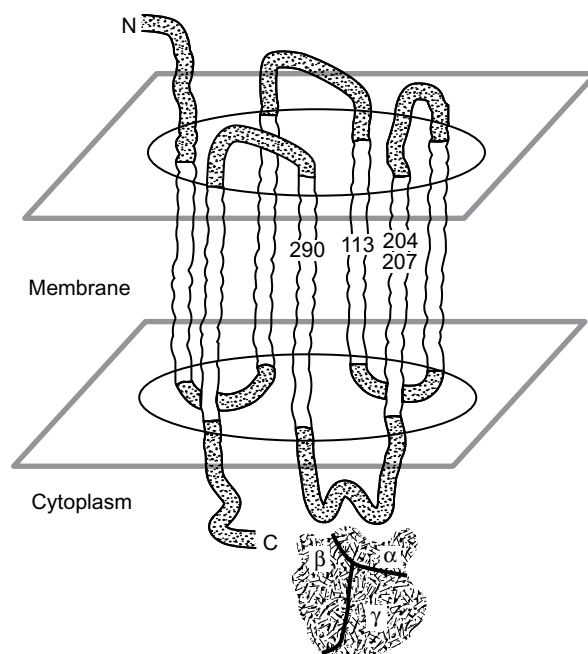

Figure 38-8. G-protein-coupled receptor complex.

aspartate amino acid (residue 113) in the third transmembrane domain (TM3). The two catechol hydroxyl groups of epinephrine form hydrogen bonds with the free hydroxyl groups of two serine amino acids at residues 204 and 207 in TM5, and the aromatic ring of epinephrine forms a hydrophobic bond with that of a phenylalanine at residue 290 in TM6. The location of G protein-coupled receptors within the membrane underscores the importance of size and configuration in the molecular structure of both agonists and antagonists for these receptors. Some negatively charged and peptide ligands do bind to an extracellular domain, however.

Among some families of G protein-coupled receptors there is considerable structural homology; i.e., the same amino acids and the same sequences make up large portions of a number of different receptors. Consequently, a number of antagonist receptor ligands bind to these similar arrangements of amino acids in the transmembrane domains. For example, many of the antipsychotic drugs (i.e., neuroleptics) are antagonists not only at dopamine receptors, where they are thought to exert their therapeutic effects, but also at  $\alpha_1$ -adrenergic, serotonin, histamine, and muscarinic receptors, thereby producing hypotension, sedation, blurred vision, dry mouth, and constipation as side-effects.

The G proteins closely associated with the third cytoplasmic loop of the receptors are heterotrimers composed of three different subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ . Upon receptor activation, the  $\alpha$  subunit exchanges a bound GDP for a GTP and dissociates from the  $\beta\gamma$  subunits to activate a membrane enzyme such as adenylyl cyclase or to influence an ion channel. In some cases, the  $\beta\gamma$  subunits may interact with the same or a different intracellular effector. The duration of action of the active GTP- $\alpha$  subunit is determined by the hydrolysis of GTP to GDP by a GTPase, which is intrinsic to the  $\alpha$  subunit, and its reassociation with the  $\beta\gamma$  subunits. This process is of longer duration than the association of the ligand with the ligand-G protein-coupled receptor, resulting in amplification of the original signal.

In the case of adenylyl cyclase activation, this enzyme synthesizes cAMP from ATP. As a *second messenger*, cAMP then goes on to activate one or several protein kinase As that phosphorylate one or several other proteins to produce the appropriate cellular effects. The targeted protein may be an enzyme, a transport protein, a contractile protein, or an ion channel. The specificity of these regulatory effects depends on the distinct protein substrates that are expressed in different cells (e.g., liver vs. smooth muscle). The actions of cAMP are terminated by several types of intracellular phosphodiesterases that convert cAMP to 5'-AMP. Competitive inhibition of phosphodiesterases to prolong the actions of cAMP is one of the mechanisms by which caffeine produces its effects.

As if the foregoing is not sufficiently complicated, the activity of adenylyl cyclase also can be inhibited by activation of different G protein-coupled receptors. The G proteins coupled to inhibitory receptors are designated  $G_i$  proteins, as opposed to those coupled to stimulatory receptors and designated  $G_s$  proteins.  $G_i$  proteins also are heterotrimers, and receptor activation of  $G_i$  also leads to GTP binding to the  $\alpha$  subunit and its dissociation from the  $\beta\gamma$ , but  $G_i$  proteins differ structurally from  $G_s$  proteins. Examples of  $G_s$ -coupled receptors are  $\beta$ -adrenergic, dopamine-1, histamine-2, glucagon, and adrenocorticotropic hormone. Examples of  $G_i$ -coupled receptors are  $\alpha_2$ -adrenergic, dopamine-2, muscarinic, and opioid. A number of different  $G_s$  and  $G_i$  protein-coupled receptors can exist on the same cell, so that the activity of adenylyl cyclase can be fine-tuned between zero and maximum.

Another important group of G protein-coupled receptors activate the enzyme phospholipase C (PLC) to hydrolyze a minor component of the plasma membrane, phosphatidylinositol-4,5-bisphosphate, into two second messengers, diacylglycerol (DAG) and  $IP_3$ . In contrast to the cAMP systems, receptors coupled to PLC are only excitatory. Examples are  $\alpha_1$ -adrenergic, muscarinic, Substance P, and thyrotropin-releasing hormone

receptors. The second messenger DAG is confined to the membrane, where it activates a protein kinase C, of which nine distinct types have been identified. The other second messenger,  $IP_3$ , diffuses through the cytosol to release calcium from intracellular stores. Calcium is involved in many cellular regulatory activities, including activation of calcium-calmodulin, which regulates the activities of other enzymes including other kinases. The kinases, in turn, phosphorylate enzymes, ion channels, or other proteins to produce cellular effects. When the phosphoinositide and cAMP signaling systems coexist, they can oppose or complement one another in complex ways.

A third second-messenger system uses cyclic guanosine-3',5'-monophosphate (cGMP) in intestinal mucosa and vascular smooth muscle. It is synthesized from GTP by activation of guanylyl cyclase and activates protein kinase G, which then dephosphorylates myosin light chains in vascular smooth muscle, thereby producing muscle relaxation. Agonists, e.g., acetylcholine and histamine, cause the release of nitric oxide from vascular endothelial cells, which then diffuses into the smooth muscle cells to activate guanylyl cyclase. A direct receptor-mediated activation is produced by atrial natriuretic factor, a blood-borne peptide hormone. In this case, the receptor domain is outside the membrane and is connected through a single transmembrane domain to the intracellular guanylyl cyclase enzyme, which is activated by receptor binding.

### TYROSINE KINASE-LINKED RECEPTORS

The tyrosine kinase-linked receptors are composed of an extracellular receptor domain, a single transmembrane domain, and an intracellular catalytic domain that catalyzes phosphorylation of tyrosine residues on target proteins. Some receptors are composed of single proteins, whereas others are assembled from two subunits (e.g., insulin receptors). Activation of insulin receptors triggers increased uptake of glucose and amino acids and regulates metabolism of glycogen and lipids in the cell. The catalytic actions persist for a number of minutes after insulin leaves the binding site. Several growth factors also exert their complex cellular effects by activating tyrosine kinase or similar receptors. Growth factors trigger changes in membrane transport and other metabolic events, including regulation of DNA synthesis.

### INTRACELLULAR RECEPTORS THAT CONTROL DNA TRANSCRIPTION

Activation of intracellular receptors for steroids (e.g., glucocorticoids, mineralocorticoids, sex steroids, vitamin D) and thyroid hormones stimulates the transcription of certain genes by binding to specific DNA sequences in the nucleus. The receptors generally are composed of a single protein with a ligand-binding domain, a DNA-binding domain, and a transcription-activating domain. In the inactivated state, the receptor protein is bound to another protein, a heat shock protein (hsp 90), which dissociates upon activation by a hormone, permitting DNA binding and transcription of mRNA, which then is translated into new protein. This process typically takes several hours, and the effects can last for days or weeks if there is a slow turnover of the newly synthesized proteins. A similar process accounts for the induction of drug-metabolizing enzymes in the liver by certain drugs and other chemicals. In this process, formation of a heterodimeric complex between a second protein and the ligand-bound receptor is required for DNA binding.

### ENZYME INHIBITION

Enzymes are very large, complex proteins or associated proteins that evolved to catalyze specific biochemical reactions that are essential to normal cellular function. A number of very selective drugs exert their effects by inhibiting particular enzymes, so that their abilities to process their normal substrates are blocked or impaired. Enzyme inhibitors can produce competitive blockade at a substrate or cofactor binding site on the enzyme. For example, the stimulant effect of digitalis glycosides

on cardiac muscle contraction is mediated by competitive inhibition of a sodium pump, Na<sup>+</sup>,K<sup>+</sup>-ATPase, which leads indirectly to an increase in intracellular calcium to interact with contractile proteins. Other enzyme inhibitors act noncompetitively at allosteric sites (sites remote from the substrate binding site), which prevent the enzyme from performing its catalytic function. For example, aspirin binds irreversibly to a site on cyclooxygenase that is remote from the binding site for arachidonic acid, which is normally converted to prostaglandins by the enzyme. The binding of related drugs such as ibuprofen is reversible. Irreversible inhibition by the formation of covalent bonds between a drug and an enzyme typically is long lasting because new enzyme must be synthesized to restore function.

## RECEPTOR REGULATION

The regulation of receptor numbers or density normally is constant, because synthesis keeps pace with degradation of the proteins. However, continuous stimulation of receptors with agonists can lead to desensitization or down-regulation of receptor sensitivity or number. Desensitization can occur rapidly without a change in receptor number, whereas down-regulation usually implies a decline in receptor number. For example, excess use of  $\beta$ -adrenergic agonists for treating bronchial asthma can lead to loss of receptor sensitivity to the agonist, caused by changes in coupling mechanisms to the G proteins. Chronic blockade of receptors can lead to up-regulation, which, in some cases, is due to synthesis of new receptors. An example is chronic blockade of  $\beta$ -adrenergic receptors in the heart, in which new  $\beta$ -receptors are synthesized, leading to supersensitivity upon abrupt withdrawal of the blocker. Another form of supersensitivity is demonstrated by denervation of skeletal muscle, which is followed by a proliferation of nicotinic receptors within and adjacent to the neuromuscular junction.

## INTRODUCTION

Drugs differ widely in their pharmacodynamic effects and clinical applications, as well as in penetration, absorption, and usual route of administration. They also differ in their distribution among the body tissues, and in disposition and mode of termination of action. Certain general principles that help explain the differences have both pharmaceutical and therapeutic implications. These principles facilitate an understanding of both the features that are common to a class of drugs and the differences among the members of that class.

To have the desired action, a drug must achieve absorption and transport to the appropriate tissue or organ, penetrate to the responding cell surface or subcellular structure, and elicit a response or alter ongoing processes. The drug may be distributed simultaneously or sequentially to a number of tissues, be bound or stored, be metabolized to inactive or active products, or be excreted. The basic entry, movement, and disposition of drugs and metabolites within the body are summarized in Figure 39-1. Each of the processes or events depicted relates importantly to therapeutic and toxic effects of a drug and to the mode of administration, and drug design must take each into account. The extent to which all the components of absorption, distribution, metabolism (biotransformation), and elimination apply varies enormously with the drug or xenobiotic (the latter being a term widely used to refer to not only drugs but any chemical not part of the normal biochemistry and physiology of the body) and the dose (level of exposure), and to some extent is subject to inter-individual variation, the latter often arising from genetic and disease state influences.

Pharmacokinetics is the science that treats the rate and extent of absorption, rates of distribution among body compartments, rate of elimination, and related phenomena. Because of its importance, other chapters in this book are devoted to the subject. This chapter will consider the physiological bases of the processes.

## STRUCTURE AND PROPERTIES OF MEMBRANES

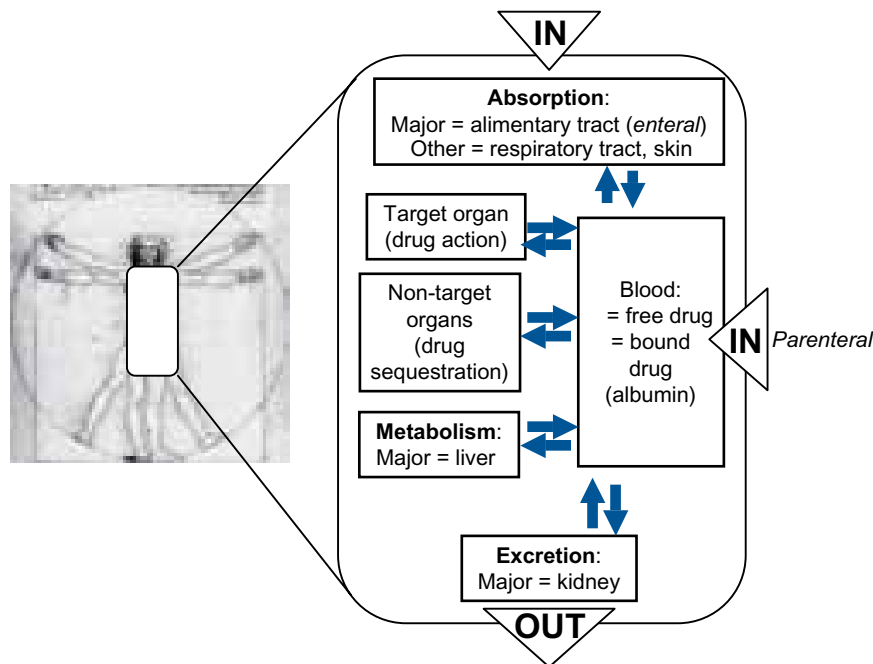

In almost all stages of absorption, distribution, metabolism (biotransformation), and elimination, a drug must pass through several to many biological membranes during the processes. Since membranes are traversed in all of these events, a brief description of biological membranes and membrane processes is in order, as well as the relationship of the physicochemical properties of a drug molecule to penetration and transport.

Numerous sophisticated techniques have established the nature of the plasma, mitochondrial, nuclear, and other cell membranes. The description of the plasma membrane that follows is much oversimplified, but it will suffice to provide a

background for an understanding of drug penetration into and through membranes. The cell membrane has been characterized as a bimolecular layer of lipid material entrained between two parallel monomolecular layers of protein. However, rather than forming a continuous layer, the protein layer comprises “islands” sporadically scattered over the surfaces. For many proteins, much of the protein is below the surface and within the fatty bilayer. The lipid bilayer can be envisaged as a somewhat orderly, lamellar array of phospholipid molecules associated tail-to-tail, each tail being an alkyl chain or steroid group, and the heads being polar groups. The disorder that does exist is the result of the different degrees of saturation of the fatty acids and the interspersed cholesterol molecules that break up the close packing of the fatty acid tails. Cholesterol maintains the mechanical stability of cell membranes, is a determinant of membrane fluidity, and—with relevance to drug passage across membranes—decreases permeability to water-soluble molecules. Moreover, the lamellar portion is penetrated by large globular proteins with a highly hydrophobic interior (like the lipid layers), and by some fibrous proteins as well.

The plasma membrane is asymmetrical. The lipid composition varies from cell type to cell type and perhaps from site to site on the same membrane. There are, for example, differences between the membrane of the endoplasmic reticulum and the plasma membrane, even though the membranes are co-extensive. The membrane surface facing the cytoplasm is rich in phosphatidylethanolamine and phosphatidylserine, while the surface facing the outside is rich in phosphatidylcholine and sphingomyelin. Oligosaccharide chains linked to lipids (glycolipids), and oligo- and polysaccharide chains attached to proteins (glycoproteins) are confined to non-cytosolic facing surfaces. Sugar moieties attached to the outer proteins are most often attached to the asparagine residue. These sugar moieties are important to both cellular and immunological recognition and adhesion, and they have other functions as well. Where membranes are double, the inner and outer layers differ considerably; the inner and outer membranes of mitochondria have strikingly different compositions and properties.

The cell membrane appears to be perforated by water-filled pores of various sizes, varying from about 4 to 10 Å, most of which are about 7 Å. Probably all major ion (water-filled) channels penetrate the large proteins assemblies that traverse the membrane. Through these pores pass inorganic ions and small organic molecules. Among the common inorganic ions, because sodium ions are more hydrated than potassium and chloride ions, they are larger and do not pass as freely through the pores as do potassium and chloride. Ion (ion plus water) movement can be by diffusion down a chemical concentration gradient. However, movement of ions through the pores can be controlled by counterion transport, or expenditure of intracellular

**Figure 39-1.** Interrelationship of the major components of drug entry, distribution, metabolism, and elimination within the body.

energy—adenosine triphosphate (ATP) hydrolysis—by so-called ABC transporters (see Excretion in this chapter). Vascular endothelium appears to have pores at least as large as 40 Å, but these seem to be interstitial passages rather than transmembrane pores. Lipid molecules small enough to pass through the cell membrane pores may do so, but they have a higher probability of entering into the lipid layer (since pores constitute less than 1 percent of the cell surface upon which the drug molecule impinges); from there these molecules will equilibrate chemically with the interior of the cell. Other proteins may be confined to one or the other surface and not traverse the membrane. Often proteins on the inner surface protein are linked to intracellular structural proteins that contribute to cell shape.

## DIFFUSION AND TRANSPORT

Transport is the movement of a drug from one place to another within the body. The drug may diffuse freely in uncombined form with a kinetic energy appropriate to its thermal environment, or it may move in combination with extracellular or cellular constituents, sometimes in connection with energy-yielding processes that allow the molecule or complex to overcome barriers to simple diffusion.

