A catalogue record for this book is available from the British Library.

This book is adapted from contributions published in *Remington: The Science and Practice of Pharmacy* 22<sup>nd</sup> edition.

# Contents

<b>Preface v</b>			
<b>About the editor vii</b>			
<b>Contributors ix</b>			
<b>Chapter 1</b>	Information resources in pharmacy and the pharmaceutical sciences <i>Robin H. Bogner, PhD and Sharon Giovenale, MSLS</i>	1	
<b>Chapter 2</b>	Analysis of medicinals <i>Raymond D. Skwierczynski, PhD</i>	9	
<b>Chapter 3</b>	Quality assurance and control <i>John H. Parker, PhD and John E. Enders, PhD, MBA</i>	29	
<b>Chapter 4</b>	Stability of pharmaceutical products <i>Allan D. Bokser, PhD and Patrick B. O'Donnell, PhD</i>	37	
<b>Chapter 5</b>	Bioavailability and bioequivalence <i>Steven B. Johnson, PharmD</i>	51	
<b>Chapter 6</b>	Dissolution <i>Vijai Kumar, MS, MBA and Praveen Hiremath, PhD</i>	63	
<b>Chapter 7</b>	Modern-day drug discovery and development <i>Rick G. Schnatz, PharmD</i>	81	
<b>Chapter 8</b>	The New Drug Approval Process <i>Linda A. Felton, PhD and Dennis W. Raisch, PhD, RPh</i>	93	
<b>Chapter 9</b>	Metrology and pharmaceutical calculations <i>Roger L. Schnaare, PhD and Shelly J. Prince, PhD</i>	101	
<b>Chapter 10</b>	Statistics <i>Sanford Bolton, PhD and Richard Hirsch, PhD</i>	133	
<b>Chapter 11</b>	Molecular structure, properties and states of matter <i>Thomas Rades, PhD, Keith C. Gordon, PhD and Kirsten Graeser, PhD</i>	177	
<b>Chapter 12</b>	Thermodynamics <i>Timothy S. Wiedmann, PhD</i>	207	
<b>Chapter 13</b>	Solutions and phase equilibria <i>Pardeep K. Gupta, PhD</i>	219	
<b>Chapter 14</b>	Separation methods <i>Loyd V. Allen, Jr., PhD, RPh</i>	241	
<b>Chapter 15</b>	Ionic solutions and electrolytic equilibria <i>Barbara R. Conway, PhD</i>	257	
<b>Chapter 16</b>	Tonicity, osmoticity, osmolality, osmolarity <i>Andrew Ingham, MRPharmS, PhD and Cathy Y. Poon, PharmD</i>	277	
<b>Chapter 17</b>	Chemical kinetics <i>Rodney J. Wigent, PhD</i>	301	
<b>Chapter 18</b>	Complex formation <i>Thorsteinn Loftsson, MSPharm, MSc, PhD and Marcus E. Brewster, PhD</i>	317	
<b>Chapter 19</b>	Interfacial phenomena <i>Paul M. Bummer, PhD and Yvonne Perrie, PhD</i>	329	
<b>Chapter 20</b>	Colloidal dispersions <i>Bill J. Bowman, RPh, PhD, Clyde M. Ofner III, PhD, Hans Schott, PhD and Yvonne Perrie, PhD</i>	343	
<b>Chapter 21</b>	Coarse dispersions <i>James Swarbrick, DSc, PhD, Joseph T. Rubino, PhD, RPh and Orapin P. Rubino, PhD</i>	371	
<b>Chapter 22</b>	Rheology <i>Lawrence H. Block, PhD</i>	393	
<b>Chapter 23</b>	Powders <i>Yi-Bo Wang and Robert O. Williams III, PhD</i>	411	
<b>Chapter 24</b>	Solutions, Emulsions, Suspensions, and Extracts <i>Michael M. Crowley, PhD</i>	435	
<b>Chapter 25</b>	Sterilization Processes and Sterility Assurance <i>James Agalloco, BEChE, MSChE, MBA, William G. Lindboem, Jr., PhD and Russell E. Madsen, MS</i>	469	
<b>Chapter 26</b>	Parenteral Preparations <i>Michael J. Akers, PhD</i>	495	
<b>Chapter 27</b>	Pharmaceutical Compounding – USP <797> Sterile Preparations <i>Catherine Cone, PharmD, BCPS, Linda A. Felton, PhD, Amy Bachyrycz, PharmD</i>	533	
<b>Chapter 28</b>	Ophthalmic Preparations <i>Masood Chowhan, PhD, John C. Lang, PhD, Paul Missel, PhD</i>	541	
<b>Chapter 29</b>	Medicated Topicals <i>Lawrence H. Block, PhD</i>	565	
<b>Chapter 30</b>	Oral Solid Dosage Forms <i>Ahmed Adel Sakr, PhD and Fars K. Alanazi, PhD</i>	581	

<b>Chapter 31</b>	Coating of Pharmaceutical Dosage Forms <i>Stuart C. Porter, PhD</i>	611	<b>Chapter 36</b>	Pharmaceutical Excipients <i>William J. Reilly, Jr., MBA</i>	683
<b>Chapter 32</b>	Oral Modified-Release Drug Delivery Systems <i>Ali R. Rajabi-Siahboomi, PhD, Manish S. Rane, PhD and Linda A. Felton, PhD</i>	623	<b>Chapter 37</b>	Basic pharmacokinetics and pharmacodynamics <i>Raymond E. Galinsky, PharmD and Craig K. Svensson, PharmD, PhD</i>	705
<b>Chapter 33</b>	Aerosols <i>John J. Sciarra, PhD and Christopher J. Sciarra, BS, MS Industrial Pharmacy</i>	633	<b>Chapter 38</b>	Drug action and effect <i>Donald N. Franz, PhD</i>	727
<b>Chapter 34</b>	Biotechnology and Drugs <i>Ara H. DerMarderosian, PhD and Zhiyu Li, PhD</i>	651	<b>Chapter 39</b>	Drug absorption, distribution, metabolism and excretion <i>Michael R. Franklin, PhD</i>	739
<b>Chapter 35</b>	Pharmaceutical Packaging <i>C. Jeanne Taborsky, BSChem and Kathleen Deiss, RN</i>	667	<b>Chapter 40</b>	Pharmacokinetics/pharmacodynamics in drug development <i>George L. Drusano, MD</i>	755
			<b>Index</b>		763

# Preface

*Remington's* has been in print for more than 100 years and is a well-known reference text for pharmacists, pharmacy students, and pharmaceutical scientists alike. Over the past century, each edition has been updated to reflect the current state of the science and practice of pharmacy. Following the recent publication of the 22<sup>nd</sup> edition, the publishers asked me, as the editor of the Pharmaceutical Dosage Forms: Manufacturing and Compounding section, to create a version of this reference that focuses exclusively on pharmaceuticals. This new text, entitled 'Remington: Essentials of Pharmaceutics', is truly a historic event in the long and prestigious legacy of the Remington brand and I am honored to be part of this innovative project.