### SIMPLE NONIONIC DIFFUSION AND PASSIVE TRANSPORT

Molecules in solution move in a purely random fashion, provided they are not charged and moving in an electrical gradient. Such random movement is called diffusion; if the molecule is uncharged, it is called nonionic diffusion. In a population of drug molecules, the probability that during unit time any drug molecule will move across a boundary is directly proportional to the number of molecules adjoining that boundary and, therefore, to the drug concentration. Except at dilutions so extreme that only a few molecules are present, the actual rate of movement (molecules per unit time) is directly proportional to the probability of movement and, therefore, to the concentration. Once molecules have passed through the boundary to the opposite side, their random motion may cause some to return and others to continue to move farther away from the boundary. The rate of return is likewise proportional to the concentration on the opposite side

of the boundary. It follows that, although molecules are moving in both directions, there will be a net movement from the region of higher to that of lower concentration, and the net transfer will be proportional to the concentration differential. If the boundary is a membrane, which has both substance and dimension, the rate of movement is also directly proportional to the permeability and inversely proportional to the thickness. These factors combine into Fick's law of diffusion:

$$dQ/dt = \bar{D}A(C_1 - C_2)/x$$

where  $Q$  is the net quantity of drug transferred across the membrane,  $t$  is time,  $C_1$  is the concentration on one side and  $C_2$  that on the other,  $x$  is the thickness of the membrane,  $A$  is the area, and  $\bar{D}$  is the diffusion coefficient, related to permeability. Since a biological membrane is heterogeneous, with pores of different sizes and probably with varying thickness and composition, both  $\bar{D}$  and  $x$  probably vary from place to place. Nevertheless, some mean values can be assumed. It is customary to combine the membrane factors into a single constant, called a permeability constant or coefficient,  $P$ , so that  $P = \bar{D}/x$ , and  $A$  in the equation above has unit value. The rate of net transport (diffusion) across the membrane then becomes:

$$dQ/dT = P(C_1 - C_2)$$

As diffusion continues,  $C_1$  approaches  $C_2$ , and the net rate,  $dQ/dt$ , approaches zero in exponential fashion, characteristic of a first-order process. Equilibrium is defined as that state in which  $C_1 = C_2$ . The equilibrium is, of course, dynamic, with equal numbers of molecules being transported in each direction during unit time. If water also is moving through the membrane, it may either facilitate the movement of drug or impede it, according to the relative directions of movement of water and drug; this effect of water movement is called solvent drag.

### IONIC OR ELECTROCHEMICAL DIFFUSION

If a drug is ionized, the transport properties are modified. The probability of penetrating the membrane is still a function of concentration, but it is also a function of the potential difference or electrical gradient across the membrane. A cationic

drug molecule will be repelled from the positive charge on the outside of the membrane, and only those molecules with a high kinetic energy will pass through the ion barrier. If the cation is polyvalent, it may not penetrate at all.

Once inside the membrane, a cation will be simultaneously attracted to the negative charge on the intracellular surface of the membrane and repelled by the outer surface; it is said to be moving along the electrical gradient. If it is also moving from a higher toward a lower concentration, it is said to be moving along its electrochemical gradient, which is the sum of the influences of the electrical field and the concentration differential across the membrane.

Once inside the cell, cations will tend to be kept inside by the attractive negative charge on the interior of the cell, and the intracellular concentration of drug will increase until—by sheer numbers of accumulated drug particles—the rate of outward diffusion or mass escape equals that of inward transport. At this point electrochemical equilibrium is said to have occurred. At electrochemical equilibrium at body temperature (37°C), ionized drug molecules will be distributed according to the Nernst equation:

$$\pm \log C_0/C_i = ZE/61$$

where  $C_0$  is the molar extracellular and  $C_i$  the intracellular concentration,  $Z$  is the number of charges per molecule, and  $E$  is the membrane potential in millivolts.  $\log C_0/C_i$  is positive when the molecule is negatively charged and negative when the molecule is positively charged.

### FACILITATED DIFFUSION

Sometimes a substance moves more rapidly through a biological membrane than can be accounted for by the process of simple diffusion. This accelerated movement is termed facilitated diffusion. It is due to the presence of a special molecule within the membrane, called a carrier, with which the transported substance combines. There is considered to be greater permeability to the carrier–drug complex than to the drug alone, so that the transport rate is enhanced. After the complex has traversed the membrane, it dissociates. For the carrier process to be continuous, either the carrier must return to the original side of the membrane to be used again, or it must constantly be produced on one side and eliminated on the other. Many characteristics of facilitated diffusion, formerly attributed to ion carriers, can be explained by ion exchange. Facilitated diffusion only transports a molecule along its electrochemical gradient.

### ACTIVE TRANSPORT

Active transport can be defined as energy-dependent movement of a substance through a biological membrane against an electrochemical gradient. It is characterized as follows:

1. The substance is transported from a region of lower to one of higher electrochemical activity.
2. Metabolic poisons (that most often reduce ATP concentrations) interfere with transport.
3. The transport system shows a requirement for specific chemical structures.
4. Closely related chemicals are competitive for the transport system.
5. The transport rate approaches an asymptote (i.e., saturates) as concentration increases.

Characteristics 3, 4, and 5 are in common with those of carrier-mediated facilitated diffusion.

Many drugs are secreted by active transport from the renal tubules into urine, from liver cells into bile or blood, from intestinal cells into the lumen of the gastrointestinal (GI) tract, or from the cerebrospinal fluid into blood, but the role of active transport of drugs in the distribution into most body compartments and tissues has been less extensively documented, although it is now an active area of research. Active transport is

often required for the movement of drug metabolites, entities that generally have less lipid solubility than the parent drug, across cell membranes.

### PINOCYTOSIS AND EXOCYTOSIS

Many (perhaps all) cells are capable of a type of phagocytosis called pinocytosis. The cell membrane has been observed to invaginate into a sac-like structure containing extracellular materials and then pinch off the sac at the membrane, so that the sac remains as a vesicle or vacuole within the interior of the cell. Because metabolic activity is required and because an extracellular substance can be transported against an electrochemical gradient, pinocytosis shows some of the same characteristics as active transport. However, pinocytosis is relatively slow and inefficient compared with most active transport, except in GI absorption, where for some xenobiotics pinocytosis may be of some importance.

It is not known to what extent pinocytosis contributes to the transport of most drugs, but many macromolecules and even larger particles can be absorbed by the gut. Exocytosis is the reverse of pinocytosis. Granules, vacuoles, or other organelles within the cell move to the cell membrane, fuse with it, and extrude their contents into the interstitial space.

### PHYSICO-CHEMICAL FACTORS IN PENETRATION

Drugs and other substances may traverse the membrane primarily either through the pores, or by movement into the membrane lipids and subsequent diffusion from the membrane into the cytosol or other fluid on the far side of the membrane. The physicochemical prerequisites differ according to which route is taken. To pass through the pores, the *diameter* of the molecule must be smaller than the pore, but the molecule can be longer than the pore diameter. The probability that a long, thin molecule will be suitably oriented, however, is low unless there is also bulk flow, and therefore transmembrane passage of such molecules is slow.

Water-soluble molecules with low lipid solubility are usually thought to pass through the membrane mainly via the pores. If there is a membrane carrier or active-transport system, a low solubility of the drug in membrane lipids is no impediment to penetration, because the drug–carrier complex is assumed to have an appropriate solubility, and energy from an active-transport system enables the drug to penetrate the energy barrier imposed by the lipids. Actually, the lipids are not an important energy barrier; rather, the barrier is the force of attraction of the solvent water for its dipolar-to-polar solute, so that it is difficult for the solute to leave the water and enter the lipid.

Drugs with a high solubility in the membrane lipids pass easily through the membrane. Even when their dimensions are small enough to permit passage through pores, lipid-soluble drugs primarily pass through the membrane lipids, not only because chemical partition favors the lipid phase but also because, as mentioned previously, the surface area occupied by pores is only a small fraction of the total membrane area.

### LIPID SOLUBILITY AND PARTITION COEFFICIENTS

Over a century ago, the importance of lipid solubility in the penetration and absorption of drugs was being investigated. Eventually it was recognized that more important than lipid solubility was the lipid-to-water partition (or distribution) coefficient; in other words, a high lipid solubility does not favor penetration unless the water solubility is low enough so that the drug is not entrained in the aqueous phase. When the water solubility of a substance is so low that a significant concentration in water or extracellular fluid cannot be achieved, absorption may be negligible despite a favorable partition coefficient. Hence, such substances as mineral oil or petrolatum are virtually unabsorbed. The optimal partition coefficient for permeation of the skin appears to be lower than that for the permeation of the cell membrane, perhaps being as low as unity.

## DIPOLARITY, POLARITY, AND NONIONIC DIFFUSION

The partition coefficient of a drug depends upon the polarity and the size of the molecule. Drugs with a high dipole moment, even though nonionized, have low lipid solubility and hence penetrate poorly. An example of a highly dipolar substance with a low partition coefficient, which does not penetrate into cells, is sulfisoxazole. Sulfadiazine is somewhat less dipolar, has a chloroform-to-water partition coefficient 10 times that of sulfisoxazole, and readily penetrates cells. Ionization not only greatly diminishes lipid solubility but also may impede passage through charged membranes.

It is often stated that ionized molecules do not penetrate membranes, except for ions of small diameter. This is not necessarily true because of the presence of membrane carriers for some ions that effectively shield or neutralize the charge (formation of ion pairs). The renal tubular transport systems, which transport such obligate ions as tetraethylammonium, probably form ion pairs. Furthermore, if an ionized molecule has a large non-polar moiety such that appreciable lipid solubility is imparted to the molecule despite the charge, the drug may penetrate, though usually at a slow rate. Nevertheless, when a drug is a weak acid or base, the nonionized form, with a favorable partition coefficient, passes through a biological membrane so much more readily than the ionized form that for all practical purposes, only the nonionized form is said to pass through the membrane. This has become known as the principle of nonionic diffusion.

## ABSORPTION OF DRUGS

Absorption is the process of movement of a drug from the site of application into the extracellular compartment of the body. Inasmuch as there is a great similarity among the various membranes through which a drug may pass to gain access to the extracellular fluid, it might be expected that the particular site of application (or route) would make little difference to the successful absorption of the drug. Actually it makes a great deal of difference; many factors, other than the structure and composition of the membrane, determine the ease with which a drug is absorbed. These factors are discussed in the following sections, along with an account of the ways that drug formulations can be manipulated to alter the ability of a drug to be absorbed readily.

## ROUTES OF ADMINISTRATION

Drugs can be administered by many different routes, including oral, rectal, sublingual or buccal, parenteral, inhalation, and topical. The choice of a route depends upon both convenience and necessity.

### ORAL ROUTE

This is obviously the most convenient route for access to the systemic circulation, providing that various factors do not militate against it. Oral administration does not always give rise to plasma concentrations sufficiently high to be effective; some drugs are absorbed unpredictably or erratically; patients occasionally have an absorption malfunction. Drugs cannot be given by mouth to patients who have GI intolerance, are being prepared for anesthesia, or have had GI surgery. Oral administration is also precluded in comatose patients.

In the drug development setting, Lipinski's "Rule of Five" predicts that, in general, an orally active drug has no more than one violation of the following criteria:

- not more than five hydrogen bond donors (oxygen or nitrogen atoms with one or more hydrogen atoms)
- not more than ten ( $2 \times 5$ ) hydrogen bond acceptors (nitrogen or oxygen atoms)
- a molecular mass not greater than ( $100 \times 5$ ) 500 daltons
- an octanol-to-water partition coefficient  $\log P$  not greater than 5.

### RECTAL ROUTE

Drugs that are ordinarily administered by the oral route can usually be administered by injection or by the alternative lower enteral route, through the anal portal into the rectum or lower intestine. With regard to the latter, rectal suppositories or retention enemas were formerly used quite frequently, but their popularity has abated somewhat as a result of improvements in parenteral preparations. Nevertheless, they continue to be valid—and sometimes very important—ways of administering a drug, especially in pediatric and geriatric patients, and retention enema may offer a useful substitute for the oral route. However, rectal suppositories may be inadequate when rapid absorption and high plasma levels are required.

### SUBLINGUAL OR BUCCAL ROUTE

Even though an adequate plasma concentration may eventually be achievable by the oral route, it may rise much too slowly for use in some situations when a rapid response is desired. In such situations parenteral therapy is usually indicated. However, patients with angina pectoris may get quite prompt relief from an acute attack by the sublingual or buccal administration of nitroglycerin, so that parenteral administration can be avoided. When only small amounts of drugs are required to gain access to the blood, the buccal route may be very satisfactory, providing the physicochemical prerequisites for absorption by this route are present in the drug and dosage form.

### PARENTERAL ROUTES

These routes, by definition, include any route other than the oral-GI (enteral) tract, but in common medical usage the term excludes topical administration and includes only various hypodermic routes. Parenteral administration includes the intravenous, intramuscular, and subcutaneous routes. Parenteral routes are an option whenever enteral routes are contraindicated or are inadequate.

The intravenous route may be preferred on occasion, even when a drug may be well absorbed by the oral route. There is no delay imposed by absorption before the administered drug reaches the circulation, and blood levels rise virtually as rapidly as the time necessary to empty the syringe or infusion bottle. Consequently, the intravenous route is the preferred route when an emergency calls for an immediate response.

In addition to the rapid rise in plasma concentration of drug, another advantage of intravenous administration is the greater predictability of the peak plasma concentration, which with some drugs can be calculated with a fair degree of precision. Smaller doses are generally required by the intravenous than by other routes, but this usually affords no advantage, inasmuch as the sterile injectable dosage form costs more than enteric preparations, and the requirements for medical or paramedical supervision of administration also may add to the cost and inconvenience.

Because of the rapidity with which drug enters the circulation, dangerous side effects to the drug may occur that often are not extant by other routes. The principal untoward effect is a depression of cardiovascular function. Consequently, some drugs must be given quite slowly to avoid vasculotoxic concentrations of drug in the plasma. Acute, serious allergic responses are also more likely to occur by the intravenous route than by other routes.

Many drugs are too irritating to be given by the oral, intramuscular, or subcutaneous route, and must of necessity be given intravenously. However, such drugs also may cause damage to the veins (phlebitis) or, if extravasated, cause necrosis around the injection site. Consequently, such irritant drugs may be diluted in isotonic solutions of saline, dextrose, or other media, and given by slow infusion, providing that the slower rate of delivery does not negate the purpose of the administration in emergency situations.

Absorption by the intramuscular route is relatively fast, and this parenteral route may be used when an immediate effect

is not required but a prompt effect is desirable. Intramuscular deposition can also be made of certain repository preparations where rapid absorption is not desired. Absorption from an intramuscular depot is more predictable and uniform than from a subcutaneous site. Irritation around the injection site is a frequent accompaniment of intramuscular injection, depending upon the drug and other ingredients. Because of the dangers of accidental intravenous injection, medical supervision is generally required. Sterilization is necessary.

In subcutaneous administration, the drug is injected into the connective tissue just below the skin. Absorption is slower than by the intramuscular route but nevertheless can be prompt with some drugs. Often, however, absorption by this route may be no faster than by the oral route. Therefore, when a fairly prompt response is desired with some drugs, the subcutaneous route may not offer much advantage over the oral route, unless for some reason the drug cannot be given orally.

The slower rate of absorption by the subcutaneous route is usually the reason for choosing the route, and the drugs given by this route are usually those for which it is desirable to distribute the drug's action over several hours, to avoid either too intense a response, too short a response, or frequent injections. Examples of drugs given by this route are insulin and sodium heparin, neither of which is absorbed orally, and both of which should be absorbed slowly over many hours. In the treatment of asthma, epinephrine is usually given subcutaneously to avoid the dangers of rapid absorption and consequent dangerous cardiovascular effects. Many repository preparations, including tablets or pellets, are given subcutaneously. As with other parenteral routes, irritation may occur. Sterile preparations are also required. However, medical supervision is not always required, and self-administration by this route is customary with certain drugs, such as insulin.

Intradermal injection, in which the drug is injected into the dermis instead of below it, is rarely used, except in certain diagnostic and test procedures, such as screening for allergic or local irritant responses.

Occasionally, even by the intravenous route, it is not possible, practical, or safe to achieve plasma concentrations high enough so that an adequate amount of drug penetrates into special compartments (e.g., the cerebrospinal fluid) or various cavities (e.g., the pleural cavity). The brain is especially difficult to penetrate with water-soluble drugs. The name blood-brain barrier is applied to the impediment to penetration. When drugs do penetrate, the choroid plexus often secretes them back into the blood very rapidly, so that adequate levels of drugs in the cerebrospinal fluid can be difficult to achieve. Consequently, intrathecal or intraventricular administration may be indicated.

Body cavities such as the pleural cavity are normally wetted by a small amount of effusate that is in diffusion equilibrium with the blood and hence is accessible to drugs. However, infections and inflammations may cause the cavity to fill with serofibrinous exudate that is too dense to be in rapid diffusion equilibrium with the blood. Intracavitary administration thus may be required. It is extremely important that sterile, non-irritating preparations be used for intrathecal or intracavitary administration.

## INHALATION ROUTE

Inhalation may be employed for delivering gaseous or volatile substances into the systemic circulation, as with most general anesthetics. Absorption is virtually as rapid as the drug can be delivered into the alveoli of the lungs, since the alveolar and vascular epithelial membranes are quite permeable, blood flow is abundant, and there is a very large surface for absorption.

Aerosols of nonvolatile substances can also be administered by inhalation, but the route is used infrequently for delivery into the systemic circulation because of various factors that contribute to blood concentrations that are erratic or difficult to achieve. Whether or not an aerosol reaches and is retained in pulmonary alveoli depends critically upon particle size.

Particles larger than 1 micrometer in diameter tend to settle in the bronchioles and bronchi, whereas particles smaller than 0.5 micrometer fail to settle and mainly are exhaled. Aerosols are employed mostly when the purpose of administration is an action of the drug upon the respiratory tract itself. An example of a drug commonly given as an aerosol is isoproterenol, which is employed to relax the bronchioles during an asthma attack.

## TOPICAL ROUTE

Although the stratum corneum is not a membrane in the same sense as a cell membrane, it offers a barrier to diffusion, which is of significance in the topical application of drugs. The stratum corneum consists of several layers of dead, keratinized, cutaneous epithelial cells enmeshed in a matrix of keratin fibers and bound together with cementing desmosomes and penetrating tonofibrils of keratin. Varying amounts of lipids and fatty acids from dying cells, sebum, and sweat are contained among the dead squamous cells. Immediately beneath the layer of dead cells and above the viable epidermal epithelial cells is a layer of keratohyaline granules and various water-soluble substances, such as amino acids, purines, monosaccharides, and urea.

Both the upper and lower layers of the stratum corneum are involved in the cutaneous barrier to penetration. The barrier to penetration from the surface is in the upper layers for water-soluble substances and the lower layers for lipid-soluble substances, and the barrier to the outward movement of water is in the lowest layer.

Topical administration is employed to deliver a drug at, or immediately beneath, the point of application. Although occasionally enough drug is absorbed into the systemic circulation to cause systemic effects, absorption is too erratic for the topical route to be used routinely for systemic therapy. However, various transdermal preparations are employed quite successfully for systemic use. A large number of topical medicaments are applied to the skin, although topical drugs are also applied to the eye, nose, throat, ear, vagina, etc.

In humans, percutaneous absorption probably occurs mainly from the surface. Absorption through the hair follicles occurs, but the follicles in humans occupy too small a portion of the total integument to be of primary importance. Absorption through sweat and sebaceous glands generally appears to be minor. When the medicament is rubbed on vigorously, the amount of the preparation that is forced into the hair follicles and glands is increased. Rubbing also forces some material through the stratum corneum without molecular dispersion and diffusion through the barrier. When the skin is diseased or abraded, the cutaneous barrier may be disrupted or defective, so that percutaneous absorption may be increased. Since much of a drug that is absorbed through the epidermis diffuses into the circulation without reaching a high concentration in some portions of the dermis, systemic administration may be preferred in lieu of, or in addition to, topical administration.

## FACTORS THAT AFFECT ABSORPTION

In addition to the physicochemical properties of drug molecules and biological membranes, various factors affect the rate of absorption and determine, in part, the choice of route of administration.

### CONCENTRATION

It is self-evident that the concentration, or more exactly, the thermodynamic activity, of a drug in a drug preparation will have an important bearing upon the rate of absorption, since the rate of diffusion of a drug away from the site of administration is directly proportional to the concentration. Thus, a 2 percent solution of lidocaine will induce local anesthesia more rapidly than a 0.2 percent solution. However, drugs administered in solid form are not necessarily absorbed at the maximal rate (see, Physical State of Formulation and Dissolution Rate below).

After oral administration the concentration of drugs in the gut is a function of the dose, but the relationship is not necessarily linear. Drugs with a low aqueous solubility quickly saturate the GI fluids, so that the rate of absorption tends to reach a limit as the dose is increased. The peptizing and solubilizing effects of bile and other constituents of the GI contents assist in increasing the rate of absorption but are in themselves somewhat erratic. Furthermore, many drugs affect the rates of gastric, biliary, and small intestinal secretion, which causes further deviations from a linear relationship between concentration and dose.

Drugs that are administered subcutaneously or intramuscularly also may not always show a direct linear relationship between the rate of absorption and the concentration of drug in the applied solution, because osmotic effects may cause dilution or concentration of the drug if the movement of water or electrolytes is different from that of the drug. Whenever possible, drugs for hypodermic injection are prepared as isotonic solutions. Some drugs affect the local blood flow and capillary permeability, so that at the site of injection there may be a complex relationship between concentration achieved and the concentration administered.

### PHYSICAL STATE OF FORMULATION AND DISSOLUTION RATE

The rate of absorption of a drug may be affected greatly by the rate at which the drug is made available to the biological fluid at the site of administration. The intrinsic physicochemical properties, such as solubility and the thermodynamics of dissolution, are only some of the factors that affect the rate of dissolution of a drug from a solid form. Other factors include not only the unavoidable interactions among the various ingredients in a given formulation but also deliberate interventions to facilitate dispersion or retard it. There also are factors that affect the rate of delivery from liquid forms. For example, a drug in a highly viscous vehicle is absorbed more slowly from the vehicle than a drug in a vehicle of low viscosity; in oil-in-water emulsions the rate depends upon the partition coefficient. These manipulations are the subject of biopharmaceutics.

### AREA OF ABSORBING SURFACE

The area of absorbing surface is an important determinant of the rate of absorption. To the extent that the therapist must work with the absorbing surfaces available in the body, the absorbing surface is not subject to manipulation. However, the extent to which the existing surfaces may be used is subject to variation. In those rare instances in which percutaneous absorption is intended for systemic administration, the entire skin surface is available.

Subsequent to subcutaneous or intramuscular injections, the site of application can be massaged to spread the injected fluid from a compact mass to a well-dispersed deposit. Alternatively, the dose can be divided into multiple small injections, although this recourse is generally undesirable.

The different areas for absorption afforded by the various routes partly account for differences in the rates of absorption by those routes. The large alveolar surface of the lungs allows extremely rapid absorption of gases, vapors, and properly aerosolized solutions; with some drugs the rate of absorption can be nearly as fast as with intravenous injection. In the gut the small intestine is the site of the fastest, and hence the greatest, absorption because of the small lumen and highly developed villi and microvilli; the stomach has a relatively small surface area, so that even most weak acids are absorbed predominantly in the small intestine despite a pH partition factor that should favor absorption from the stomach (see The pH Partition Principle below).

### VASCULARITY AND BLOOD FLOW

Although the thermal velocity of a freely diffusible, average drug molecule is on the order of meters per second, in solution

the rate at which it will diffuse away from a reference point will be much slower. Collisions with water and/or other molecules that cause a random motion, and the forces of attraction between the drug and water or other molecules, slow the net mean velocity.

The time taken to traverse a given distance is a function of the square of the distance; on average it would take about 0.01 second for a net outward movement of 1 micrometer, 1 second for 10 micrometers, 100 seconds for 100 micrometers, etc. In a highly vascular tissue such as skeletal muscle, in which there can be more than 1000 capillaries per square millimeter of cross section, a drug molecule would not have to travel more than a few micrometers, hence less than a second on average, to reach a capillary from a point of extravascular injection.

Once the drug reaches the blood, diffusion is not important to transport and the rate of blood flow determines the movement. The velocity of blood flow in a capillary is about 1 mm/second, which is 100 times faster than the mean net velocity of drug molecules 1 mm away from their injection site. The velocity of blood flow is even faster in the larger vessels. Overall, less than a minute is required to distribute drug molecules from the capillaries at the injection site to the rest of the body.

From the above discussion it follows that absorption is most rapid in the vascular tissues. Drugs are absorbed more rapidly from intramuscular sites than from less vascular subcutaneous sites, etc. Despite the small absorbing surface for buccal or sublingual absorption, the high vascularity of the buccal, gingival, and sublingual surfaces favors an unexpectedly high rate of absorption. Because of hyperemia, absorption will be faster from inflamed than from normal areas, unless the presence of edema lengthens the mean distance between capillaries and thus negates the effects of hyperemia on absorption.

Vasoconstriction can have a profound effect upon the rate of absorption. When a local effect of a drug is desired, as in local anesthesia, absorption away from the infiltrated site can be impeded greatly by vasoconstrictors included in the preparation. Unwanted vasoconstriction (e.g., cold-induced) can sometimes cause serious problems. During shock, blood flow is also diminished.

Extravascularly injected molecules too large to pass through the capillary endothelium will of necessity enter the systemic circulation through the lymph. Thus, the lymph flow can be important to the absorption of a few drugs.

### MOVEMENT

Several factors combine so that movement at the site of injection increases the rate of absorption. In the intestine, segmental movements and peristalsis aid in dividing and dispersing the drug mass. The continual mixing of the chyme helps keep the concentration maximal at the mucosal surface. The pressures developed during segmentation and peristalsis may also favor a small amount of filtration. Movement at the site of hypodermic injection also favors absorption, as it tends to force the injected material through the tissue, increasing the surface area of drug mass and decreasing the mean distance to the capillaries. Movement also increases the flow of blood and lymph. The selection of a site for intramuscular injection may be determined by the amount of expected movement, according to whether the preparation is intended as a fast-acting or a repository preparation.

### GASTRIC MOTILITY AND EMPTYING

The motility of the stomach is more important to the rate at which an orally administered drug is passed on to the small intestine than it is to the rate of absorption from the stomach itself, since for various reasons noted above, absorption from the stomach may be of minor importance.

The average emptying time of the unloaded stomach is about 40 minutes, and the half-time is about 10 minutes, although it varies according to stomach contents, to reflex and psychological factors, and to the action of certain autonomic drugs or some types of disease. The effect of food to delay absorption is

partly due to its action to prolong emptying time. The emptying time causes a delay in the absorption of drug, which may be unfavorable or favorable according to what is desired. In the case of therapy with antacids, gastric emptying is a nuisance, since it removes the antacid from the stomach where it is needed.

### SOLUBILITY AND BINDING

The dissolution of drugs of low solubility is generally a slow process. Indeed, low solubility is the result of a low rate of departure of drug molecules from the undispersed phase. Furthermore, since the concentration around the drug mass is low, the concentration gradient from the site of deposition to the plasma is small, and the rate of diffusion is low, accordingly.

When it is desired that a drug have a prolonged action but not a high plasma concentration, a derivative of low solubility is often sought. The insoluble estolates and other esters of several steroids have durations of action of weeks because of the slow rates of absorption from the sites of injection. Insoluble salts or complexes of acidic or basic drugs also are employed as repository preparations; for example, the procaine salt of penicillin G has a low solubility and is used in a slow-release form of the antibiotic.

The solubility of certain macromolecules depends critically on the ionization of substituent groups. When they are amphiprotic, they are least soluble at their isoelectric pH. Insulin is normally soluble at the pH of the extracellular fluid, but by combining insulin with the right proportion of a basic protein, such as protamine, the isoelectric pH can be made to be approximately 7.4 from 5.1, and the complex can be used as a low-solubility, prolonged-action drug.

Some drugs may bind with natural substances at or near the site of application. The strongly ionized mucopolysaccharides in connective tissue, ground substance, and mucous secretions of the gut retard the absorption of a number of drugs, especially large cationic or polycationic molecules. In the gut, the binding is the least at low pH, which should favor absorption of large cations from the stomach; however, absorption from the stomach is slow (see above), so that the absorption of large cations occurs mainly in the upper duodenum where the pH is still relatively low. Pharmacologically inactive quaternary ammonium compounds are sometimes included in an oral preparation of a quaternary ammonium drug for the purpose of saturating the binding sites of mucin and other mucopolysaccharides, and thereby enhancing the absorption of drug.

In addition to mucopolysaccharides in mucous secretions, food in the GI tract binds many drugs and slows absorption. Antacids, especially aluminum hydroxide plus other basic aluminum compounds and magnesium trisilicate, bind amine and ammonium drugs, interfering with absorption.

### DONNAN EFFECT

The presence of a charged macromolecule on one side of a semi-permeable membrane (impermeable to the macromolecule) will alter the concentration of permeant ionized particles according to the Donnan equilibrium. Accordingly, drug molecules of the same charge as the macromolecule will be constrained to the opposite side of the membrane. The pull of large anionic blood plasma proteins will concentrate small membrane-diffusible cations around them, but not small diffusible anions, which will tend to concentrate on the other side. The presence of appropriately charged macromolecules will not only influence the distribution of drug ions in accordance with the Donnan equation but also increase the rate of transfer of the drug across the membrane, because of mutual ionic repulsion. This effect is sometimes used to facilitate the absorption of ionizable drugs from the GI tract. The Donnan effect also operates to retard the absorption of drug ions of opposite charge; however, the mutual electrostatic attraction of a macromolecule and a drug ion generally results in actual binding, which is more important than the Donnan effect.

### VEHICLES AND ABSORPTION ADJUVANTS

Drugs that are to be applied topically to the skin and mucous membranes are often dissolved in vehicles that are thought to enhance penetration. For a long time it was thought that oleaginous vehicles promoted the absorption of lipid-soluble drugs. However, the role and effect of the vehicle has proven to be quite complex. In the skin at least five factors are involved:

1. The effect of the vehicle to alter the hydration of the keratin in the barrier layer
2. The effect of the vehicle to promote or prevent the collection of sweat at the surface of the skin
3. The partition coefficient of the drug in a vehicle-water system
4. The permeability of the skin to the undissolved drug
5. The permeability of the skin to the vehicle.

The effect of the vehicle to aid in the access of the drug to the hair follicles and sebaceous glands may also be involved, although in humans the follicles and glands are probably ordinarily of minor importance to absorption.

A layer of oleaginous material over the skin prevents the evaporation of water, so that the stratum corneum may become macerated and more permeable to drugs. In dermatology it is sometimes the practice to wrap the site of application with plastic wrap or some other waterproof material for the purpose of increasing the maceration of the stratum corneum. However, the layer of perspiration that forms under an occlusive vehicle may become a barrier to the movement of lipid-soluble drugs from the vehicle to the skin, but it may facilitate the movement of water-soluble drugs. Conversely, polyethylene glycol vehicles remove the perspiration and dehydrate the barrier, which decreases the permeability to drugs; such vehicles remove the aqueous medium through which water-soluble drugs may pass down into the stratum corneum but at the same time facilitate the transfer of lipid-soluble drugs from the vehicle to the skin.

Even in the absence of a vehicle, it is not clear what physicochemical properties of a drug favor cutaneous penetration—high lipid solubility being a prerequisite according to some authorities, and an ether-to-water partition coefficient of approximately unity according to others. Yet, the penetration of ethanol and dibromomethane are nearly equal, and other such enigmas exist. It is not surprising, then, that the effects of vehicles are not altogether predictable.

A general statement might be made that if a drug is quite soluble in a poorly absorbed vehicle, the vehicle will retard the movement of the drug into the skin. For example, salicylic acid is 100 times as permeant when absorbed from water as from polyethylene glycol, and pentanol is five times as permeant from water as from olive oil. Yet, ethanol penetrates five times faster from olive oil than from either water or ethanol, all of which denies the trustworthiness of generalizations about vehicles.

For several decades there has been some interest in certain highly dielectric, aprotic solvents, especially dimethyl sulfoxide. Such substances generally prove to be excellent solvents for both water- and lipid-soluble compounds, and for some compounds not soluble in either water or lipid solvents. The extraordinary solvent properties probably are due to a high polarizability and van der Waals bonding capacity, a high degree of polarization (dipole moment), and a lack of association through hydrogen bonding. As a vehicle, dimethyl sulfoxide greatly facilitates the permeation of the skin and other biological membranes by numerous drugs, including such large molecules as insulin.

### OTHER FACTORS THAT AFFECT DRUG ABSORPTION

Several other, less well-defined factors affect the absorption of drugs, some of which may operate, in part, through factors already cited above. Disease or injury has a considerable effect upon absorption. For example, debridement of the stratum corneum increases the permeability to topical agents, meningitis

increases the permeability of the blood–brain barrier, biliary insufficiency decreases the absorption of lipid-soluble substances from the intestine, and acid–base disturbances can affect the absorption of weak acids or bases. Certain drugs, such as ouabain, that affect active-transport processes may interfere with the absorption of certain other drugs. The condition of the ground substance, or intracellular cement, probably bears on the absorption of certain types of molecules. Hyaluronidase, which depolymerizes the mucopolysaccharide ground substance, can be demonstrated to facilitate the absorption of some, but not all, drugs from subcutaneous sites.

## DISTRIBUTION

The term drug disposition is used variously to include all processes that tend to lower the plasma concentration of drug, as opposed to drug absorption, which elevates the plasma level. Consequently, the distribution of drugs to the various tissues is a component of disposition, as are biotransformation and excretion, two components that contribute to drug elimination. The term distribution denotes the partitioning of a drug among the numerous locations where a drug may be contained within the body. Biotransformations are the alterations in the chemical structure of a drug that are imposed upon it by the life processes. Excretion is, in a sense, the converse of absorption—namely, the transportation of the drug or its products out of the body. The term applies whether or not special organs of excretion are involved.

The body can be considered to comprise a number of compartments: enteric (GI), plasma, interstitial, cerebrospinal fluid, bile, glandular secretions, urine, storage vesicles, cytoplasm or intracellular space, etc. Some of these compartments, such as urine and secretions, are open-ended, but since their contents relate to those in the closed compartments, they must also be included.

At first thought, it may seem that if a drug was distributed passively (i.e., by simple diffusion) and the plasma concentration could be maintained at a steady level, the concentration of a drug in the water in all compartments ought to become equal. It is true that some substances, such as ethanol, are distributed nearly equally throughout the body water, but they are more the exception than the rule. Such substances are mainly small, uncharged, non-dissociable, highly water-soluble molecules.

The condition of small size and high water solubility allows passage through the pores without the necessity of carrier or active transport. Small size also places a limit on van der Waals binding energy and configurational complementarity, so that binding to proteins in plasma, or cells, is slight. The presence of a charge on a drug molecule makes for unequal distribution across charged membranes, in accordance with the Donnan distribution. Dissociability causes unequal distribution when there is a pH differential between compartments, as discussed under The pH Partition Principle (see next section). Thus, even if a drug is distributed passively, its distribution may be uneven throughout the body. When active transport occurs into, or rapid biotransformation occurs within some compartments, uneven distribution is also inevitable.

## THE pH PARTITION PRINCIPLE

An important consequence of nonionic diffusion is that a difference in pH between two compartments will have an important influence upon the partitioning of a weakly acidic or basic drug between those compartments. The partition is such that the nonionized form of the drug has the same concentration in both compartments, since it is the form that is freely diffusible; the ionized form in each compartment will have the concentration that is determined by the pH in that compartment, the  $pK_a$ , and the concentration of the nonionized form. The governing effect of pH and  $pK_a$  on the partition is known as the pH partition principle.