As the name implies, 'Remington: Essentials of Pharmaceutics' focuses on the pharmaceutical aspects of pharmacy practice. Chapters from the original parent text were specifically selected to create this new edition. The text pulls heavily from the Pharmaceutics and Pharmaceutical Dosage Forms sections. Various delivery systems and dosage forms, including powders, tablets and capsules, solutions, topicals and transdermals, aerosols, and ophthalmics, are covered. In addition, parenterals, sterilization processes, and sterile compounding are also presented. One chapter addresses pharmaceutical excipients and another discusses pharmaceutical packaging. Pharmaceutical analysis, product characterization, quality control, stability, bioavailability, and dissolution are also covered. Fundamental scientific concepts including thermodynamics, ionic solutions

and electrolyte equilibria, tonicity, chemical kinetics, rheology, complex formation and interfacial phenomenon are presented. The text also provides an introduction to pharmacokinetics and pharmacodynamics and the principles of absorption, distribution, metabolism and excretion. In addition, some introductory concepts on drug discovery and drug product approval as well as information resources in pharmacy and the pharmaceutical sciences are presented.

While there are many text books on drug delivery systems currently published, many focus on a specific route of delivery or a particular type of delivery system. Some of these books only touch on the underlying scientific principles of such systems while others delve so heavily on the theoretical that the reader may feel lost. In contrast, this new title provides a concise yet detailed resource covering all aspects of pharmaceuticals, from the scientific fundamentals to the dosage forms and drug delivery systems to drug product analyses. As with the original parent text, this book will be useful for anyone interested in pharmaceuticals and drug delivery. The focus on the essential concepts of pharmaceuticals and drug delivery, however, make this text an exceptionally valuable resource for scientists new to the pharmaceutical industry as well as pharmacy and graduate students. With several chapters focused on parenteral products and sterilization, this book is also an excellent reference for compounding pharmacists involved in the preparation of sterile products.

# Contributors

- James Agalloco, BEChE, MSChE, MBA** / President, Agalloco and Associates, Belle Mead, NJ, USA
- Michael J. Akers, PhD** / Baxter Healthcare Corporation (Retired), Bloomington, IN, USA
- Fars K. Alanazi, PhD** / Professor of Pharmaceutics, Kayyali Chair for Pharmaceutical Industries, Department of Pharmaceutics, King Saud University, Riyadh, Saudi Arabia
- Loyd V. Allen Jr., PhD, RPh** / Professor Emeritus, University of Oklahoma School of Pharmacy, Editor-in-Chief *International Journal of Pharmaceutical Compounding*, Edmond, OK, USA
- Amy Bachyrycz, PharmD** / Assistant Professor, University of New Mexico, Albuquerque, NM, USA
- Lawrence H. Block, PhD** / Professor Emeritus, Mylan School of Pharmacy, Duquesne University, Pittsburgh, PA, USA
- Robin H. Bogner, PhD** / Associate Professor, Department of Pharmaceutical Sciences, University of Connecticut School of Pharmacy, Storrs, CT, USA
- Allan D. Bokser, PhD** / Independent Consultant, San Diego, CA, USA
- Sanford Bolton, PhD** / College of Pharmacy, University of Arizona, Tucson, AZ, USA
- Bill J. Bowman, RPh, PhD** / Assistant Professor of Pharmaceutical Sciences, Arizona College of Pharmacy-Glendale, Midwestern University, Glendale, AZ, USA
- Marcus E. Brewster, PhD** / Distinguished Research Fellow, Johnson & Johnson Pharmaceutical Research and Development, Beerse, BE
- Paul M. Bummer, PhD** / Associate Professor, Department of Pharmaceutical Sciences, College of Pharmacy, University of Kentucky, Lexington, KY, USA
- Masood Chowhan, PhD** / Senior Director, Drug Formulation and Delivery, Alcon Laboratories, Inc., Fort Worth, TX, USA
- Catherine Cone, PharmD, BCPS** / Assistant Professor, Department of Pharmacy Practice and Administrative Sciences, University of New Mexico Health Sciences Center, Albuquerque, NM, USA
- Barbara R. Conway, PhD** / Professor of Pharmaceutics, Division of Pharmacy and Pharmaceutical Sciences, School of Applied Sciences, University of Huddersfield, Queensgate, Huddersfield, UK
- Michael M. Crowley, PhD** / President, Theridian Technologies, LLL, Austin, TX, USA
- Kathleen Deiss, RN** / Quality Assurance Manager, SciRegs International, Inc., Columbia, MD, USA
- Ara H. DerMarderosian, PhD** / Research Professor of Pharmacognosy, Department of Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA, USA
- George L. Drusano, MD** / Co-Director, Ordway Research Institute, Albany, NY, USA
- John E. Enders, PhD, MBA** / Chief Operating Officer, Tech Manage Associates, Inc., Dalton, PA, USA
- Linda A. Felton, PhD** / Chair Department of Pharmaceutical Sciences, Associate Professor of Pharmaceutics College of Pharmacy, University of New Mexico, Albuquerque, NM, USA
- Michael R. Franklin, PhD** / Professor of Pharmacology and Toxicology, Department of Pharmacology and Toxicology, College of Pharmacy, University of Utah, Salt Lake City, UT, USA
- Donald N. Franz, PhD** / Professor Emeritus, Department of Pharmacology and Toxicology, University of Utah School of Medicine, Salt Lake City, UT, USA
- Raymond E. Galinsky, PharmD** / Professor of Pharmaceutics, Department of Industrial and Physical Pharmacy, Purdue University College of Pharmacy, West Lafayette, IN, USA
- Sharon Giovenale, MSLS** / Pharmacy Librarian, University of Connecticut Pharmacy Library, Storrs, CT, USA
- Keith C. Gordon, PhD** / Professor of Physical Chemistry, Department of Chemistry, University of Otago, Dunedin, Otago, NZ
- Kirsten Graeser, PhD** / Formulation Research, F. Hoffmann-La Roche Ltd., Basel, CH
- Pardeep K. Gupta, PhD** / Associate Professor of Pharmaceutics, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia, Philadelphia, PA, USA
- Praveen Hiremath, PhD** / Principal Scientist – Pharmaceutical Formulation, Bayer Healthcare, Overland Park, KS, USA
- Richard Hirsch, PhD** / Faculty for Applied Sciences, Cologne University of Applied Sciences, Cologne, DE
- Andrew Ingham, MRPharmS, PhD** / Lecturer in Pharmacy/ Pharmaceutical Delivery, School of Life and Health Sciences, Aston University, Birmingham, UK
- Steven B. Johnson, PhD** / Vice President, Regulatory Affairs, Novo Nordisk, Princeton, NJ, USA
- Vijai Kumar, MS, MBA** / General Manager and Vice President of Technical Operations and Research and Development, Pharmaceutics International, Hunt Valley, MD, USA
- John C. Lang, PhD** / Senior Director, AZYP, and Senior Research Scientist/ Adjunct Professor University of Texas at Arlington, Arlington, TX, USA