To illustrate the principle, consider the partition of salicylic acid between the gastric juice and the interior of a gastric mucosal cell (Figure 39-2). Assume the pH of the gastric juice to be 1, which it can occasionally become, and the  $pK_a$  of salicylic acid is 4. With the Henderson–Hasselbalch equation,  $pH = pK_a + \log \frac{[\text{ionized}]}{[\text{nonionized}]}$ . It may be calculated that the drug is only 0.1 percent ionized at pH 1. The intracellular pH of most cells is about 7. Assuming the pH of the mucosal cell to be the same, it may be calculated that salicylic acid will be 99.9 percent ionized within the cells. Since the concentration of the nonionized form is theoretically the same in both gastric juice and mucosal cells, it follows that the total concentration of the drug (ionized + nonionized) within the mucosal cell will be 1000 times greater than that in gastric juice. Such a relatively high intracellular concentration can have important osmotic and toxicological consequences. If stomach antacid or proton pump inhibitor drug, or even ingested food materials raised the stomach content pH to 5, the lumen-to-cell concentration would only be 100 times greater, an order of magnitude difference in the “concentration differential.”

Had the drug been a weak base instead of an acid, the high concentration would have been in the gastric juice. In the small intestine, where the pH can range from 7.5 to 8.1, the partition of a weak acid or base will be the reverse of that in the stomach, but the concentration differential will be lower, because the pH differential from intestinal lumen to mucosal cells, etc., will be lower. The reversal of partition as the drug moves from the stomach to the small intestine accounts for the phenomenon that some drugs can be absorbed from one GI segment and returned to another. The weak base atropine is absorbed from the small intestine, but because of pH partition, it is secreted into the gastric juice.

The pH partition of drugs has never been demonstrated to be as marked as that illustrated in Figure 39-2 and in the text. Not only do many drug ions probably pass through the pores of the membrane to a significant extent, but some may also pass through the lipid phase. Furthermore, formation of ion pairs in carrier transport also bypasses nonionic diffusion. All processes that tend toward an equal distribution of drugs across membranes and among compartments will cause further deviations from theoretical predictions of pH partition.

## ELECTROCHEMICAL AND DONNAN DISTRIBUTION

A drug ion may be distributed passively across a membrane in accordance with the membrane potential, the charge on the

**Figure 39-2.** A scheme illustrating and calculating (using the Henderson–Hasselbalch equation) the extent of ion trapping between two body compartments, and for the compartments shown, how it facilitates the absorption of weak acids in the stomach. HA, weak acid; A<sup>-</sup>, ionic form of weak acid.

drug ion, and the Donnan effect. The relationship of the membrane potential to the passive distribution of ions is expressed quantitatively by the Nernst equation and has already been discussed. Barring active transport, pH partition, and binding, the drug will be said to be distributed according to the electrical gradient or to its equilibrium potential. If the membrane potential is 90 mV, the concentration of a univalent cation will be 30 times as high within the cell as without; if the drug cation is divalent, the ratio will be 890. The distribution of anions would be just the reverse. If the membrane potential is but 9 mV, the ratio for a univalent cation will be only 1.4 and for a divalent cation only 2.0. It thus can be seen how important membrane potential may be to the distribution of ionized drugs.

Large potentials derive from active transport of ions but small potentials may result from Donnan distribution. According to the Donnan membrane theory, the ratio of intracellular to extracellular concentration of a permeant univalent anion is equal to the ratio of extracellular to intracellular concentration of a permeant univalent cation. A more general mathematical expression that includes ions of any valence is

$$\left(\frac{A_i}{A_e}\right)^{1/Z_a} = \left(\frac{C_e}{C_i}\right)^{1/Z_c} = r$$

where  $A_i$  is the intracellular and  $A_e$  the extracellular concentration of anion,  $Z_c$  is the valence of cation,  $Z_a$  is the valence of anion,  $C_i$  is the intracellular and  $C_e$  the extracellular concentration of cation, and  $r$  is the Donnan factor. The value of  $r$  depends upon the average molecular weight and valence of the macromolecules (mostly protein) within the cell, and the intracellular and extracellular volumes. Since the macromolecules within the cell are charged negatively, the cation concentration will be higher within the cell; that is,  $C_i > C_e$ . Since a Donnan distribution results in a membrane potential, the distribution of drug ion also will be in keeping with the membrane potential.

The Donnan distribution also applies to the distribution of a charged drug between the plasma and interstitial compartment, because of the presence of anionic proteins in the plasma. The same equation applies, but requires changing the subscript  $i$  to  $p$  (for plasma), and  $e$  to  $i$ , (for interstitial). The Donnan factor,  $r$ , for plasma-to-interstitial space partition is about 1.05:1.

## BINDING AND STORAGE

Drugs are frequently bound to plasma proteins (especially albumin), interstitial substances, intracellular constituents, and bone and cartilage. If binding is extensive and firm, it will have a considerable impact upon the distribution, excretion, and sojourn of the drug in the body. Obviously, a drug that is bound to a protein or any other macromolecule will not pass through the membrane in the bound form; only the unbound form can negotiate among the various compartments.

The partition among compartments is determined by the binding capacity and binding constant in each compartment. As long as the binding capacity exceeds the quantity of drug in the compartment, the following equation generally applies:

$$\log D_b = \log K + a \log D_f$$

where  $D_b$  is the concentration of bound drug,  $D_f$  is the concentration of free drug, and  $a$  and  $K$  are constants characteristic of the drug and binding macromolecule. The equation is that of a Freundlich isotherm. As the binding capacity is approached, the relationship no longer holds. For a non-dissociable drug at equilibrium,  $D_f$  will be the same in all communicating compartments, so that it would be possible to calculate the partition if  $K$  and  $a$  are known for each compartment. Except for plasma, the values of  $K$  and  $a$  are generally unknown, but the percentage bound is often known.

From the percentage bound, the partition also can be calculated. A drug 50 percent bound in one compartment [free (1) = bound (1); total = 2] and 90 percent bound in a second compartment [free (1), bound (9); total = 10] partitions 2:10, since only free (unbound) drug can pass through the membrane. However, the logarithmic relationships shown serve as a reminder that the percentage bound changes with the concentration, so that the partition will vary with the dose. If the drug is a weak acid or base, the nonionized free form negotiates among the compartments, but the ionized form is often the more firmly bound, and calculations must take into account the dissociation constant and the different  $K$  and  $a$  values of the ionized and nonionized forms.

It is commonly misbelieved that binding in the plasma interferes with the activity of a drug, and that the intracellular binding in a responsive cell increases activity or toxicity. Both binding in plasma and in the tissues decreases the concentration of free drug, but this is easily remedied by adjusting the dose to give a sufficient concentration for pharmacological activity. The distribution and activity of the free form are not affected by binding. The principal effect of binding is to increase the initial dose requirement for the drug and create a reservoir of drug from which the drug can be withdrawn as the free form is excreted or metabolized. However, if the binding is extremely firm and release is slow, the rate of release may not be sufficient to sustain the free form at a level sufficient for pharmacological activity; in such instances the bound drug cannot be considered a reserve.

The effect of binding upon the sojourn of a drug may be considerable. For example, quinacrine, which may be concentrated in the liver to as much as several thousand times the concentration in plasma, may remain in the body for months. Some iodine-containing, radiopaque diagnostic agents are bound strongly to plasma protein and may remain in the plasma for as long as 2 years. In pathological conditions such as nephrosis, diabetes, or cirrhosis, in which plasma protein levels may be decreased, the plasma protein binding, loading dose, and duration of action all may be decreased.

If a drug is bound to a functional macromolecule, binding may relate to pharmacological activity and toxicity, providing that the binding is at a critical center of the macromolecule. The binding by nucleic acids of certain antimalarials, such as quinacrine, undoubtedly contributes to the parasitocidal actions as well as to toxicity.

Most drugs are bound to proteins by relatively weak forces, such as van der Waals forces (from London, Keesom, and/or Debye forces), or hydrogen or ionic bonds. Consequently, binding constants generally are small, and binding is usually readily reversible. The larger the molecule, the greater is the van der Waals bonding, so that large drug molecules are more likely to be bound strongly than are small ones.

Just as shape and the nature of functional groups are important to drug-receptor combination, so they also are to binding. Drugs of similar shape and/or chemical affinities may bind at the same sites on a binding protein and hence compete with one another. For example, phenylbutazone displaces warfarin from human plasma albumin, which may cause an increase in the anticoagulant effect of warfarin. Some drugs may also displace protein-bound endogenous constituents. For example, sulfisoxazole displaces bilirubin from plasma proteins; in infants with kernicterus the freed bilirubin floods the central nervous system and causes sometimes fatal toxicity.

Depending on the lipid-to-water partition coefficient, a drug may be taken up into fatty tissue. The ratio of concentration in fat to that in the plasma will not be the same as dictated by the partition coefficient, because of the content of water and nonlipids in adipose tissue, and because electrolytes and other solutes alter the dielectric constant and hence solubilities from those of pure water. Lipoproteins and even non-polar substituents on plasma proteins also take up lipid-soluble molecules, so that solubility in plasma can be considerably higher than that

in water. The relatively high solubility of ether in plasma makes plasma a pool for diethyl ether, the filling of which delays the onset of anesthesia. However, ether and other volatile anesthetics are taken up gradually into the adipose tissue, which acts as a store of the anesthetic. The longer the anesthetic is administered, the greater the store, and the longer it takes for anesthesia to terminate when inhalation has been discontinued.

Another notable substance that is taken up readily into fat is thiopental. Even though there is a high solubility of this barbiturate in fat, the low rate of blood flow in fat limits the rate of uptake. Because the blood flow in the brain is very high, thiopental rapidly enters brain tissue. However, it soon equilibrates with the other tissues, and the brain concentration falls as that in the other tissues (e.g., muscle or liver) increases. As the brain concentration falls, anesthesia ceases. Gradually, the fat accumulates the drug at the expense of other compartments.

### NONEQUILIBRIUM AND REDISTRIBUTION

Thus far, the distribution of drugs has been discussed mainly as though equilibrium or steady-state conditions exist after a drug is absorbed and distributed. However, since most drugs are administered at intervals and the body content of drug rises and falls with absorption and biotransformation–excretion, neither a true equilibrium among the body compartments nor a steady state exists.

The term equilibrium is used misleadingly to describe the conditions that exist when the plasma concentration and the concentration in a tissue are equal. But equilibrium between plasma and fat occurs much later than equilibrium between plasma and muscle, so that no true equilibrium really exists among all the compartments. Furthermore, a crossover point (equal concentration) for plasma and a tissue is not necessarily an equilibrium point, because the rates of ingress and egress from the tissue are not necessarily equal when the internal and external concentrations are equal. Recall that there are numerous factors that make for unequal distribution (pH partition, Donnan effect, electrochemical distribution, active transport, binding, etc.).

For instance, the distribution of thiopental discussed earlier continually changes during a period (e.g., 3 hours) of observation. At the end of such a period, the content in fat is still increasing, while that in each of the other compartments is decreasing. This time-dependent shift in partition is called redistribution. Eventually the content in fat will reach a peak, which would represent as nearly a true equilibrium point as could be achieved in the dynamic situation where biotransformation and a slight amount of excretion of the drug is taking place. Once the concentration in the fat has reached its peak, its content will decline in parallel with that in the other tissues, and the partition among the compartments would remain essentially constant. Redistribution, then, takes place only until the concentration in the slowest-filling compartment reaches its peak, so long as the kinetics of elimination are constant.

An index of distribution known as the volume of distribution (amount of drug in the body divided by plasma concentration) is of considerable usefulness in pharmacokinetics but is of limited value in defining the way in which a drug is partitioned in the body.

The word “space” is often used synonymously with volume of distribution. It is employed especially when the distributed substance has a volume of distribution that is essentially identical to a physical real space or body compartment. *N*-Acetyl-4-aminoantipyrine is distributed evenly throughout the total body water and is not bound to proteins or other tissue constituents. Thus, the acetylaminopyrine space, or volume of distribution, coincides with that of total body water. Inulin, sucrose, sulfate, and a number of other substances essentially are confined to extracellular water, so that an inulin space, for example, measures the extracellular fluid volume. Evans blue is confined to the plasma, so that the Evans blue space is the

plasma volume. Such space measurements with standard space indicators are a necessary part of studies on the distribution of drugs, since it is desirable to compare the volume of distribution of a drug with the physiological spaces.

## BIOTRANSFORMATION

Most drugs are acted upon by enzymes in the body and converted to metabolic derivatives called metabolites. The process of conversion is called biotransformation. Metabolites are usually more polar and less lipid soluble than the parent drug because of the introduction of oxygen into the molecule, hydrolysis to yield more highly polar groups, or conjugation with a highly polar substance. As a consequence, metabolites often show less penetration into tissues and less renal tubular reabsorption than the parent drug, in accordance with the principle of the low penetration of polar and high penetration of lipid-soluble substances. For similar reasons, metabolites, particularly conjugates, are usually less active than the parent drug and often inactive. Even if they are appreciably active, they generally are excreted more rapidly. Therefore, the usual net effect of biotransformation can be said to be one of inactivation or detoxification.

Although there are numerous examples in which biotransformation does result in inactivation, there are also examples in which the parent drug has little or no activity of its own but is converted to a pharmacologically active metabolite: codeine to morphine [by cytochrome P450 2D6 (CYP2D6)] or codeine glucuronide [by UDP-glucuronosyltransferase-2B7 (UGT2B7)] for analgesia; parathion to paraoxon for anticholinesterase activity; chloroguanide to cycloguanil (by CYP2C19) for antimalarial activity; lovastatin to lovastatin  $\beta$ -hydroxyacid for HMG CoA reductase inhibition; irinotecan (CPT-11) to SN38 for topoisomerase I inhibition; and enalapril to enalaprilat for angiotensin-converting enzyme inhibition (the last three by hydrolysis reactions). For cytochrome P450 nomenclature, see next heading, Endoplasmic Reticulum and Microsomal System; for UDP-glucuronosyltransferases nomenclature, see Phase II Conjugation Enzymes in this chapter.

When a delayed or prolonged response to a drug is desired or an unpleasant taste or local reaction is to be avoided, it is a common pharmaceutical practice to prepare an inactive or non-offending precursor, such that the active form can be generated in the body. This practice has been termed drug latency. Chloramphenicol palmitate and the estolates of various steroid hormones are examples of deliberately latencyed drugs. Because inactive metabolites do not always result from biotransformation, the term detoxification should not be used as a synonym for biotransformation.

Biotransformations take place principally in the liver, although the kidney, skeletal muscle, intestine, or even plasma may be important sites of the enzymatic attack on some drugs. Biotransformations in plasma are mostly hydrolytic.

## ENDOPLASMIC RETICULUM AND MICROSOMAL SYSTEM

Many biotransformations in the liver occur in the endoplasmic reticulum. The endoplasmic reticulum is a tubular system that courses through the interior of the cell but also appears to communicate with the interstitial space, and its membrane is continuous with the cell membrane. Some of the reticulum is lined with ribonucleoprotein particles, called ribosomes, that are engaged in protein synthesis; this is the rough endoplasmic reticulum. The smooth endoplasmic reticulum lacks such a granular appearance. The smooth endoplasmic reticulum is the most heavily invested with numerous enzymes that biotransform many drugs and some endogenous substances.

When a broken-cell homogenate of the liver is prepared, the reticulum becomes fragmented, and the fragments form vesicular structures called microsomes which can be isolated

from other subcellular organelles by differential centrifugation. Microsomes are separated from cytosol by 60 minutes' centrifugation of the 10000g supernatant of a liver homogenate at 100000g. Although the microsomes are artifacts, it is often the practice to refer to drug metabolism as occurring in microsomes rather than in the endoplasmic reticulum.

The microsomal system is peculiar in that both oxidations, and some reductions, usually require the reducing cofactor, reduced nicotinamide adenine dinucleotide phosphate (NADPH). This is because most microsomal oxidations proceed by way of the introduction of oxygen rather than by dehydrogenation, and NADPH is essential to reduce one of the atoms of molecular oxygen. For the major source of microsomal oxidations, the drug first binds to an oxidized (ferric) cytochrome P450. The ferric heme of the drug-cytochrome P450 complex is then reduced to ferrous by NADPH-cytochrome P450 reductase; the reduced complex then combines with oxygen. With an additional electron from NADPH-cytochrome P450 reductase, the oxidized metabolite is released, a molecule of water is formed from the second oxygen atom of molecular oxygen, and ferric cytochrome P450 is regenerated. Cytochrome P450 is a generic term for a superfamily of enzymes.

The general designation of the cytochromes P450 is CYP followed by a number (the family) and a letter (the subfamily) subdivisions. The classification is based on amino acid sequence homology. To belong to the same family, the homology must be greater than 40 percent, and to the same subfamily it must be greater than 59 percent. The subfamily individual is indicated by a number that is based upon the chronological discovery order, independent of the animal species in which it was found. Thus, for example, humans do not have six forms of CYP2D6; CYP2D1 through CYP2D5 are found in other animal species. The major forms involved in drug metabolism in the human liver are CYP1A1 and CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, CYP3A5, and CYP3A7. In concentration, CYP3A forms compose 40 percent of the liver P450, CYP2C forms compose 25 percent, and CYP1A2 about 15 percent. CYP3A forms are involved in the metabolism of about 40 percent of the commonly used drug that undergo oxidative metabolism. In contrast to the balance in "abundance" and "demand" of the CYP3A forms, CYP2D6

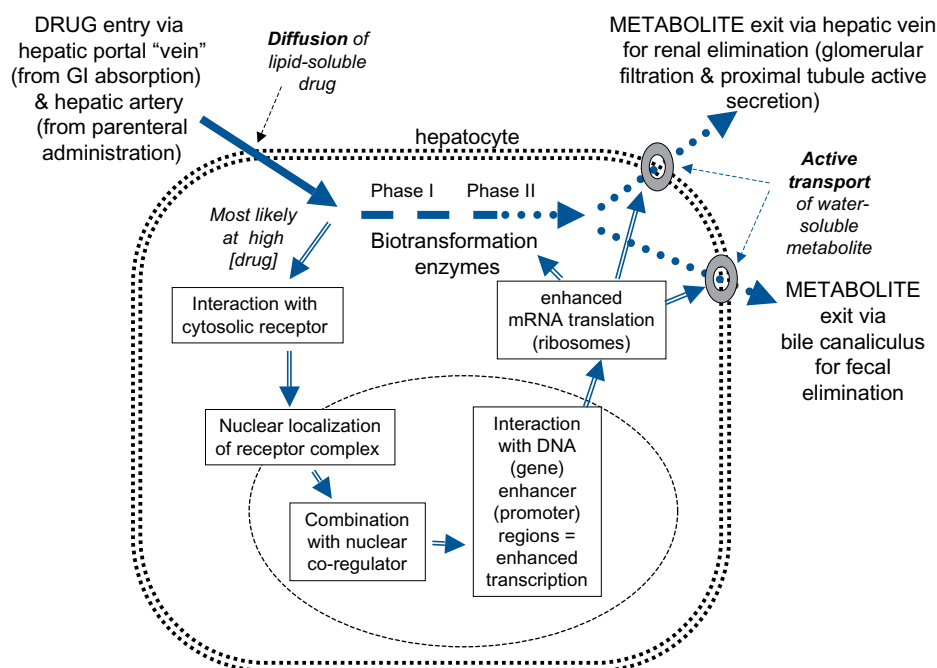

represents less than 5 percent of the liver P450 but metabolizes about one-fourth of currently used drugs. Further complicating abundance and demand considerations are the presence of genetic polymorphisms. Polymorphisms are indicated by an asterisk (\*) followed by a number greater than 1 (1 is wild type; e.g., CYP2D6\*4 is the most common activity-decreasing CYP2D6 polymorphism in Caucasians, resulting in 5–10 percent of the population being "poor metabolizers"). The different isozymes present in humans, together with which drugs they metabolize, are of increasing importance in understanding drug interactions and toxicities, and individual responses to standardized doses.

In addition to cytochrome P450, the endoplasmic reticulum contains non-heme-containing flavoprotein monooxygenases (abbreviated FMO), which are also responsible for the oxidative metabolism of drugs. The mechanism of oxidation differs from that of cytochrome P450, involving a hydroperoxyflavin-oxidizing species, and their substrate selectivity (drugs containing a nucleophilic heteroatom) is much less. Of five of these enzymes present in the human genome, FMO3 is the major human liver form.

### DRUG-METABOLIZING ENZYME INDUCTION

Some of the enzymes of the microsomal system are quite easily induced; that is, a drug may increase considerably the activity of the enzyme by increasing the biosynthesis of the enzyme. An increase in the amount of endoplasmic reticulum sometimes occurs concomitantly with enzyme induction. Although most extensively studied by monitoring cytochrome P450 changes, induction is not confined to cytochrome P450s, nor is it confined to enzymes in the endoplasmic reticulum.

At least four major mechanisms of induction have been elucidated for cytochrome P450s in the liver, and additional mechanism(s) are present for some other enzymes. For the cytochrome P450s, the same general scheme applies to all (Figure 39-3). The cytosol contains proteins that have a high affinity for certain inducing agents. When the inducing agent binds to its receptor, there is a conformational change and/or displacement of chaperone proteins that allows the receptor-inducer complex to translocate into the nucleus. Within the nucleus the complex links with an additional nuclear factor, and the ensemble interacts with a regulatory element on the

**Figure 39-3.** The general pathway resulting in hepatic drug-metabolizing enzyme and membrane transporter induction to counteract possible accumulation of drugs and drug metabolites in the hepatocyte.

DNA, causing the assembling of factors and enzymes necessary for RNA transcription at the gene promoter region. The genes of several cytochrome P450s, as well as other enzymes, have identical or closely similar regulatory elements, so the binding of multiple ensembles results in the enhanced production of messenger RNAs from a number of genes and, after translation on the ribosomes attached to the endoplasmic reticulum, an enhanced abundance of drug-metabolizing enzymes. This phenomenon is generally viewed as a self-protective mechanism against the accumulation of excessive amounts of exogenous chemicals (either from high dose or excessively frequent dosing) within the liver. In the event that the liver contains insufficient amounts of enzyme to metabolize exogenous chemicals to promote their excretion, the induction mechanism provides an acute response to remedy the deficiency.

For cytochrome P450s, it has been noted that CYP1A2 is induced preferentially by polycyclic aromatic hydrocarbons and other chemicals contained in cigarette smoke and charcoal-broiled meats, as well as by components in cruciferous vegetables. CYP2A6 is induced by barbiturates, as are CYP2C9 and CYP3A4. CYP2C9, CYP2C19, and CYP3A4 are all induced by rifampicin, but CYP3A4 is additionally induced by many drugs including carbamazepine, phenytoin, glucocorticoids (dexamethasone), clotrimazole, sulfapyrazole, and macrolide antibiotics such as troleandomycin. CYP2E1 can be induced by ethanol and isoniazid. Ironically, given its low percentage abundance in the human liver, there are no known inducers of CYP2D6. The changes elicited by rifampicin and polycyclic aromatic hydrocarbons occur through two different pathways. For rifampicin, the cytosolic receptor is the pregnane X receptor (abbreviated PXR), the associating nuclear factor is the 9-*cis*-retinoic acid-activated receptor (abbreviated RXR), and the regulatory element is termed a pregnane X receptor response element (abbreviated PXRE). For the planar polycyclic aromatic hydrocarbons, the cytosolic receptor is the aryl hydrocarbon receptor (abbreviated AhR), the associating nuclear factor is the aryl hydrocarbon receptor nuclear translocator (abbreviated ARNT), and the regulatory region with its defined base sequence different from that of the PXRE is termed a xenobiotic-response element (abbreviated XRE). Other delineated pathways for cytochrome P450 induction include a pathway responsive to phenobarbital and a pathway responsive to peroxisome proliferators. Enzymes in addition to cytochrome P450s are induced by all these mechanisms, commonly uridine diphospho-glucuronosyltransferases and glutathione *S*-transferases (GSTs). A further and different type of mechanism for induction of non-P450 enzymes exists, a pathway that is responsive to certain chemicals that alter the redox state of the liver cell. Activation of this pathway results in the release of nuclear factor erythroid 2-related factor 2 protein (abbreviated Nrf2) from its Kelch-like ECH-associated protein 1 (abbreviated KEAP1) extranuclear anchor and its interaction with the antioxidant response element (abbreviated ARE) of certain genes, most notably GSTs, epoxide hydrolase, and NADH quinone oxidoreductase.

Regulation of enzyme synthesis can vary with species. Induction via the PXR receptor differs markedly between rodents and human, with rodent PXR almost unresponsive to rifampicin, the prototype PXR agonist in humans.

Treatment of an experimental subject with an inducing agent will often increase the rate of metabolism of the inducing agent. Whether this will necessitate larger and more frequent dosing, or smaller dosing and/or decreased frequency, will depend on whether the metabolism results in pharmacological inactivation (requiring the former) or whether the agent is a prodrug activated by metabolism (requiring the latter).

Induction may also create other therapeutic problems. Given the promiscuity of most drug-metabolizing enzymes, the metabolism of many other drugs may also be affected, producing what are now referred to as drug-drug interactions. For example, the use of phenobarbital or rifampicin during treatment with warfarin increases the dose requirement for warfarin. If the

physician is unaware of this interaction and fails to increase the dose, the patient may suffer a thrombotic episode. If the dose of warfarin has been increased and the phenobarbital or rifampicin is then discontinued, the rate of metabolism of warfarin may drop to its previous level, so that the patient is overdosed, with hemorrhagic consequences. Knowing which enzymes are induced by which drugs, and which drugs are metabolized by a given enzyme or enzymes is now a key component of therapy involving multiple drugs and in medicating patients with multiple conditions, each possibly requiring treatment with a different class of pharmacological agent. The required knowledge base has also been expanded to include nutritional supplements and other plant products that are now known to contain inducing chemicals, in some cases quite potent. Adverse drug-drug interactions have been documented in consumers of St John's wort, which contains the potent PXR agonist, hyperforin.

## DRUG-METABOLIZING ENZYME INHIBITION

Some drugs inhibit rather than induce the microsomal enzymes. Whether this results in a need to increase or decrease the doses for adequate therapeutic effect also depends on whether the metabolism inhibited results in drug inactivation or prodrug activation. With multiple drug therapy, as with enzyme induction, enzyme inhibition can result in the altered metabolism of drugs other than that designated as the inhibitor. Where two drugs are in competition for metabolism at the same enzyme, the mechanism of inhibition appears as competitive. In this scenario, the enzyme is not "inhibited" per se; it may be performing metabolism at a similar rate as if only a single drug were present, but now the metabolism is split between two compounds. Thus, to the external observer, the metabolism of each appears to be less (i.e., inhibited). Given the promiscuity of drug-metabolizing enzymes, this is a relatively common occurrence; however, whether the effect is of clinical significance will depend on the steepness of the dose-response curve, the relative concentration of the two or more drugs, and the relative inhibitory affinity of the drugs. With *in vitro* kinetic analysis, competitive inhibition will show as an increase in the Michaelis constant,  $K_m$  ( $1/\text{affinity}$ ; concentration of drug necessary to elicit half the maximum velocity), with no change in  $V_{\max}$ . For some drug-enzyme combinations, a drug may not be metabolized by the enzyme it inhibits, but it nevertheless binds and blocks the metabolism of others. An example is quinidine, which potently binds to and inhibits CYP2D6 but is metabolized by CYP3A4. At the extreme, this high-affinity inhibition will manifest itself as non-competitive inhibition, because the inhibitory drug binds with such avidity that other drugs are unable to outcompete or displace it. Non-competitive inhibition is a phenomenon often seen with cytochrome P450, because several chemical entities present in drug molecules have a relatively high affinity for the heme of this enzyme. Perhaps the most notable group of agents in this regard are the antifungal *N*-substituted imidazoles and triazoles. With *in vitro* kinetic analysis, non-competitive inhibition will show as a decrease in  $V_{\max}$ , but no change in  $K_m$ . Practically, few inhibitory interactions manifest as purely competitive or purely non-competitive. For some interactions, and especially with cytochrome P450s, this lack of purity has a defined mechanistic basis—mechanism-based (suicide) inhibition. During the metabolism of a drug, an intermediate or product is formed that fails to leave the enzyme, often because of an extremely strong affinity for the enzyme (quasi-irreversible), or because of the formation of a covalent bond with protein (irreversible), or for cytochrome P450, the heme moiety. The list of compounds exhibiting suicide inhibition continues to expand. Erythromycin and some related antibiotics were among the earliest drugs identified that demonstrated quasi-irreversible inhibition of cytochrome P450.

Occasionally, an inhibition of the metabolism of drug can arise from depletion of reaction cofactors, or for phase II conjugations (see below Types of Biotransformations), cosubstrates. Sulfate conjugation is particularly prone to this effect,

as cellular content of 3'-phosphoadenosine-5'-phosphosulfate (PAPS) can be limiting, or depleted by high concentrations of drugs undergoing sulfate conjugation. Depletion of hepatocyte glutathione concentration, an effect often seen as a result of exposure to hepatotoxins, affects the ability of the liver to undertake glutathione conjugation, and since this is often the method of sequestration of harmful electrophiles, further exacerbates liver damage. Glucuronidation, on the other hand, rarely suffers from this effect because uridine diphosphoglucuronic acid (UDPGA) is readily generated from plentiful liver glycogen stores.

The activity of the microsomal biotransformation enzymes is affected by many factors other than the presence of drugs. Age, sex, nutritional status, pathological conditions, and genetic factors are among the influences that have been identified. Age in particular has received considerable attention. Neonates and infants have a less well-developed microsomal biotransformation system as compared to adults.

## TYPES OF BIOTRANSFORMATIONS

Biotransformations can be degradative, wherein the drug molecule is diminished to a smaller structure, or synthetic, wherein one or more atoms or groups may be added to the molecule. However, it is more useful to categorize biotransformations with respect to metabolic (non-conjugative) biotransformations and conjugative biotransformations. The former is called phase I and the latter phase II. The general map of major pathways of metabolism (by chemical grouping) is shown in Figure 39-4. In phase I, pharmacodynamic activity may be lost; however, active and chemically reactive intermediates may also be generated. The polarity of the molecule may or may not be increased sufficiently to increase excretion markedly. In phase II, metabolites from phase I may be conjugated, and sometimes the original drug may be conjugated, thus bypassing phase I. Phase II frequently generates metabolites of high polarity, which are excreted readily. Rarely do drugs undergo a single phase I and phase II reaction. This has been interpreted to indicate the defensive objective of drug metabolism; however, the body's ability to modify a foreign compound to enhance its elimination will probably be employed. Thus, phase I reactions may occur at more than one site on the drug molecule (not necessarily to

the same extent), and more than one conjugation may occur for the reactive center introduced by phase I metabolism or already present in the parent drug. The former is illustrated with the drug tamoxifen, which undergoes *N*-demethylation at one end of the molecule, and aromatic hydroxylation at the other. This latter is evident for the drug acetaminophen, where the aromatic hydroxyl group can undergo either glucuronidation or sulfation, and both conjugates are found in the urine.

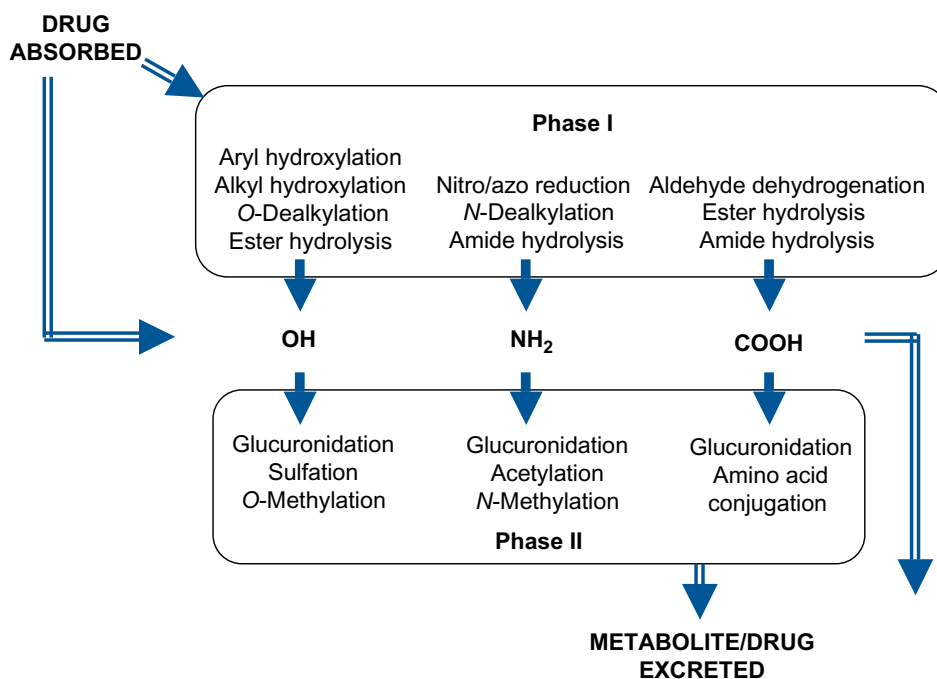

Phase I biotransformations are for convenience often considered in terms of the chemical reaction: oxidation, reduction, and hydrolysis. Phase II biotransformations are usually considered in terms of the endogenous biochemical entity added.

The activity and selectivity of the enzymes of biotransformation vary greatly from species to species, so that care must be exercised in extrapolating experimental findings in laboratory animals to humans.

## Phase I Oxidation

Oxidation is a very common type of biotransformation. Oxidations that occur primarily in the liver microsomal system include side-chain (alkyl) hydroxylation; aromatic hydroxylation; deamination (which is oxidative and results in the intermediate formation of RCHO); *N*-, *O*-, and *S*-dealkylation (which involve hydroxylation of the alkyl group followed by oxidation to the aldehyde); and sulfoxide formation. As indicated earlier, these microsomal oxidations are catalyzed by two types of enzymes, most frequently by the hemoprotein cytochrome P450, but also by flavin monooxygenases. The reactions as listed do not divide themselves among various members of the cytochrome P450 superfamily; thus, depending on the drug molecule, a given enzyme (e.g., CYP3A4) might catalyze aromatic hydroxylation of one molecule, *N*-demethylation of another, and *O*-demethylation of a third. It might also catalyze these reactions at different sites on a single drug molecule. A single drug molecule may also be metabolized differently by two different enzymes; the *N*-demethylation of tamoxifen mentioned above is largely catalyzed by CYP3A4; the aromatic hydroxylation of tamoxifen is largely catalyzed by CYP2D6.

The major oxidations that occur elsewhere, other than the microsomes, are generally dehydrogenations with NAD<sup>+</sup> as the

**Figure 39-4.** The major reactions associated with the formation and conjugation of the major chemical entities during the hepatic metabolism of drugs, and their place within the general disposition of drugs and other xenobiotics.

acceptor. Examples are the oxidation of alcohols by alcohol dehydrogenase, the oxidation of aldehydes by aldehyde dehydrogenase, and the deamination of monoamines by monoamine oxidase and diamines by diamine oxidase. There are numerous alcohol and aldehyde dehydrogenase enzymes, each with some degree of selectivity.

### Phase I Reduction

Reduction is a relatively uncommon reaction that occurs mainly in liver microsomes (if at all). However, it occasionally takes place in other tissues. Examples are the reduction of nitro and nitroso groups (as in chloramphenicol, nitroglycerin, and organic nitrites), of the azo group (as in Prontosil, the first commercially available antibiotic), and of certain aldehydes to the corresponding alcohols.