- Thorsteinn Loftsson, MSPharm, PhD** / Professor of Physical Pharmacy, Department of Pharmaceutical Sciences, University of Iceland, Hofsvallagata, IS
- Zhiyu Li, PhD** / Assistant Professor of Pharmaceutical Sciences, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia, Philadelphia, PA, USA
- William G. Lindboe, Jr., PhD** / Independent Consultant, East Brunswick, NJ, USA
- Russell E. Madsen, MS** / President, The Williamsburg Group, LLC, Gaithersburg, MD, USA
- Paul Missel, PhD** / Modeling and Simulation, Alcon Research, Ltd, Fort Worth, TX, USA
- Patrick B. O'Donnell, PhD** / Senior Director, Pharmaceutical Development, Ambit Biosciences Corporation, San Diego, CA, USA

- John H. Parker, PhD** / President, Tech Manage Associates, Dalton, PA, USA
- Yvonne Perrie, PhD** / Head of Pharmacy, Professor in Pharmaceutics/Drug Delivery, Aston University, Birmingham, UK
- Cathy Y. Poon, PharmD** / Professor and Vice Dean, Department of Pharmacy Practice and Pharmacy Administration, Philadelphia College of Pharmacy, University of the Sciences, Philadelphia, PA, USA
- Stuart C. Porter, PhD** / Senior Director, Global Pharmaceutical Applications RandD, International Specialty Products, Wayne, NJ, USA
- Shelly J. Prince, PhD** / Associate Professor of Pharmaceutics, College of Pharmacy, Southwestern Oklahoma State University, Weatherford, OK, USA
- Thomas Rades, PhD** / Faculty of Health and Medical Sciences, Department of Pharmacy, University of Copenhagen, Copenhagen, DK
- Dennis W. Raisch, PhD, MS, RPh** / Professor and Chair, Graduate Program in Pharmacoeconomics, Epidemiology, Pharmaceutical Policy, and Outcomes Research, College of Pharmacy, University of New Mexico, Albuquerque, NM, USA
- Ali R. Rajabi-Siahboomi, PhD** / Vice President and Chief Scientific Officer, Colorcon, Inc., Harleysville, PA, USA
- Manish S. Rane, PhD** / Formulation Technologies Manager, Colorcon, Inc., West Point, PA, USA
- William J. Reilly, Jr., MBA** / Director of Technical Services, Lannett Pharmaceuticals, Inc., Philadelphia, PA, USA
- Joseph T. Rubino, PhD, RPh** / Pharmacist/Consultant, Towaco, NJ, USA
- Orapin P. Rubino, PhD** / Director, Formulation and Product Development, Glatt Air Techniques, Inc., Ramsey, NJ, USA
- Ahmed Adel Sakr, PhD** / Distinguished Chaired Professor of Industrial Pharmacy and Pharmaceutics, Board of Trustees, Chair Assistant, Graduate Studies, Research and International Affairs, Future University Egypt, Cairo, Egypt
- Roger L. Schnaare, PhD** / Professor Emeritus of Pharmacy, Philadelphia College of Pharmacy, University of the Sciences in Philadelphia; Senior Pharmaceutics Fellow, Biosyn, Inc., Philadelphia, PA, USA
- Rick G. Schnatz, PharmD** / Senior Scientific Liaison, Compounding Expert Committee, Healthcare Quality and Compendia Affairs, United States Pharmacopeia, Rockville, MD, USA
- Hans Schott, PhD** / Professor Emeritus of Pharmaceutics and Colloidal Chemistry, Temple University, Philadelphia, PA, USA
- Christopher J. Sciarra, BS, MS** / Industrial Pharmacy Vice President, Scientific, Sciarra Laboratories, Inc., Hicksville, NY, USA
- John J. Sciarra, PhD** / Professor Emeritus and President, Sciarra Laboratories, Inc., Hicksville, NY, USA
- Raymond D. Skwierczynski, PhD** / Senior Director, Analytical Development Millennium: The Takeda Oncology Company, Cambridge, MA, USA
- Craig K. Svensson, PharmD, PhD** / Dean, College of Pharmacy Professor of Medicinal Chemistry and Molecular Pharmacology, Purdue University, West Lafayette, IN, USA
- James Swarbrick, DSc, PhD** / President, PharmaceuTech Pinehurst, NC, USA
- C. Jeanne Taborsky, BSChem** / President and Chief Executive Officer, SciRegs International, Inc., Columbia, MD, USA
- Yi-Bo Wang** / Graduate Student in Pharmaceutics, The University of Texas at Austin, College of Pharmacy, Austin, TX, USA
- Timothy S. Wiedmann, PhD** / Professor, Department of Pharmaceutics, University of Minnesota College of Pharmacy, Minneapolis, MN, USA
- Rodney J. Wigent, PhD** / Professor of Chemistry, Research Professor of Pharmaceutics, Dean, College of Graduate Studies, Director, Research Administration, University of the Sciences in Philadelphia, Philadelphia, PA, USA
- Robert O. Williams III, PhD** / Johnson and Johnson Centennial Professor of Pharmaceutics, Division Head, Pharmaceutics, The University of Texas at Austin, College of Pharmacy; Editor-in-Chief, Drug Development and Industrial Pharmacy, Austin, TX, USA

# Information Resources in Pharmacy and the Pharmaceutical Sciences

Robin H. Bogner, PhD and Sharon Giovenale, MSLS

## INTRODUCTION 1

### INTRODUCTION

This chapter describes many significant information resources used by the pharmacy professional student, the pharmaceutical sciences graduate student, the pharmacist, and the pharmaceutical scientist. It is not possible to be comprehensive, since there is a vast array of resources, which is growing exponentially. This chapter arranges the resources in three categories: the original research literature or primary literature, which comprises the largest volume of the literature; the secondary literature, which provides access to the primary literature; and the tertiary literature, which sums up the best practice based on the primary literature. Pharmacy practitioners and PharmD students use the literature to provide evidence-based medicine or the integration of the best research evidence into their practice or studies. Pharmaceutical scientists and their graduate students use the literature to support research in such fields as pharmacology, toxicology, medicinal chemistry, and pharmaceuticals.

### LOCATING APPROPRIATE TYPES OF INFORMATION RESOURCES

The nature and depth of the question and the level of experience of the researcher will determine the appropriate type of literature used. Whereas an expert may go directly to a database, a less experienced pharmacy student who is asked to find primary literature to write a paper on a therapeutic or pharmaceutical topic may first need to get general background information from a tertiary resource, such as a textbook, handbook, or subject encyclopedia either online or in print. Once the student is familiar with the basics and the professional vocabulary, he or she will frequently perform a search in either the PubMed/Medline database or the International Pharmaceutical Abstracts database to locate relevant review articles (secondary sources) and original research (primary sources). Fortunately, these databases often provide links to the full text of the journal article. A basic search statement for these databases should include synonyms for the search terms, including professional or scientific terms. The terms can be combined using the OR logical operator. The search can be refined by adding a term, using the AND operator. For example, if a student is looking for primary literature on possible future improvements in HPV vaccines, they could try searching for: (future OR advances OR second generation) AND (HPV vaccines OR papillomavirus vaccines). Nesting the parallel terms using parentheses will result in the most relevant articles. Additional limits, such as a date range and language, can easily be applied to the search.

A subject specialist often pursues one or more topics over a longer period and can create a series of search alerts in a database or set up RSS feeds to receive timely, updated search results from a specialized database. More information on search updates can be found in the section on Databases.

### PRIMARY LITERATURE

The first formal reports of scientific or clinical findings are found in journals. Journals can be distinguished from trade magazines by the lack of advertisements. Some primary liter-

ature, however, can be found in several trade magazines under sections entitled “Peer-reviewed reports”. The peer review process is a rigorous evaluation of manuscripts submitted to the journal. After concluding a study, authors write up their findings in a format consistent with the journal’s “instructions for authors.” The editor of the journal assigns two or more reviewers who are experts in the particular area of research. The reviewers are volunteers from the scientific community who elect to participate in the peer-review process. In addition to the reviewers’ recommendations to the editor on whether to publish the manuscript, they provide feedback to the authors, such as how to make the study design more clear to the reader and any additional experiments to allow the conclusions to be stronger. The peer-review process can take several months before the reviewers, authors, and editor agree on the final text for publication. The process is designed so only those manuscripts with clear scientific merit pass peer-review and are published. Each journal has its own criteria for acceptance of manuscripts, which can include whether the manuscript reports results within the area of research covered by that journal and whether the contribution is important to the scientific community.

The discrimination of the peer-review process is not uniform among all journals. For someone new to a field, it is difficult to discern which journals provide the clearest reports that are reproducible and for which the interpretation of the results is thorough without being too speculative. It is prudent to consult an expert in the field to determine which journals are best. Additionally, a general ranking system has been devised by the Institute for Scientific Information (ISI), which is now part of Thomson Reuters, which measures the “impact” of a journal. The Impact Factor of a journal for a given year is the average number of times articles published in that journal in the preceding two years is cited by others. Although this provides a general guide, the Impact Factor has its critics.

Experts, as well as those new to a field, follow the primary literature in a few publications related to their area of interest. Scanning the titles of the research articles, reviewing the abstracts of key articles, and reading those closely related to a particular area of research is the traditional approach to keep up to date on the general trends, as well as progress in one’s own specific area. This can be done by subscribing to print journals or simply accessing the websites of the journals of interest on which the titles and abstracts are generally available without charge. In addition, “open access” journals allow non-subscribers access to the full-length detailed articles. The Directory of Open Access Journals (<http://www.doaj.org/>) provides an up-to-date list. In some cases, journals allow open access to non-subscribers after a period of time, during which only subscribers can view full-length articles on-line.

Of the thousands of journals spanning the areas of clinical and pharmaceutical research, as well as related areas, pharmaceutical scientists often publish in:

*Journal of Medicinal Chemistry* (Eaton, PA; American Chemical Society)

*Journal of Natural Products* (Washington, DC; American Chemical Society and American Society of Pharmacognosy)

*Journal of Pharmacology and Experimental Therapeutics* (Baltimore, MD; Williams & Wilkins)  
*Pharmaceutical Research* (New York, NY; Kluwer Academic Publishers)

Clinical pharmacists refer to major medical and pharmacy journals:

*American Journal of Health-System Pharmacy* (Bethesda, MD; American Society of Health-System Pharmacists)  
*JAMA—The Journal of the American Medical Association* (Chicago, IL; American Medical Association)  
*Journal of the American Pharmacists Association* (Washington, DC; American Pharmacists Association)  
*New England Journal of Medicine* (Boston, MA; Massachusetts Medical Society)

Clinical pharmacists also refer to journals that focus on a particular disease state or patient population:

*Circulation* (Dallas, TX; American Heart Association)  
*American Journal of Veterinary Research* (Chicago, IL; American Veterinary Medical Association)  
*Diabetes* (Alexandria, VA; American Diabetes Association)  
*Pediatrics* (Evanston, IL; American Academy of Pediatrics)

A guide to journals and trade magazines recommended for the collections of libraries associated with schools/colleges of pharmacy has been developed and is updated by the Libraries/Educational Resources Section of the American Association of Colleges of Pharmacy. (<http://www.aacp.org/governance/SECTIONS/Libraryinformationscience/Pages/LibraryInformationScienceSpecialProjectsandInformation.aspx>) The 2010 list has 79 entries.

When searching for primary resources, patents and dissertations should also be considered. The purpose of a patent is to protect intellectual property, not disclose research findings. So, information claimed in patents should not be considered equal to that found in peer-reviewed research articles. Similarly, dissertations have not undergone the rigorous peer-review process; however, they can be quite useful to find details of studies that are too lengthy to include in a journal article.

## SECONDARY LITERATURE-REVIEWS AND DATABASES

Secondary literature is created by experts in the subject field. These resources are organized to either describe or evaluate the original primary literature and to provide useful access to this literature. Secondary literature consists of review articles, including systematic reviews and meta-analyses and bibliographic databases, such as PubMed.

## REVIEWS/SYSTEMATIC REVIEWS

As individual articles, the findings in the primary literature are often more useful to those working in that specialty than to those new to the field. A review article that integrates the information from individual articles from the primary literature may be more useful to someone outside the field or new to the field, as reviews provide the perspective gained from many authors over many years. Reviews provide a good starting place for a literature search into a new area. When beginning a literature search, one can often “refine” his or her search of a database to identify only review articles. Additionally, there is an increasing number of journals consisting of only review articles, such as *Trends in Pharmacological Sciences* (Amsterdam; Elsevier) and *Advanced Drug Delivery Reviews* (Amsterdam; Elsevier).

Systematic reviews are those with a more structured methodology to collect and evaluate the primary literature relevant to a particular research question. The most common type of systematic review in pharmacy literature is the meta-analysis. Using carefully selected sets of data from the primary literature and weighting their findings according to a protocol, the meta-analysis can use the much larger pool of data to produce quantitative findings. The use of statistical measures and the large

number of data can often produce a clearer answer from many sometimes contradictory findings in the primary literature. More information on meta-analysis can be found in *Cochrane Handbook for Systematic Reviews of Interventions*.<sup>1</sup>

## DATABASES

Bibliographic databases provide access to original research articles or the primary literature and cover a wide range of specialties, depth, and breadth of the literature. It is important for the searcher to consider the goal when selecting a database. If the searcher is unsure of where to begin or how to structure the search, he or she should consult the librarian or information specialist. In the absence of a resource person, there are subject guides and tutorials available online that can assist the searcher. A basic Google search will include non-peer reviewed and non-scholarly resources, so it is more effective to search professional scholarly databases. Occasionally, a Google Scholar search is useful in searching a new interdisciplinary area.