### Phase I Hydrolysis

Hydrolysis is a common biotransformation among esters and amides. Esterases are located in many structures besides the microsomes. For example, cholinesterases are found in plasma, erythrocytes, liver, nerve terminals, junctional interstices, and postjunctional structures, and procaine esterases are found in plasma. Many esterases will hydrolyze both esters and amides, albeit the metabolism of amides is generally slower than that of esters. Various phosphatases and sulfatases are also distributed widely in tissues and plasma, although few drugs are appropriate substrates. The hydrolytic deamidation of meperidine occurs primarily in the hepatic microsomes.

The hydration of epoxides, often generated by cytochrome P450 oxidations to form dihydrodiols, is an important detoxification reaction. For the metabolism of xenobiotic epoxides, two epoxide hydrolases exist, one in the endoplasmic reticulum (microsomal EH) and another in the cytoplasm (soluble EH).

Other biotransformations include desulfuration, in which oxygen may replace sulfur, and dehalogenation. Desulfuration takes place in the liver. Thiopental is converted in part to pentobarbital by desulfuration, and parathion is transformed to paraoxon. Dehalogenation of certain insecticides and various halogenated hydrocarbons may take place, principally in the liver but not in the microsomes.

### Phase II Conjugation Chemistry

In considering the outcome of the bulk of phase I reactions, the formation of three chemical entities (reactive centers), hydroxyl ( $-OH$ ), amine ( $-NH_2$ ), and carboxyl ( $-COOH$ ) compose the majority (Figure 39-4.). Aromatic and alkyl oxidation, and *O*-dealkylation and ester hydrolysis, produce metabolites with a hydroxyl group; *N*-demethylation, nitro and azo reduction, and amide hydrolysis produce metabolites with an amine group; aldehyde dehydrogenation, and ester and amide hydrolysis produce metabolites with a carboxyl group. Major conjugations therefore center on the additional metabolism of these functional groups. Conjugation is the biosynthetic process of combining a drug or drug metabolite with a highly polar and water-soluble endogenous biochemical to yield, with a couple of exceptions, an even more water-soluble and easily excreted, usually pharmacologically inactive, product. In almost all conjugations, the endogenous biochemical cosubstrate involved in the reaction is required to be in a "high-energy" form. The exception is conjugation with glutathione ( $\gamma$ -glutamylcysteinyl glycine), where the center of reactivity, the nucleophilic sulfhydryl of cysteine, is sufficiently reactive toward electrophiles that the conjugation can occur directly, and in some cases in the absence of an enzyme. Also unusual with glutathione conjugation is a further metabolism of the conjugate. Through a series of enzymatic reactions, the  $\gamma$ -glutamyl and glycyl residues are removed, the remaining cysteine conjugate is *N*-acetylated, and the product spontaneously dehydrates to form a mercapturic acid, the excreted product.

Glucuronic acid is the most frequent partner added to the drug in conjugation. Actually, the drug reacts with UDPGA rather than with simple glucuronic acid. UDPGA is formed from the  $NAD^+$ -supported oxidation of UDP-glucose, which in turn is formed from glucose-1-phosphate (readily available from the catabolism of liver glycogen stores) and UTP. The drug or drug metabolite combines at the number 1 carbon (aldehyde "end") and not at the carboxyl group of glucuronic acid. The hydroxyl group of an alcohol or a phenol attacks the number 1 carbon of the pyran ring to replace uridine diphosphate. The product is a hemiacetal-like derivative. Since the product is not an ester, the term glucuronide is appropriate. Rarely, thiols and amines may also form analogous glucuronides. Carboxyl compounds form esters, appropriately called glucuronates, in replacing the uridine diphosphate. Some acyl glucuronates are subject to intramolecular acyl migration, and some of these products are noted for their toxicity. The greater instability of acyl glucuronates as compared to ether glucuronides in alkaline conditions requires some care in their detection and quantification from biological matrices.

The alternative conjugation of carboxylic acids with an amino acid, usually glycine but also glutamine, is an amidation conjugative process. An example is benzoic acid, which is conjugated with glycine to form hippuric acid. In amino acid conjugation, the drug or drug metabolite is first adenylated (by reaction with ATP) and then converted to its coenzyme A derivative before conjugation with the amino acid.

Sulfuric acid is also a frequent conjugant, especially with phenols and to a lesser extent with simple alcohols. The cosubstrate for this reaction is PAPS. The sulfated product is called an ethereal sulfate. Occasionally sulfuric acid conjugates with aromatic amines to form sulfamates. Phosphoric acid also conjugates with phenols and aromatic amines.

Aromatic amines and occasionally aliphatic amines or heterocyclic nitrogens frequently are acetylated. Acetyl coenzyme A is the biological reagent rather than acetic acid itself. Unlike most other conjugates, the acetylate (amide) is usually less water soluble than the parent compound. The acetylation of the *p*-amino group of the sulfonamides is a prime example of this type of conjugation. Many amines, especially derivatives of  $\beta$ -phenylethylamine and heterocyclic compounds, are methylated in the body. The products are usually biologically active, sometimes more so than the parent compound. *N*-Methylation may occur in the cytoplasm of the liver and elsewhere, especially in chromaffin tissue in the case of phenylethylamines. Phenolic compounds may be *O*-Methylated. *O*-Methylation is the principal route of biotransformation of catecholamines such as epinephrine and norepinephrine, the methyl group being introduced on the *meta*-hydroxy substituent. Both *N*- and *O*-methylation require *S*-adenosylmethionine as the cosubstrate.

### Phase II Conjugation Enzymes

Although many conjugations occur in the liver, some occur in the kidney or in other tissues. All the drug conjugation reactions are catalyzed by specialized enzymes, termed transferases, and all are present in multiple forms. Glucuronidation is catalyzed by UDP-glucuronosyltransferases (UGTs), located in the endoplasmic reticulum. UGTs are classified in two major classes (UGT1As and UGT2Bs) based on amino acid homology, but the two classes also differ in gene structure and substrate selectivity. UGT1As preferentially react with planar drugs, and UGT2Bs preferentially react with three-dimensionally bulkier molecules. Whereas the various UGT2Bs exist as separated six-exon genes in the genome, the UGT1As exist as a nested complex and the individual enzymes are formed from transcription and translation of a combination of one of several first exons to a common set of four exons. In both UGT1As and UGT2Bs, the amino-terminal region of the enzyme is responsible for drug (the aglycone) recognition, while the carboxy-terminal end is involved in binding UDPGA and as such appears to reside on

the cytoplasmic side of the endoplasmic reticulum. As with cytochrome P450s, these enzymes are inducible, and the two classes differ in their response to various drugs and other chemicals.

Sulfation is catalyzed by sulfotransferases (SULTs), located in the cytoplasm. The many isozymes exhibit substrate selectivity, and some differ in thermal stability. Unlike most major drug-metabolizing enzymes, SULTs do not appear to respond to drug-mediated induction.

Glutathione conjugations are catalyzed by GSTs, also located in the cytoplasm. The multiple isozymes involved in xenobiotic or drug metabolite metabolism exist in four major classes: alpha, mu, pi, and theta. The isozymes have relatively low substrate (electrophile) selectivity.

Acetylation is catalyzed by cytoplasmic *N*-acetyltransferases, NAT1, and in the liver, NAT2. NAT2 exhibits a genetic polymorphism, resulting in “fast” and “slow” acetylator phenotypes with differing incidences in various populations (slow acetylators are more common in Middle Eastern, less common in Asian populations). The acetylation reaction proceeds through an acetylated enzyme intermediate. Methylation reactions are catalyzed by cytoplasmic *O*-, *N*-, and *S*-methyltransferases, and each of these exists in multiple forms.

## EXCRETION

Although some drugs are not biotransformed in the body, most that are readily absorbed require modification for efficient elimination. Although the kidney is the most important organ of excretion, some substances are excreted in bile, sweat, saliva, or gastric juice, or from the lungs. Urine analysis will often reveal the presence of unchanged drug in addition to metabolites, but for the majority of drugs they constitute only a minor fraction.

## RENAL EXCRETION

The excretory unit of the kidney is called the nephron. There are several million nephrons in the human kidney. The nephron is essentially a filter funnel called Bowman's capsule, with a long stem called a renal tubule. The final collecting duct is also functionally a part of the nephron. The blood vessels that invest the capsule and the tubule are also an essential part of the nephron.

Bowman's capsule is packed with a tuft of branching interconnected capillaries that provide a large surface area of capillary endothelium through which fluid and small molecules can filter into the capsule and begin passage down the tubule. The capillary network, together with Bowman's capsule, constitutes the glomerulus. The glomerular capillary endothelium and the supporting layer of Bowman's capsule have channels ranging upward to 40 Å in diameter. Consequently, all unbound solutes in plasma pass or are forced by pressure into the glomerular filtrate.

The postglomerular blood vessels, which lie close to the tubules, are critically important to renal function in that substances resorbed from the filtrate by the tubule are returned to the blood along these vessels. The tubule first makes a number of convolutions (called a proximal convoluted tubule), then courses down and back up a long loop (called the loop of Henle), makes more convolutions (the distal convoluted tubule), and finally joins the collecting duct. The loop of Henle is divided into a proximal (descending) tubule, a thin segment, and a distal (ascending) tubule.

As the glomerular filtrate passes through the proximal tubule, some solute may be resorbed (tubular resorption) through the tubular epithelium and returned to the blood. Resorption occurs in part by passive diffusion and in part by active transport, especially with sodium and glucose. Chloride follows sodium obligatorily.

In the proximal region the tubule is quite permeable to water, so that resorbed solutes are accompanied by enough water to keep the resorbate isotonic. Consequently, although the filtrate

becomes diminished in volume by approximately 80 percent in the proximal tubule, it is not concentrated.

Some acidification occurs in the proximal tubule as the result of carbonic anhydrase activity in the tubule cells and the diffusion of hydronium ions into the lumen. In the lumen the hydronium ion reacts with bicarbonate ion, which is converted to resorbable nonionic CO<sub>2</sub>.

There is also active transport of organic cations and anions into the lumen (tubular secretion), each by a separate system. These active-transport systems are extremely important in the excretion of a number of drugs; for example, penicillin G is secreted rapidly by the anion transport system, and tetraethylammonium ion by the cation transport system. Probenecid is an inhibitor of anion secretion and, hence, decreases the rate of loss of penicillin from the body.

Tubular secretion can be considered to occur in two phases: movement from the blood into the tubule cell and from the cell into the urine. There are active-transport systems at both tubule cell surfaces. Transporters moving compounds into the cell are predominantly members of the solute carrier protein family. Different transporters have differing substrate preferences, but for drug elimination they can be broadly divided into organic-anion transporters and organic-cation transporters. It should be noted that glucuronic acid and sulfate conjugates are organic anions existing almost entirely in the ionized form at physiological pH values, so in addition to increasing water solubility, metabolism has made the drug more suitable for transporter elimination. The affinity of the transporters for their substrates is generally higher than the affinity of the drug or metabolite for albumin, so in contrast to glomerular filtration in the Bowman's capsule, in the proximal tubule, drugs and metabolites can be stripped from albumin for elimination. On the lumen (urine) cell surface, these transporters are augmented by transporters of the ATP-binding cassette (ABC) family. Structurally, these are similar to the solute carrier proteins in having many (around 12) transmembrane-spanning regions that within the membrane can form a cylindrical pore through which the transported molecule travels across the lipid bilayer membrane. As the name implies, however, among the cytoplasmic loops linking the transmembrane-spanning regions of ABC transporters are adenosine triphosphatase sites (two), and these transporters use the energy released in ATP hydrolysis to provide conformational changes that can, if necessary, drive the movement of a molecule *up* a chemical concentration gradient (i.e., from a low to a high concentration). The two major classes of ABC transporters for drugs and drug metabolites are multidrug resistance proteins (MDRs; MDR1 is also known as P-glycoprotein and abbreviated Pgp), the products of *ABCB* genes; and multidrug resistance related protein (MRP), the product of *ABCC* genes. The MRPs, particularly MRP2 (also known as the canalicular multispecific organic-anion transporter, abbreviated cMOAT), with their preference for anions, are those involved in the forced elimination of glucuronic acid and sulfate conjugates.

As the filtrate travels through the thin segment it becomes concentrated (especially at the bottom), as a result of active resorption and a countercurrent-distribution effect enabled by the recurrent and parallel arrangement of the ascending segment, the parallel orientation of the collecting duct, and the similar recurrent geometry of the associated capillaries. In the thick segment of the ascending loop of Henle, both sodium and chloride are transported actively. In the distal tubule, sodium resorption occurs in exchange for partly potassium (potassium secretion) and partly for hydronium ions. Adrenal mineralocorticoids promote distal tubular sodium resorption, and potassium and hydronium secretion. Ammonia secretion also occurs, so that the urine either may be acidified or alkalinized, according to acid-base and electrolyte requirements. Water is resorbed selectively from the distal end of the distal convoluted tubule and the collecting ducts; water resorption is under the control of the antidiuretic hormone. The collecting duct also

resorbs sodium, secretes potassium, and acidifies and concentrates the urine.

Drugs may also be resorbed in the distal tubule; the pH of the urine there is extremely important in determining the rate of resorption, in accordance with the principle of nonionic diffusion and pH partition. Amines will tend toward a greater degree of ionization the more acid the urine, so less of the amine present will be in the nonionized form and be able to diffuse back through the lipid bilayer from the urine to blood (i.e., trapped in urine and thereby destined for elimination). The effect of urinary pH on the excretion of a weak acid is the opposite: the more acid the urine, the more will be in the nonionized form and be able to diffuse back into the blood.

The urinary pH and, hence, drug excretion may fluctuate widely according to the diet, exercise, drugs, time of day, and other factors. Obviously, the excretion of weak acids and bases can be controlled partly with acidifying or alkalinizing salts, such as ammonium chloride or sodium bicarbonate, respectively. Comparative studies on potency and efficacy in humans have demonstrated the importance of controlling urinary pH. Urinary pH is important only when the drug in question is a weak acid or base of which a significant fraction is excreted. The plasma levels will change inversely to the excretory rate. For example, it has been shown clinically with quinidine that alkalinization of the urine not only decreases the urine concentration but also increases the plasma concentration and toxicity.

#### **BILIARY EXCRETION AND FECAL ELIMINATION**

Many drugs are secreted into the bile and then pass into the intestine. For metabolites generated within the liver cell, secretion

into bile canaliculus is an alternative to secreting them into the bloodstream for subsequent renal elimination. A drug that is passed into the intestine via the bile may be reabsorbed and not lost from the body. A drug conjugate entering the intestine may be deconjugated by enzymes and the parent drug reabsorbed. This cycle of biliary secretion and intestinal resorption is called enterohepatic circulation. The biliary secretory (transporter) systems greatly resemble those of the kidney tubules. The enterohepatic system may provide a considerable reservoir for a drug. If a drug is not absorbed completely from the intestine, the unabsorbed fraction will be eliminated in the feces. An unabsorbable drug that is secreted into the bile will likewise be eliminated in the feces. Such fecal elimination is called fecal excretion. Only rarely are drugs secreted into the intestine through the succus entericus (intestinal secretions), although a number of amines are secreted into gastric juice.

#### **ALVEOLAR EXCRETION**

The large alveolar area and high blood flow make the lungs ideal for the excretion of appropriate substances. Only volatile liquids or gases are eliminated from the lungs. Gaseous and volatile anesthetics essentially are eliminated completely by this route. Only a small amount of ethanol is eliminated by the lungs, but the concentration in the alveolar air is related so constantly to the blood alcohol concentration that the analysis of expired air is acceptable for legal purposes. The high aqueous solubility and relatively low vapor pressure of ethanol at body temperature account for the retention of most of the substance in the blood. Carbon dioxide from those drugs that are partly degraded also is excreted in the lungs.

## PHASE II CLINICAL TRIAL VALIDATION OF DOSE FOR USE IN PHASE II TRIALS

Drug development is a long, expensive process of discovery and preclinical development followed by clinical trials resulting in the submission of a package of data to a regulatory agency that will ultimately lead to licensure of that product for sale.

The goal of drug development is to find a dose of a drug for a specific indication that attains the desired therapeutic outcome while engendering a low probability of the patient experiencing a toxic event. Pharmacokinetics and pharmacodynamics can straightforwardly lead to attaining this goal. Indeed, in the last one to two decades there has been a marked increase in our understanding of the relationship between drug exposure and response. This is related to wider availability of the appropriate mathematical modeling methodologies. The application of these techniques in the timeline of drug development is presented in Figure 40-1.

The clearest example of employing a pharmacokinetic/pharmacodynamic approach to drug development can be seen in the area of anti-infective agents. Part of the reason for this is that these drugs are unique in that we are not attempting to dock a molecule into a receptor in the human body. Rather, the target of drug action and the site to which we are attempting to bind the drug is a receptor in the pathogen of interest. This has several important consequences.

The first is toxicity. Anti-infective targets are chosen specifically so that they have little sequence homology to similar mammalian targets. A straightforward example is the topoisomerase enzymes seen in bacteria but also in man. The fluoroquinolone antimicrobials have a 100- to 1000-fold difference in the concentrations necessary for microbiological effect relative to activity for topoisomerase targets in man.<sup>1</sup> In contrast, there is often a narrow therapeutic index, for example, between normal human cells and cancerous cells, meaning that oncologic chemotherapy is often (but not always) saddled with considerable toxicity.

The other important consequence is the ease with which pharmacodynamic relationships can be developed both preclinically as well as in clinical trials. The reason is that almost always (Hepatitis C is currently an exception to the rule) one can straightforwardly grow the pathogen of interest *in vitro* and determine a measure of drug exposure that will affect the growth of the pathogen in some standardized way. For example, for viruses, we can measure an  $EC_{50}$ , a drug concentration that will cause a 50% downturn in the number of rounds of replication per unit time. For bacteria, we can measure indices such as MICs or MBCs, that are defined as drug concentrations that will keep the bacteria from growing enough over an 18- to 24-hour period to cause turbidity in the growth medium (MIC) or to cause the number of bacteria to be reduced by 1000-fold over the 18–24 hour timeframe (MBC). This ability to measure the difficulty a drug will encounter inhibiting or killing different

pathogens allows the drug exposure necessary to achieve different endpoints to be normalized across pathogens. In contrast, if one were to try to develop an antihypertensive agent, the true between-patient variability in the affinity with which a drug will bind to the receptor cannot currently be measured. Certainly, in the near future, the widespread use of pharmacogenomic profiling, looking, for example, for specific single nucleotide polymorphisms (SNPs) or deletions will allow identification of patients likely to respond less well to therapy. Currently, however, this true between-patient variance in receptor affinity is completely unobserved variability.

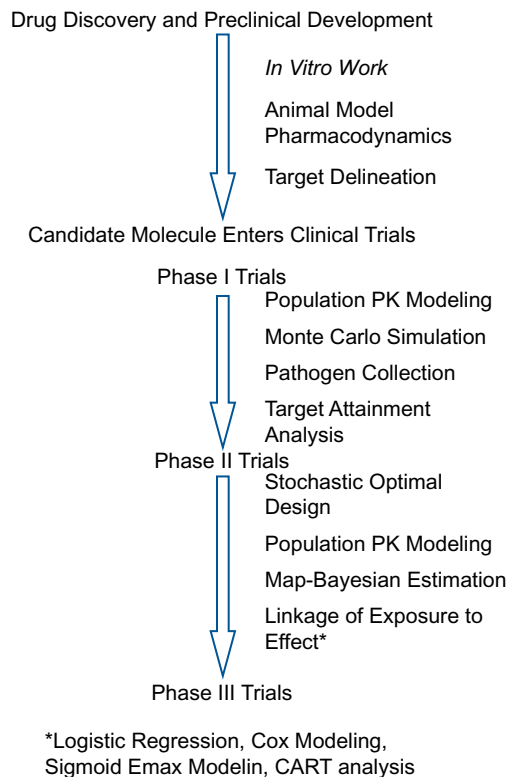

## CREATING A PHARMACODYNAMIC RELATIONSHIP

### MEASURE OF DRUG EXPOSURE

The process of creating a pharmacodynamic relationship starts with the idea of linking some measure of drug exposure to the outcome of interest. There are a number of measures of drug exposure that can be employed. Some of the most common are Peak concentration, Area Under the concentration-time Curve (AUC) and Time > Threshold. Many other measures of drug exposure are possible (e.g., trough concentrations), but they are usually related in some way to those mentioned above.

The critical idea behind which of these metrics is most closely linked to a specific measure of outcome is that the shape of the concentration–time curve may have an impact on the outcome measure. For example, for agents where the range of concentration that mediates minimal effect to that which mediates maximal effect is small, Time > Threshold will be the most useful metric for exposure. That is because higher concentrations will not produce significantly more effect than moderate concentrations. The overall effect will then be maximized by maintaining the drug concentration above the level that produces the degree of effect that is required. In contrast, many drugs are quite concentration-dependent in the effect that they produce. Here, much more effect will be produced at higher concentrations with much less being produced as concentrations decline. This will produce a situation where the total drug exposure will be linked to effect and AUC will be the most useful measure of drug exposure. Peak concentrations may be seen as linked to effect when an irreversible event occurs, such as covalent binding to a receptor that only occurs above a specific concentration. Here, only peak concentrations will produce enough exposure to have the binding occur in the appropriate timeframe. This is the rarest situation seen in the development of pharmacodynamic relationships. Peak concentrations can also appear to be linked to outcome when there is a mixture of populations of sensitive and less sensitive targets present. This will be discussed in greater detail below under the topic of suppression of emergence of resistance.

For the development of such relationships for anti-infective agents, the exposure measures are normalized to the measure

**Figure 40-1.** Use of pharmacodynamics in the drug development process.

of susceptibility of the pathogen to the drug being studied (e.g., MIC,  $EC_{50}$ ). This produces a hybrid measure that explicitly depends on the drug exposure, but also on the pathogen being studied. So we can now measure  $\text{Time} > \text{MIC}$ ,  $\text{AUC}/\text{MIC}$  ratio, or Peak Concentration/MIC ratio.

As an example of the shape of the curve having an impact on the effect developed by drug exposure, the  $\beta$ -lactam antibiotic imipenem/cilastatin was studied in a neutropenic mouse thigh infection model by Flückiger, Segessenmann, and Gerber.<sup>2</sup> The actual idea that the shape of the curve can affect the endpoint measured was popularized by the laboratory of Craig,<sup>3-5</sup> but arguably the clearest demonstration was by Flückiger.<sup>2</sup> In this study, the effect of a dose of drug was determined on the number of organisms present at the primary infection site. In parallel, a second cohort of animals received the same drug dose, but on a highly fractionated basis, so that the resultant concentration–time curve had a much lower peak concentration, but remained above the MIC for a much longer time interval. The  $\text{AUC}/\text{MIC}$  ratios developed in the two cohorts were nearly identical. The results are shown in Figure 40-2. The number of organisms killed was much greater when the  $\text{Time} > \text{MIC}$  was longer. This indicates that there was no benefit derived from the high peak concentrations developed in the first group and that keeping the drug concentrations in excess of the MIC was the effect driver in this circumstance.

An example of exactly the opposite linkage can be seen with fluoroquinolone antimicrobials, as well as other agents like aminoglycosides, or the new antiMRSA agent, daptomycin. For these drugs, there is a clear relationship between drug concentration and the rate of organism kill that is engendered. In this circumstance,  $\text{AUC}/\text{MIC}$  ratio is the exposure variable most closely linked to outcome.

In a study by Louie *et al.*,<sup>6</sup> a mouse thigh infection model study was performed using methodology similar to that described above, but without the massive dose fractionation. An exposure–response curve was described (Figure 40-3). On the steep part of the curve Q 24 hour, Q 12 hour, and Q 6 hour administration schedules were studied, so that the 24-hour AUC

**Figure 40-2.** Effect of the shape of the concentration–time curve on the ability of imipenem/cilastatin to kill *P. aeruginosa* in a mouse thigh infection model. (From Flückiger U, Segessenmann C, Gerber AU. *Antimicrob Agents Chemother* 1991; 35: 1905.)

was the same for each group (same  $\text{AUC}/\text{MIC}$  ratio), but that the once daily dosing group had the highest Peak concentrations (and hence Peak concentration/MIC ratio) while the Q 6 hour dosing group attained the longest  $\text{Time} > \text{MIC}$ . When the results for these groups were tested for differences by analysis of variance, no differences could be discerned (Table 40-1). This indicates that for daptomycin,  $\text{AUC}/\text{MIC}$  ratio is the exposure variable most closely linked to outcome.

**Table 40-1. *Staphylococcus Aureus* Densities in Thigh Muscles of Mice That Were Treated with Various Doses of Daptomycin, Administered in One, Two, or Four Divided Doses**

Staphylococcus aureus phylococcus aureus Densities ( $\log_{10}$ (CFU/g) + 1 Standard Deviation) with:				
Total Dosage (mg/kg)	1 Dose	2 Divided doses <sup>b</sup>	4 Divided doses <sup>c</sup>	P value <sup>a</sup>
2.5	6.54 ± 0.98	6.83 ± 0.88	6.61 ± 0.93	0.64
5.6	5.12 ± 0.66	4.96 ± 0.59	5.02 ± 0.52	0.73
15.0	3.73 ± 0.48	3.82 ± 0.55	3.68 ± 0.43	0.59

<sup>a</sup>Statistical testing was performed by analysis of variance. A *P* value of 0.05 was considered statistically significant.

<sup>b</sup>One-half of the single dose was administered at 0 hour and then 12 hours later.

<sup>c</sup>One-quarter the single dose was administered at 0 hour and then 6, 12, and 18 hours later.

## CHOOSING THE TARGET

In the examples given above, a microbiological endpoint was chosen. This is because we were dealing with animal model systems. It is important to recognize that in the drug development process, there will be a progression from a preclinical stage to the performance of clinical trials to document safety and efficacy.

Prior to the inception of clinical trials, animal model and *in vitro* systems are required for the determination of the true pharmacodynamically linked effect variable (e.g., AUC/MIC ratio, Time MIC). After the start of clinical trials, we can examine either clinical or microbiological endpoints. These endpoints can be dichotomous in nature (succeed/fail, eradication/persistence) or can be continuous (microbiological quantitative repetitive sampling from an infection site). The target that is chosen in either of these circumstances will determine, to a great degree, the dose that is required to attain the target.

In the preclinical circumstance, one can examine the ability of a regimen (dose and schedule) to kill organisms at a primary infection site (Figures 40-2 and 40-3). Alternatively, one could examine a mortality endpoint. In either circumstance, the model system could be developed so that the animal was either normal or rendered immunocompromised. In each instance, this will change the interpretation of the endpoint chosen and, in the case of an immunocompromised animal system, will require a larger drug exposure to achieve whatever endpoint is desired. The reason to perform these studies in immunocompromised animals is twofold. First, it is a conservative measure of the drug exposure required to achieve whatever target is desired. It is a more direct measure of “bug versus drug.” Second, and perhaps as important, it is much easier to find strains of pathogens that will grow in whatever model is being used. In the presence of the full immune system of the animal, many pathogens will self-clear over the period of observation in the no-treatment control group. This renders the interpretation of the experiment much more difficult.

It is also important to recognize that the animal system being employed should accurately reflect the local pharmacokinetics of the drug for the indication being sought. While a mouse thigh infection model may accurately represent the ability of the drug to kill organisms in a skin/skin structure infection, the lessons learned and exposure targets derived would not be helpful if the drug were going to be studied for a meningitis indication in clinical trials.

This also raises the issue of what endpoint will be chosen. Do we wish merely to shut off organism growth or to kill the organism at the primary infection site to a specific degree (e.g., 1 log<sub>10</sub> (CFU/g) kill, 2 log<sub>10</sub> (CFU/g) kill, 80 percent of maximal kill). Figure 40-3 demonstrates that an AUC/MIC ratio of 43.4 is required to shut off growth of the organism, whereas attaining 80 percent of the maximal bacterial kill for this strain of *Staphylococcus aureus* requires a larger exposure, with an AUC/MIC ratio of 92.4. For a relatively uncomplicated skin and skin structure infection, attaining an exposure target that will result in organism stasis is likely all that is required. However, for a complicated skin and skin structure infection, particularly if bacteremia would be likely, an exposure target that would drive some high percentage of the maximal bacterial kill (80–90 percent of maximal kill) would be more appropriate. This choice of target is crucial to the successful choice of an appropriate drug dose for clinical trial.

## SUPPRESSION OF EMERGENCE OF RESISTANCE AS AN ENDPOINT

Until recently, little has been done with suppression of emergence of resistance as an endpoint for the choice of drug dose. The key idea underlying the problem of emergence of resistance is the population burden of bacterial cells at an infection site relative to the inverse of the mutational frequency to resistance. If the population burden exceeds the inverse of the

**Figure 40-3.** Relationship between the 24-h AUC/MIC ratio of daptomycin and log<sub>10</sub> CFU of *S. aureus* per gram of thigh muscle (mean  $\pm$  1 SD) when the total daily dose of daptomycin is given as one dose in 24h, two equally divided doses every 12h, or four equally divided doses every 6h. The total daily doses of 2.5, 5.6, and 15.0 mg of daptomycin/kg resulted in AUC/MIC ratios of approximately 21, 44, and 115, respectively. The AUC/MIC ratio for a given total daily dose was similar regardless of whether a total daily dose was administered as one, two, or four equally divided doses over 24h. (From Louie A, Kaw P, Liu W *et al. Antimicrob Agents Chemother* 2001; 45: 845.)

mutation frequency, there will be a high probability (but not a certainty) that organisms bearing a resistance mechanism will already be present. The larger the burden relative to the frequency, the higher will be the probability. This means there will be multiple populations of organisms present at the time that drug therapy is initiated. It is not surprising that the population bearing a resistance mechanism will respond quite differently to the pressure of drug therapy than will the population without this mechanism. Again, as above, the example used will be from the anti-infective literature, but the lessons are clearly applicable in the realm of oncolytic chemotherapy.

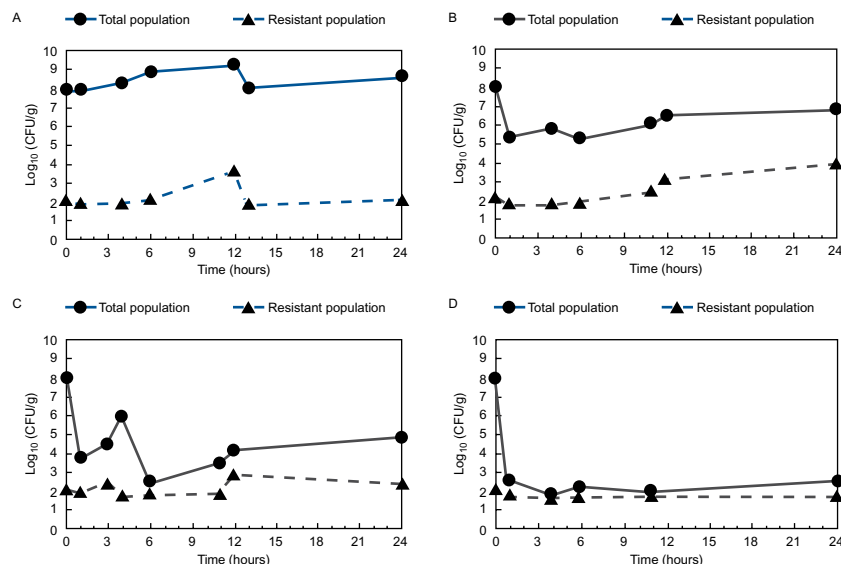

In Figure 40-4 Panels A–D, the effect of different doses (including a no-treatment control) of the fluoroquinolone levofloxacin on the total and resistant populations of *Pseudomonas aeruginosa* is displayed.<sup>7</sup> As the effect was determined at multiple time points, it allowed the effect of the drug concentrations on the two populations to be modeled simultaneously for all regimens.<sup>7</sup> This allowed a calculation of dose to maximally amplify the resistant population as well as a dose to hold the number of clones in the resistant population steady. These doses were then studied prospectively over a longer time frame (24 versus 48 hours) as a validation of the modeling result. This is displayed in Figure 40-5.

This is the first prospective validation that a target drug exposure can be derived to suppress the amplification of mutant subpopulations. This makes the point that the choice of the exposure target is flexible and is a choice that should be made with great care if the drug is to achieve the hoped-for results when it enters clinical trials. If the toxicity profile of the drug allows it, a suppression of resistance endpoint may be wise, as it will extend the lifetime of the drug.

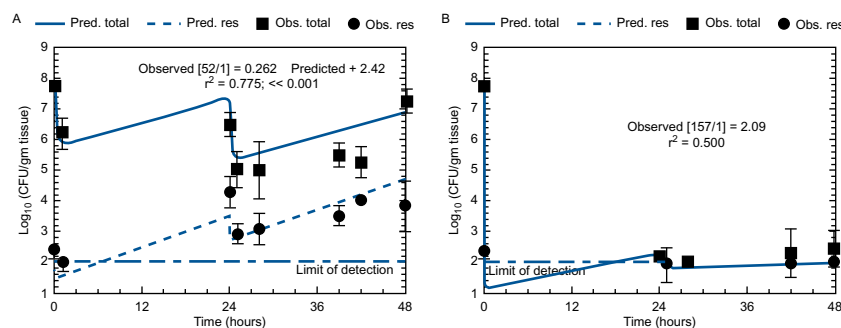

## CHOOSING A DRUG DOSE FROM PRECLINICAL PLUS PHASE I DATA

Once the appropriate animal or *in vitro* models have been chosen and the drug studied in these systems, the linked pharmacodynamic variable will have been elucidated and the exposure target(s) identified for the indications that are to be sought for the drug. A critical issue is how to employ the pharmacodynamic

**Figure 40-4.** Effect of 4 drug doses of levofloxacin on the total and resistant bacterial populations of *Pseudomonas aeruginosa* over 24 hours. Drug doses were 0, 90, 215, and 600 mg/kg (Figure 40-3, panels A–D, respectively). The 90 mg/kg dose allowed amplification of the resistant population by almost 2  $\text{log}_{10}$  (CFU/g). The 215 mg/kg dose allowed only minimal resistant mutant amplification. (From Jumbe N, Louie A, Leary R *et al. J Clin Invest* 2003; 112(2): 275. Reproduced with permission from the American Society for Clinical Investigation.)

**Figure 40-5.** Model validation. The emergence of resistance model developed in this study was prospectively evaluated and validated by generating response predictions for doses not previously studied that would (A) encourage selection of resistance or (B) suppress emergence of resistance. An exposure of an AUC/MIC ratio of 157/1 was calculated to prevent emergence of resistance. Experiments were performed to 48, not 24 hours as in the studies performed to generate parameter estimates, using model predicted conditions. Levofloxacin dosing occurred at time 0 and at 24 hours. The lines are model predictions (not best-fit curves). (◻) represents experimental measurements of the total population. (●) represents experimental measurements of the resistant subpopulation. The model predicted changes in the resistant mutant population well at both exposures. (From Jumbe N, Louie A, Leary R *et al. J Clin Invest* 2003; 112(2): 275. Reproduced with permission from the American Society for Clinical Investigation.)

information to allow the “correct” dose of drug to be chosen for clinical trial(s).