For comprehensive research on clinical or therapeutic topics, the searcher may begin with PubMed, which is available to anyone with an internet connection. This database is produced by the National Center for Biotechnology Information at the US National Library of Medicine (<http://www.pubmed.gov>). If access to subscription databases is unavailable, this may be the only affordable option. PubMed has an excellent thesaurus of professional terms, or a controlled vocabulary named MeSH, which stands for Medical Subject Headings. Common search terms are “mapped” to the MeSH terms, which are also searched by PubMed. For example, if the term “tylenol” is entered in the search box, acetaminophen is also automatically searched. Another useful tool, which requires free registration, is My NCBI. A My NCBI account allows the researcher to run search alerts and set up preferences, such as preferred display formats and colored highlighting of the search terms. While signed into My NCBI, a researcher can save a search in many of the NCBI health databases, including PubMed, and schedule email updates or alerts to run on a monthly, weekly, or even a daily basis. Email will only be received if there are new search results. References can also be saved by topics in online Collections. An author may create a bibliography of his or her own work, which can be linked to the NIH Manuscript Submission System. The data from PubMed is also available through several commercial vendors, such as the Medline database. Although the data is the same, the search platforms are proprietary and can give the searcher varying results while using the same search strategy.

International Pharmaceutical Abstracts (IPA) is a database that is focused on pharmacy and pharmaceutical science and is produced by Thompson Scientific in cooperation with the American Society of Health-System Pharmacists (ASHP). The database indexes and abstracts more than 800 pharmacy and pharmaceutical science related journals and covers drug use and development, as well as pharmacy related topics, including pharmacy education and ethics. IPA is also useful for finding articles on herbs and natural products. In addition to peer reviewed articles, IPA includes meeting abstracts from the meetings of organizations, including the American Pharmacists Association, the American College of Clinical Pharmacy, the American Association of Colleges of Pharmacy, and ASHP.

The Cochrane Library provides reliable and reasonably up-to-date information on the effects of interventions in health care. These interventions may be either therapeutic or diagnostic. There are six separate databases in the Cochrane Library, which may be searched separately or together. The well known Cochrane Systematic Reviews database provides access to the full text of the reviews and the protocols for proposed reviews. There is a Feedback tool that allows users to provide comments and criticisms of Cochrane Reviews and Protocols. The Cochrane Collaboration publishes a list of accepted comments. These comments can be used to further improve and update both Cochrane Reviews and Protocols. Abstracts of non-Cochrane systematic reviews, with a commentary on their

overall quality, are available in the Database of Abstracts of Reviews of Effects. The Cochrane Central Register of Controlled Trials merges the trials listed in Medline, Embase, and other published and unpublished sources. The bibliographic information on publications on the methods used in the conduct of controlled trials is available in the Cochrane Methodology Register. Economic evaluations of healthcare interventions are identified and appraised in the NHS Economic Evaluation Database. Free registration for saved search alerts and RSS feeds from the Cochrane Library is available to the residents of several countries. Cochrane provides a monthly Journal Club publication that introduces a recent Cochrane Review, with a podcast summarizing the review, discussion questions, and key figures and tables in the form of PowerPoint slides. You can also learn more about the Cochrane Library through various social media, including Facebook. The Cochrane Library also includes the *Cochrane Handbook for Systematic Reviews of Interventions*,<sup>1</sup> which provides a thorough methodology for evaluating the clinical research literature and strict guidelines for creating a Cochrane systematic review.

Other heavily used databases in pharmacy and pharmaceutical sciences include such specialized databases as BIOSIS Previews (Biological Abstracts); SciFinder Scholar (Chemical Abstracts and related chemical databases); Toxline and other TOXNET databases, from the US National Library of Medicine; and Embase, a comprehensive, fee-based health science database from Elsevier, which indexes and abstracts many non-English language journals and focuses heavily on pharmaceutical issues. BIOSIS Previews, SciFinder Scholar, and Embase have specialized indexing terms to help the researcher dig deeply into the life science, chemical, and pharmaceutical literature. In addition to indexing journal articles, they also include report, review, patent, and meeting abstracts. The Toxnet databases are a combination of bibliographic and full text databases, which encompass both secondary and tertiary toxicological literature. There is more on these full text databases in the section on Toxicology in the Tertiary literature section.

Important comprehensive citation databases, which allow the researcher to find which articles cited a seminal article, include SciVerse Scopus and Web of Science. Citation searching allows the searcher to see the evolution of an idea and emerging fields of research. SciVerse Scopus from Elsevier includes the data from the Embase database and is quite comprehensive in the sciences and social sciences. SciVerse Scopus also provides links to scientific websites and patents from five patent offices in its search results. Web of Science from Thomson Reuters began several decades ago with the print indexes named Science Citation Index, Social Science Citation Index, and Arts and Humanities Citation Index from the Institute for Scientific Information and has evolved into an extensive, multifunctional set of databases. In both databases, the researcher can save searches and set up search alerts or RSS feeds.

## TERTIARY

Tertiary literature provides an introduction to the research literature regarding the practice of pharmacy and the pharmaceutical sciences. It introduces key research findings and accepted concepts. It is usually written by clinical or research specialists within the subject area. These resources are particularly useful to the pharmacy professional and pharmaceutical science graduate students. They comprise textbooks, government monographs, encyclopedias, and other familiar reference works. As we move from print to electronic formats, these resources can provide additional value by allowing students, clinicians, and researchers to make notes, link to related resources, assess learning through online self tests, and share these with inter-professional teams and their peers, colleagues, or instructors. The ability to add more frequent updates to the material online, including videos, will aid the evolution of this literature.

Advantages to tertiary literature include ease of access and well vetted standards of best practice. A major disadvantage

still remaining is that the resources take years to compile and, therefore, can contain dated material.

## TEXTBOOKS

As electronic access is making it possible to use the best chapters or sections from multiple resources, the use of textbooks is evolving. Textbooks are often provided as part of electronic packages from vendors, such as AccessPharmacy from McGraw Hill. Electronic book readers also provide greater access and convenience. New editions of classic textbooks are valuable for students. They are also useful to professors or subject specialists, who can read a new edition to see the recent changes in their area. Dipiro's *Pharmacotherapy: A Pathophysiologic Approach*,<sup>2</sup> *Basic & Clinical Pharmacology*,<sup>3</sup> and *Goodman and Gilman's The Pharmacological Basis of Therapeutics*<sup>4</sup> are all available both in print, as well as electronically through Access Pharmacy. The online resources include additional online updates. The classic title *Foye's Principles of Medicinal Chemistry*<sup>5</sup> is available through a variety of ebook vendors, as well as in print.

## NOMENCLATURE

To locate comprehensive information concerning a drug, the researcher should know the nonproprietary name. Most databases use this name in its controlled vocabulary and may map the brand name to the nonproprietary or generic name. For research into the early development of drugs the chemical names, CAS registry numbers or investigational names are also useful. The two most commonly used resources for naming conventions are the *USP Dictionary of USAN and International Drug Names*<sup>6</sup> and the World Health Organization's *International Nonproprietary Names (INN)*.<sup>7</sup> The researcher should be aware that the INN name is sometimes different from the US Adopted Name.

The *American Drug Index*<sup>8</sup> is published annually and includes over the counter drugs, combination products, and drugs currently available in the United States. There is a convenient list of manufacturers and distributors included, along with other useful information at the end of the drug monographs.