The ability of a specific dose of drug to attain the desired exposure target is influenced by a small number of factors. These are (i) the true between-patient variability in drug pharmacokinetics; (ii) the variability in the MIC of the drug for the pathogens of interest (i.e., those pathogens that are likely causes of the diseases for which indications are being sought); (iii) the protein binding of the agent being studied. Each of these factors will be examined in turn.

### PHARMACOKINETIC VARIABILITY

True between-patient variability in pharmacokinetics clearly exists. The same dose of drug will produce very different drug concentration profiles if given to a large number of patients. We can account for some portion of this variance by measuring covariates such as age, sex, weight, height, creatinine clearance, etc. However, even after examining these and other covariates, there will still be true, residual between-patient variance. Accounting for this variability plays an important role in determining the correct dose for clinical trials. The basic idea is that

whatever dose is chosen, it should be adequate to attain the desired exposure target in a very high proportion of the population of interest.

It is important to obtain an idea of the degree of variability of the drug exposure achieved when a fixed dose of drug is administered. Preston *et al.*<sup>8</sup> studied 272 patients with community-acquired infections who received the fluoroquinolone antibiotic levofloxacin. In this study, all patients had a serum creatinine that was  $< 2.0$  mg/dL. Figure 40-6 shows the variability in AUC achieved in these patients with a fixed dose of drug. In this relatively normal community-based population there was a  $> 10$ -fold range of AUCs observed.

It is unusual to have such a rich data set early on in drug development. The usual reality is to have anywhere between 12 and 60 volunteers who have had the drug’s pharmacokinetics studied. These study subjects represent a very biased estimator of how the drug will be handled in the population of interest, most of whom will be older and, by definition, sicker than the normal volunteer population. Nevertheless, if these data can be employed to choose a drug dose, it will almost certainly be a conservative choice.

**Figure 40-6.** The distribution of area under the concentration–time curve (AUC) values for 272 patients receiving 500 mg of levofloxacin for the therapy of community-acquired infections.

Monte Carlo simulation is a mathematical technique that allows prior knowledge of the central tendency of a parameter and its distribution to be employed to set up a sampling distribution. That is, we can take a large number of samples (e.g., 1000, 10000, 30000) from the “known” prior distribution of parameter values. These can be used to calculate Peak concentrations, AUC values, or Time > Threshold. It provides the opportunity to perform large clinical trials “*in silico*.” These measures of drug exposure then can be employed to determine how often a specific drug dose will produce an exposure that will attain the exposure target value for a specific MIC.

### MICROBIOLOGICAL VARIABILITY

Usually the pathogen(s) of interest for a specific indication have a broad range of values. It is obvious that for whatever range of drug exposures are achieved by a specific dose, it will be more difficult to achieve the exposure target for an organism with a higher MIC value.

Luckily, the determination of the range of MIC values for organisms that are causative pathogens for the indications being studied is relatively straightforward to obtain.

### PROTEIN BINDING

As a rule, only non-protein bound drug is active. This has been most clearly seen in two studies, one of bacteria<sup>9</sup> and one of HIV.<sup>10</sup>

Merriken *et al.*<sup>9</sup> examined a group of isoxazolyl penicillins for their activity against *Staphylococcus aureus*. There were seven molecules studied. Each was chosen because it had the same MIC for the challenge strain of *Staphylococcus* and had very similar pharmacokinetics, but had very different protein binding that ranged from 30% bound to >97% bound. When examined in a mouse model, the effect of the drug was related to the free fraction of the drug concentration (Figure 40-7).

For HIV, Bilello *et al.*<sup>10</sup> examined a highly bound (ca 90%) HIV-1 protease inhibitor and examined the impact of protein binding *in vitro*. In a transitive logic set of experiments, the impact in free fraction of the major drug binding protein for this agent ( $\alpha$ -1 acid glycoprotein) was determined. In Figure 40-8A, it is demonstrated that increasing the amount of binding protein over the physiologic range of 0.5–1.5 mg/mL decreases the free fraction in a quantitative manner. It was also demonstrated (Figure 40-8B) that lower free amounts of drug were associated with less cell-associated drug. Finally, the lower cell-associated

**Figure 40-7.** The effect of protein binding on the microbiological activity of seven isoxazolyl penicillins as determined in a mouse model of staphylococcal intraperitoneal infection. (From Merriken DJ, Briant J, Rolinson GN. *J Antimicrob Chemother* 1983; 11:233.)

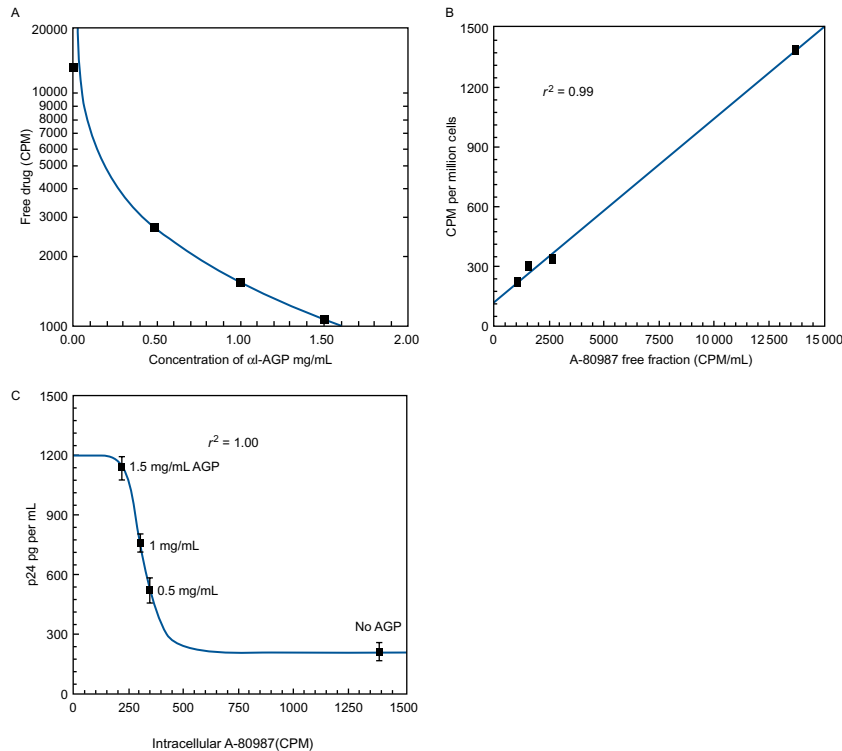

amounts of drug were shown to produce less antiviral effect, in a quantitative fashion (Figure 40-8C).

Clearly, then, protein binding has a major, quantitative effect on drug effect, particularly in microbiological systems. There are instances when protein binding has a less than anticipated impact on effect or where it appears that there is actually no effect of binding on activity. It is likely (but unproven) that in these instances drug is taken onto its binding effect site from its protein-binding site because of a major difference in  $K_d$  for the drug for the two receptors. Even so, when developing a drug and picking an effect target, it is wise to understand the drug binding characteristics and to ascertain the impact of drug binding on the effect that is desired. This is particularly important preclinically, as there may be considerably different binding seen in animal versus man.

### INTEGRATING THE SOURCES OF VARIABILITY

Once we have chosen an exposure target, studied pharmacokinetic variability, MIC (or  $EC_{50/95}$ ) variability and the impact of protein binding, the question remains as to how to use this preclinical information to choose dose(s) for clinical trials.

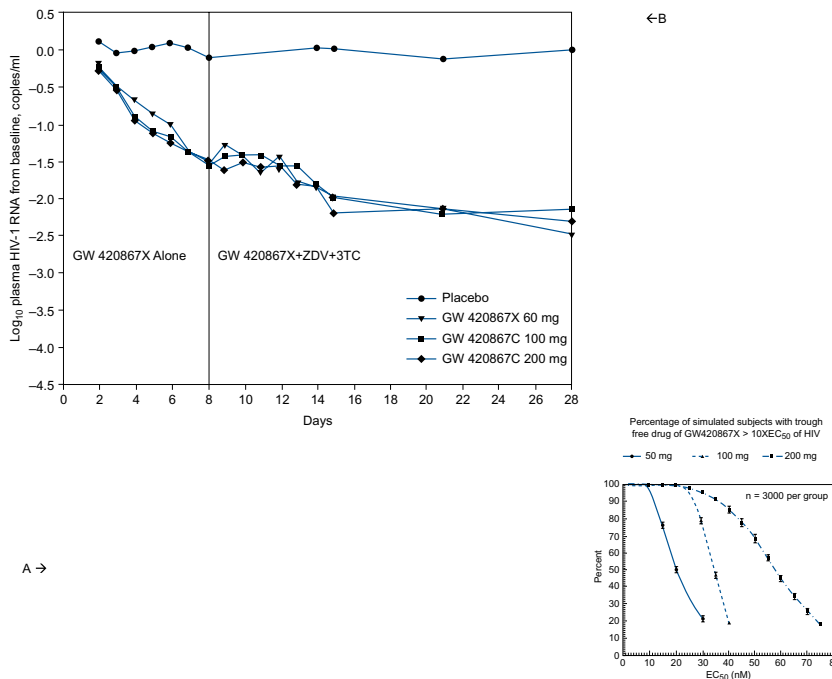

Our group<sup>11–14</sup> developed the use of Monte Carlo simulation to integrate these disparate sources of variability. In the paradigm developed, a population pharmacokinetic study is performed. The measure of central tendency (usually but not necessarily the mean parameter values) and dispersion (full or major diagonal covariance matrix) are employed to generate a Monte Carlo simulation for specific drug doses. These generated values are then corrected for protein binding, as a function of the measured impact of binding on effect. Then the fraction of the simulated population that attains the desired exposure target is determined for different values of MIC (or  $EC_{50/95}$ ). In so doing, clear breakpoint values for pathogen drug susceptibility can be determined for a specific dose of drug. Because we have information regarding the distribution of MIC (or  $EC_{50/95}$ ) values, the overall response of the population can be determined by taking a weighted average over the product of the range of target attainment rates and MIC (or  $EC_{50/95}$ ) values. An example of this technique validated with a prospective study was performed with an HIV-1 non-nucleoside reverse transcriptase inhibitor [NNRTI].<sup>14</sup> The target agreed upon was keeping trough

**Figure 40-8.** Effect of protein binding on the antiviral activity of a HIV-1 protease inhibitor. In (A), increasing amounts of the major binding protein (-1 acid glycoprotein) results in a decreasing amount of unbound drug. In (B), the decrease in unbound drug is shown to be associated with decreased cellular penetration. In (C), it is shown that decreased amounts of intracellular drug are associated with decreased antiviral effect. Together, these experiments demonstrate that protein binding has a major impact on virological activity. (From Merriken DJ, Briant J, Rolinson GN. *J Antimicrob Chemother* 1983; 11:233.)

free drug concentrations above the  $EC_{90}$  of HIV. Preclinical study demonstrated that addition of purified binding proteins to the medium increased the  $EC_{50}$  value by 7.6-fold. In addition, other preclinical studies demonstrated that there was approximately a 10-fold change in drug concentration between the  $EC_{50}$  and the  $EC_{90}$ . Therefore, a 7.6-fold adjustment was

made to the simulated trough concentrations of the drug for doses of 50 mg, 100 mg, and 200 mg. Finally, preliminary preclinical data indicated that different wild-type HIV isolates all had  $EC_{50}$  values less than 10 nM. In Figure 40-9A, the target attainment rate by  $EC_{50}$  values (not determined in the presence of binding proteins) is displayed. It is clear that if the  $EC_{50}$  value

**Figure 40-9.** In (A), three different doses of an experimental nonnucleoside reverse transcriptase inhibitor keep free drug in excess of the  $EC_{90}$  of HIV for the whole dosing interval to the same extent, as long as the  $EC_{50}$  is less than 10 nM. As is demonstrated in (B), this leads to equipotent antiretroviral activity in a Phase I/II randomized, double-blind clinical trial.

**Figure 40-10.** The relationship between the AUC/MIC ratio of levofloxacin and the probability of a good clinical outcome in 134 patients receiving this fluoroquinolone for community-acquired infections. Classification and regression tree (CART) analysis identified a breakpoint of a total drug AUC/MIC ratio of 50 (free drug AUC/MIC ratio of 35).

does not exceed 10 nM, there will be no difference in the target attainment rates for the three doses evaluated.

This analysis resulted in the prediction that no difference in viral load decline would be observed in a clinical trial. This agent was examined in a 60 patient Phase I/II randomized, double-blind trial in which 15 HIV-infected patients were each given one of the doses examined in the Monte Carlo simulation, and 15 patients served as a no-treatment control in this short term trial. The results are displayed in Figure 40-9B. On the morning of day 8 of the trial (the end of monotherapy), the median viral load decline ranged from 1.48 to 1.52  $\log_{10}$  (copies/mL), prospectively validating the predictions.

Other Monte Carlo simulation-based trial predictions have also been prospectively validated.<sup>12,13</sup> This technique where the sources of variability are quantified and integrated is a useful guide to determining drug doses for evaluation in the Phase I/II environment.

### PHASE II CLINICAL TRIAL VALIDATION OF DOSE FOR USE IN PHASE III TRIALS

Given the extensive number of patients studied and the possibility for harm if an incorrect dose is chosen for Phase III clinical trial evaluation, it is important to validate the dose(s) chosen by the use of Monte Carlo simulation. In order to do this, it is critical to pay attention to the same sources of variability as in the integration of the preclinical information.

It is important, therefore, to have an index of drug exposure for each patient participating in the analysis, a pathogen identified, and an MIC determined to the drug being employed. Finally, it is important to decide upon an endpoint (e.g., clinical success/failure, organism eradication/persistence).

The first prospective, multicentered trial of this type was published by Preston and colleagues.<sup>15</sup> Patients were enrolled in 22 centers for the therapy of community-acquired infections (respiratory tract infections, skin and skin structure infections, and urinary tract infections) with a fluoroquinolone antimicrobial (levofloxacin). A sampling scheme was derived using a stochastic D-optimal sampling technique. There were 272 patients who had pharmacokinetic data collected. These data were analyzed employing a nonparametric population modeling technique (NPEM II program of Schumitzky and Jelliffe). Individual estimates of exposure were calculated for each patient by obtaining patient-specific pharmacokinetic parameter values employing Maximum *A-posteriori* Probability (MAP) Bayesian

parameter estimation. Of these patients, there were 134 patients with a documented outcome and identified pathogen that had a levofloxacin MIC. For clinical outcome, both Peak/MIC ratio as well as AUC/MIC ratio could be linked to outcome. As there has been considerable preclinical data linking AUC/MIC ratio to fluoroquinolone effect, this relationship will be presented in Figure 40-10. The breakpoint AUC/MIC value, determined by Classification and Regression Tree (CART) analysis, was 49.8. This was for total drug. The free drug value would be 34.9. A mouse thigh infection model developed in our laboratory examined levofloxacin for the therapy of *Streptococcus pneumoniae*.<sup>16</sup> The value for an organism kill of 1  $\log_{10}$ (cfu/g) was 29.4 for a free drug AUC/MIC ratio. The free drug AUC/MIC value associated with a good outcome determined in a separate clinical study by Ambrose *et al.* only for *Streptococcus pneumoniae* for two fluoroquinolones (levofloxacin and gatifloxacin) was 27.2–33.7.<sup>17</sup> All these determinations are in excellent concordance.

What is clear is that it is possible to identify targets for desired drug action preclinically and to bridge between animal and man employing Monte Carlo simulation techniques. Further, it is also clear that these findings are robust. They have been validated in clinical trials. The paradigm for clinical validation is simple. It is set forth in Table 40-2. It is important to obtain good individual-patient estimates of their pharmacokinetic parameter values in order to perform clinical pharmacodynamic analysis. While population modeling allows good estimates of population mean parameter values, the precision with which the values are determined for an individual patient after the MAP-Bayesian step depend explicitly on how much information is present in the samples that have been obtained for *that* patient. This problem can be solved without undue patient invasion (i.e., minimizing the numbers of samples) by employing stochastic optimal design techniques.<sup>18–21</sup> Once the patients have been studied, the population values are best attained using population modeling techniques, with patient-specific values determined through MAP-Bayesian estimation. Exposure variables can then be normalized (in the case of anti-infective agents) to some measure of the degree of susceptibility of that patient's pathogen to the drug in question (Peak/MIC ratio, AUC/MIC ratio or Time MIC). These normalized exposure variables can then be linked to the probability of a good outcome (clinical/microbiological) through use of logistic regression. Breakpoints can be sought through use of CART analysis. If the outcome is a time-to-event, Kaplan-Meier analysis (when a breakpoint is available) or Cox proportional hazards analysis (for a continuous variable) can be employed. If the outcome is a continuous variable (e.g., viral load determination), some variant of a sigmoid  $E_{max}$  effect model can be employed to link exposure to effect.

**Table 40-2. Paradigm for the Development of Exposure-Response Relationships**

1. Decide on an endpoint
2. Make potency measurements of the cells to be inhibited/killed (MIC/ $EC_{50}$ , etc.)
3. Obtain drug exposure estimates for patients in these trials
  - a. Stochastic optimal sampling design
  - b. Population pharmacokinetic modeling
  - c. MAP-Bayesian parameter determinations for individual patient exposure estimates
4. Decide on an analytical tool for endpoint analysis (examples only)
  - a. Sigmoid  $E_{max}$  analysis for a continuous endpoint
  - b. Logistic regression for dichotomous/polytomous outcomes
  - c. Cox proportional hazards modeling (or a fully parametric variant) for time-to-event data
  - d. Classification and regression tree (CART) analysis for breakpoint determination

Determination of a pharmacodynamically linked variable preclinically with an exposure target combined with a target attainment analysis from Phase I/II data will allow identification of a dose for Phase III trials. Validation of this outcome in a (relatively) small Phase II trial will provide confidence that the dose chosen for large, Phase III clinical trial investigation is optimal for the effect target desired. This will maximize the speed of drug development and minimize drug failure.