The *Merck Index: An Encyclopedia of Chemicals, Drugs, and Biologicals*<sup>9</sup> provides chemical, nonproprietary, and generic names, as well as graphic chemical structures, CAS Registry Numbers, and chemical formulas. There is a comprehensive cross index to the monographs. The monographs also include useful references to articles, patents, and other tertiary sources on preparation and to comprehensive descriptions of the drug, such as the monograph of the drug in the *Profiles of Drug Substances, Excipients and Related Methodology*.<sup>10</sup> There are also many supplementary tables and organic name reactions. The online version includes structure searching as well.

*Index Nominum: International Drug Directory*<sup>11</sup> is a valuable resource for researchers searching for foreign drug substances. Information on over 5,300 drugs includes the therapeutic category and manufacturer or country. There is also information on approximately 10,000 manufactures around the world.

*Japanese Accepted Names for Pharmaceuticals*<sup>12</sup> is a free online database maintained by the Japanese National Institute of Health Sciences (<http://jpdh.nihs.go.jp/jan/index.aspx>). It is searchable by the CAS Registry Number, the chemical name, or the Japanese Accepted Name.

## PHARMACOPEIAS AND RESOURCES FOR DRUG AND EXCIPIENT STANDARDS

A pharmacopeia is a list of drugs and drug products that describes the purity, strength, method of preparation, and other information. Pharmacopeias are issued or authorized by governments or international agencies. The *United States Pharmacopeia/National Formulary*<sup>13</sup> (USP/NF) is compiled by a non-governmental organization, the United States Pharmacopeial (USP) Convention (<http://usp.org>), and recognized by the Federal Food, Drug, and Cosmetic (FDC) Act as the official

pharmacopeia of the United States. It contains a list of those drugs, drug products, dietary supplements, excipients, and other relevant compositions for which standards have been agreed to by the USP Convention. The Convention is a representative group of volunteers from the various stakeholders—health-care practitioners, industrial scientists, and educators. The USP/NF is revised yearly and supplemented by updates. The *Pharmacists Pharmacopeia*<sup>14</sup> contains the information from the USP/NF most relevant to practicing pharmacists, along with additional helpful resources, and is updated less often.

The *Japanese Pharmacopeia* is published by the Japanese government through its Pharmaceuticals and Medical Devices Agency (PMDA). It is available in both Japanese and English versions. More information on the Japanese Pharmacopeia can be found at the PMDA website (<http://www.pmda.go.jp/english/pharmacopoeia/about.html>).<sup>15</sup> The European Directorate for Quality of Medicines and Healthcare (EDQM) publishes the *European Pharmacopeia*.<sup>16</sup> (More information is available at <http://www.edqm.eu>). The International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) is working with the regulatory authorities of the United States, Japan, and Europe to find and encourage commonalities among these three major pharmacopeias.

Other countries have well-recognized pharmacopeias, such as the *British Pharmacopeia*<sup>17</sup> (BP), published by British Pharmacopoeia Commission Secretariat of the Medicines and Healthcare products Regulatory Agency. *Martindale: The Complete Drug Reference*<sup>22</sup> is the new name for Martindale's Extra Pharmacopeia, which lists more than 6,000 drugs found internationally.

Standards for excipients can be found in these pharmacopeias. In addition, the *Handbook of Pharmaceutical Excipients*,<sup>18</sup> although not an official pharmacopeia, is a widely used resource for standards and functionality of excipients. Additionally, since many excipients are also food additives, they can be found in the *Food Chemicals Codex*,<sup>19</sup> published by the United States Pharmacopoeial Convention. Finally, the "GRAS list" is a listing of additives that are generally recognized as safe (<http://www.fda.gov/Food/FoodIngredientsPackaging/GenerallyRecognizedasSafeGRAS/GRASSubstancesSCOGSDatabase/default.htm>). The list can be found in searchable form in the Select Committee on GRAS Substances (SCOGS) database. Each of more than 370 entries provides the opinion of the Select Committee and the year in which the opinion was rendered.

## DRUG INFORMATION ON PRESCRIPTION PRODUCTS

The most popular resources for finding basic background information on drugs include the following titles: The American Society of Health-System Pharmacists publishes the *AHFS Drug Information: American Hospital Formulary Service*,<sup>20</sup> a well-recognized reference on prescription drugs. It is organized by therapeutic category, with a general overview of the category, including drug interactions, before the individual listings of the drugs. The succeeding individual drug monographs include the uses, dosage and administration, cautions, pharmacokinetics, chemistry, and stability. Preparations and comparative pricing are included in the online version of this resource. Mobile versions of this resource are also available.

Most pharmacies have traditionally had a loose-leaf copy of *Drug Facts and Comparisons*<sup>21</sup> on their shelves. Updated monthly, it is a reliable current resource. The drug monographs are arranged by therapeutic category and class hierarchy. The online version, *Facts and Comparisons eAnswers*, includes a variety of tools, including clinical calculators, drug identifiers, and the ability to view comparative data tables and side-by-side monograph summaries of two or more drugs. There is also a mobile version of the databases.

*DRUGDEX* is part of the *MICROMEDEX* online suite of databases from Thomson Reuters and is often available at hospital pharmacies and health centers. *DRUGDEX Evaluations* mono-

graphs are remarkably thorough and well referenced. Dosing information, pharmacokinetics, cautions, and clinical applications are well covered. Although *DRUGDEX* focuses on prescription drugs, it also includes information on some investigational and nonprescription drugs. There is also a mobile version.

*Martindale: The Complete Drug Reference*<sup>22</sup> is a comprehensive listing of worldwide drugs, including herbal medicines. It is also available electronically, through a variety of vendors, and is included in the *MICROMEDEX Healthcare Series*.

Other international drug compendia include *CPS: Compendium of Pharmaceutical Specialties*,<sup>23</sup> from the Canadian Pharmaceutical Association; *Diccionario de Especialidades Farmaceuticas*,<sup>24</sup> providing drug and pharmaceutical information from Mexico; *Rote Liste*,<sup>25</sup> with complete coverage of drugs and medicines available in Germany; and *Vidal: le dictionnaire*,<sup>26</sup> a compendium of French drug and consumer health-care products.

The *Orange Book: Approved Drug Products with Therapeutic Equivalence Evaluations*<sup>27</sup> is often simply referred to as the Orange Book. It is available for free at the US Food and Drug Administration website (<http://www.fda.gov/cder/ob>). This government resource is searchable by active ingredient, proprietary name, or by patent number. Therapeutic equivalence, drug approval date, and marketing status (prescription, nonprescription, or discontinued) are listed on a summary page for each drug formulation, as well as patent and exclusivity information.

Trissel's *Handbook on Injectable Drugs*<sup>28</sup> summarizes information on parenteral drug stability and compatibility for clinicians. In the most recent edition, there are 372 monographs arranged alphabetically by nonproprietary name. There is also an Appendix with parenteral nutrition formulas.

The *Drug Topics Red Book*<sup>29</sup> covers both prescription and nonprescription products. Each drug entry includes product and supplier names, the National Drug Code number, route of administration, strength and quantity, and Average Wholesale Price and Direct Price. This book is used primarily by pharmacists and pharmacy students for drug price information. Additionally, there are many lists, including manufacturers' addresses and phone numbers, state boards of pharmacy, and a product identification guide with color photos.

## DRUG INFORMATION ON COMPOUNDED PREPARATIONS

Like manufactured drug products, compounded preparations must be safe and efficacious for the entire period of their use. Existing drugs are prepared or compounded in new dosage forms, sometimes for new routes of administration designed to meet the needs of individual patients. In addition to safety and efficacy, stability, solubility, and permeability are often information required to prepare a new formulation or evaluate an existing formulation. The *United States Pharmacopeia*<sup>14</sup> and the *Pharmacists' Pharmacopeia*<sup>30</sup> contain official monographs of compounded preparations that have been evaluated by experts in the field to meet the quality and purity standards for the period prior to the "beyond use date." Additional formulations can be found in standard texts, such as *The Art Science and Technology of Pharmaceutical Compounding*.<sup>31</sup> Formulations specific for certain patient populations are found in references, such as *Plumbs' Veterinary Drug Handbook*<sup>32</sup> and *Pediatric Drug Formulations*.<sup>33</sup> Although many texts provide formulation and preparation information, one must generally search the primary literature to find the limited data on efficacy of these specialized dosage forms. International Pharmaceutical Abstracts (IPA) is the preferred database for finding such information. IPA is also a useful database to find stability information for those drugs and drug preparations not listed in *Trissel's Stability of Compounded Formulations*.<sup>34</sup> Journals that often contain new formulations along with stability data are *International Journal of Pharmaceutical Compounding* (Edmond, OK; IJPC) and *American Journal of Health-System Pharmacy* (Bethesda, MD; American Association of Health-System Pharmacists).

## DRUG INFORMATION ON NONPRESCRIPTION PRODUCTS

Although there is some information on nonprescription drug products in the prescription drug resources listed previously in this chapter, the most valuable resource for this information is the *Handbook of Nonprescription Drugs: An Interactive Approach to Self-Care*,<sup>35</sup> which is available both in print and in PharmacyLibrary, the new electronic package from the American Pharmacists Association. The handbook is arranged into sections beginning with the practitioner's role in self-care, followed by sections on diseases, with chapters arranged in each section by body systems; a section on home medical equipment; and a section on complementary and alternative medicine. To help pharmacy students develop problem-solving skills, case studies are provided in each section. Chapter updates are available for the online version.

The *Physicians' Desk Reference for Nonprescription Drugs, Dietary Supplements and Herbs*<sup>36</sup> is a useful supplement to the *Handbook of Nonprescription Drugs: An Interactive Approach to Self-Care*.<sup>35</sup> It is available in print and electronically.

## HERBAL MEDICINES AND NATURAL PRODUCTS

Herbal medicines and natural products are very popular with consumers, who often perceive the terms "natural" or "herbal" as connoting safety. Hence, there is active research in this area, and students and pharmacists need to be well informed. Luckily, there are a variety of well known textbooks and tertiary databases on this subject. *Trease and Evans' Pharmacognosy*<sup>37</sup> is a classic, basic textbook, now in its 16<sup>th</sup> edition. It focuses on the use of plants in medicine, covering plant taxonomy, commercial production, biological activity, and phytochemical examination and investigation of herbal products. *Tyler's Honest Herbal: A Sensible Guide to the Use of Herbs and Related Remedies*<sup>38</sup> provides well-referenced monographs on herbs and their efficacy and safety. It is a good starting point for researchers and useful for consumers, although consumers may view the standards for rating efficacy as too conservative. *Leung's Encyclopedia of Common Natural Ingredients Used in Food, Drugs, and Cosmetics*<sup>39</sup> is a more extensive resource covering the source, chemical composition, pharmacology and biological activity, uses, and commercial preparation of each natural ingredient. It is extensively referenced, with appendices providing glossaries of abbreviations and botanical terms and morphological descriptions of plant organs.

Online resources provide search options and special features. Two well known natural product databases are Natural Standard and Natural Medicines Comprehensive Database. Natural Standard provides evidence-based information about alternative and complementary therapies and has a variety of databases. Each therapy is graded according to the evidence for its effectiveness in treating a particular medical condition. Natural Standard databases include Foods, Herbs, and Supplements; Comparative Effectiveness; and Genomics and Proteomics. Natural Medicines Comprehensive Database from Therapeutics Research Center covers natural medicines sold in North America and has evidence-based comprehensive monographs on these medicines, as well as a natural product effectiveness checker. Checkers for interactions and depletions, patient education handouts, and Continuing Education Programs are also available with both databases. Both natural product databases have mobile and print versions and provide RSS feeds.

## DRUG INTERACTIONS, SIDE EFFECTS AND ADVERSE REACTIONS

Patients and pharmacy practitioners are very concerned about interactions, side effects, and adverse reactions. These also concern pharmaceutical scientists developing new products.

*Meyler's Side Effects of Drugs: An Encyclopedia of Adverse Reactions and Interactions*<sup>40</sup> has a long history. According to the Preface of the 15<sup>th</sup> edition of *Meyler's Side Effects of Drugs:*

*An Encyclopedia of Adverse Reactions and Interactions*, Leopold Meyler, a Dutch physician, experienced adverse drug effects in the 1940s, while undergoing treatment for tuberculosis. He searched for information on this topic and, finding only a 19<sup>th</sup> century tome, he went to work to fill this significant gap. The first edition of this work was published in Dutch in 1951, and an English edition was published in 1952. Editions of *Meyler's Side Effects of Drugs: An Encyclopedia of Adverse Reactions and Interactions* are updated by *Side Effects of Drugs Annual*<sup>41</sup> and cover prescription drugs, anesthetics, antiseptics, drugs of abuse, herbal medicines, and devices and methods in alternative medicine. *Meyler's Side Effects of Drugs: An Encyclopedia of Adverse Reactions and Interactions* is available both in print and electronic formats.

*Drug Interactions Analysis and Management*<sup>42</sup> is written by two well-known authorities in this area, Philip D. Hansten, PharmD and John R. Horn, PharmD. The focus is on the management of drug interactions and gives the reader options to avoid patient harm and decrease risk. Suggestions regarding monitoring and alternative drugs are recommended when appropriate. Specific information on each interaction also includes risk factors, the mechanism of action, a clinical evaluation of cited reports, closely related drugs that may interact in a similar manner, and references. Each interaction is also assigned a Significance Number, which is based on the intervention needed to minimize risk.

An important specialty resource is *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk*.<sup>43</sup> This resource provides fetal risk and breast feeding risk summaries, which include animal reproduction data, placental transfer, reports of human pregnancy exposure, and a list of references for more than 1200 drugs. A related database is the Drugs and Lactation Database (LactMed), one of the TOXNET set of databases. It focuses on the levels of the drug in breast milk and infant blood and the possible adverse effects on the nursing infant.

Another special topic is covered by *Food-medication Interactions*,<sup>44</sup> available either as a spiral bound book or a mobile version. More than 1000 drug monographs are arranged alphabetically and cover drug class or action; side effects; renal, hepatic, cardiac, and pregnancy information; contraindications; monitoring information; and special dietary precautions and nutritional effects. There are many tables, including a useful laboratory value table. Canadian brand names are exclusive to the mobile version.

Medication safety is a major concern. *Drug-induced Diseases: Prevention, Detection, and Management*<sup>45</sup> provides information for students and health care practitioners to address and improve the standard of care regarding drug-induced diseases. This comprehensive textbook introduces the magnitude of the problem and follows up with sections arranged by anatomical region, such as drug-induced gastrointestinal diseases.

## POISONING AND TOXICOLOGY

Two well known textbooks on toxicology are *Casarett and Doull's Toxicology: The Basic Science of Poisons*<sup>46</sup> and *Goldfrank's Toxicologic Emergencies*.<sup>47</sup> *Casarett and Doull's Toxicology* covers the various aspects of the subject, including toxicokinetics, carcinogenicity, mutagenicity, developmental toxicology, target organ toxicity, toxic agents, environmental toxicology, food toxicology, analytic toxicology, clinical toxicology, and occupational toxicology. *Goldfrank's Toxicologic Emergencies* presents in-depth information on antidotes, general principles, and techniques to evaluate and manage toxic exposures, biochemical toxicology, organ system principles, and classes of compounds. Case studies and study questions are given, and the answers are provided at the end of the book.

TOXNET is a set of databases made available by the US National Library of medicine (<http://toxnet.nlm.nih.gov/>). They provide indexing and abstracting and full text information concerning toxicology, hazardous chemicals, environmental

health, and toxic releases. Databases may be searched individually or as a set. The Hazardous Substances Databank (HSDB) contains more than 5000 chemical records and is enhanced with additional material on nanomaterials, regulatory requirements, and emergency handling procedures. Other TOXNET databases include the Chemical Carcinogenesis Research Information System (CCRIS), Integrated Risk Information System (IRIS), GENE-TOX, and the previously described LactMed database. The National Cancer Institute provides data on mutagenicity and tumor promotion and inhibition in CCRIS. IRIS contains data in support of human health risk assessment and is compiled by the US Environmental Protection Agency (EPA). GENE-TOX, created by the US EPA, contains genetic toxicology (mutagenicity) test data on more than 3000 chemicals and recommends proper testing protocols and evaluation procedures.

## FORMULATION AND MANUFACTURING

Many of the standard textbooks on formulation and manufacturing are now quite dated. There is a need for additional educational material in this area. The National Institute of Pharmaceutical Technology and Education (<http://nipte.org/>), which is dedicated to fundamental research and education in pharmaceutical product development and manufacturing, has developed a draft curriculum in this area; development of educational resources is a planned activity of the group. In the meantime, the *Encyclopedia of Pharmaceutical Technology*<sup>48</sup> has monographs on many of the aspects related to formulation and the various pharmaceutical manufacturing processes. For detailed information on drug substances necessary for pre-formulation research, Britain's *Profiles of Drug Substances, Excipients, and Related Methodology*<sup>10</sup> provides comprehensive monographs. Additionally, PharmaHub (<http://pharmahub.org/>) has an increasing array of useful databases and process modeling software for formulation and manufacturing.

## PRODUCT IDENTIFICATION

Emergency and other medical personnel need to be able to quickly identify capsules or tablets. Many resources include sections on identifying drug or related products. These include the *Physician's Desk Reference*, the *Red Book*, and several online and mobile resources, including Facts and Comparisons eAnswers and Lexi-Comp. The two most well-known titles are *Ident-a-drug Reference*,<sup>49</sup> which identifies the drug by the color, shape, size, and imprint code, and the *IDENTIDEX System*, a part of *MICROMEDEX*.

## CONSUMER DRUG INFORMATION

It is important to know where to find reliable and accurate consumer drug information, especially since consumers frequently use the internet to find information. There are many such resources on the internet. MedlinePlus from the US National Library of Medicine (<http://www.medlineplus.gov>) includes a vast array of features for the consumer, including information on drugs and supplements and a medical dictionary with pronunciation. Drugs.com includes an Interactions Checker. WebMD includes a useful Pill Identifier tool.

An example of expanded access to drug information on the internet is the Drug Information Portal (<http://druginfo.nlm.nih.gov>), which provides a search interface to information on more than 20,000 drugs from US government agencies, including the National Library of Medicine. There is information for researchers, clinicians, students, and consumers.

Two popular print resources include the *Pill Book*<sup>50</sup> and the *Complete Guide to Prescription and Nonprescription Drugs*.<sup>51</sup> The *Pill Book* includes information on affordable generic alternatives, side effects, adverse effects, drug-drug and drug-food interactions, addictiveness, safe handling of injectables, and when to call the physician. Aside from the usual drug information, the *Complete Guide to Prescription and Nonprescription Drugs* includes the length of time before a drug starts working and warnings regarding premature discontinuation of a drug.

At the beginning of the book, there is a list of commonly used drugs to treat specific diseases or conditions.

## PERSONALIZED MEDICINE

As pharmacists become more focused on the individual patient, pharmacogenetics is becoming more important than ever before. Two valuable resources in this area are Ginsberg and Willard's *Essentials of Genomic and Personalized Medicine*<sup>52</sup> and Catania's *An A-Z Guide to Pharmacogenomics*.<sup>53</sup> *Essentials of Genomic and Personalized Medicine* provides an overview of the field, with translational approaches to bring the information into the clinical world. *An A-Z Guide to Pharmacogenomics* introduces the terminology and techniques related to this growing field to students and professionals who have a basic understanding of molecular biology.

## PROFESSIONAL ASSOCIATIONS

Associations for almost every specialty of pharmacy in the various regions of the United States and around the world can be found at the Virtual Pharmacy Library (<http://www.pharmacy.org/>) by clicking on the Associations tab. The list of more than 100 pharmacy-related associations is complete, with links to the association's website.

## EMERGING TRENDS

The majority of electronic books are still simply copies of the original print versions. Although they can be accessed from anywhere at any time, they are still rather static. According to the *2011 Horizon Report*,<sup>54</sup> the product of collaboration between the EDUCAUSE Learning Initiative (ELI) and the New Media Consortium, this is rapidly changing, and the newer electronic books with added features will become more in demand than the print. Social features will connect the reader to other researchers, enabling collaboration. Self-directed, interactive experiences and activities are beginning to be provided. Videos and other audiovisual resources will integrate into these electronic resources. Links to supporting materials can enrich the reading experience. Cloud tags will make locating useful chapters or sections vastly simpler.

Mobile resources have been used by pharmacy professional students, pharmacists, and faculty for several years. According to the *2011 Horizon Report*, "Internetcapable mobile devices will outnumber computers within the next year." With the spread of smart phones and other devices, students and scientists will demand more resources and applications compatible with the platforms they have chosen. One example is PubMed on Tap, which allows the user to search PubMed and manage references from the iPod Touch, iPhone, or iPad.

Data planning and management is becoming a major thrust in the sciences. Websites, such as pharmaHUB at [pharmahub.org](http://pharmahub.org), were created to facilitate the collaborative creation and sharing of pharmaceutical engineering and science information and modeling tools. The PharmaHUB website states that their goal is to "support innovations in product and process development and manufacturing methodology for pharmaceutical products."<sup>55</sup> This is an area in which the amount of data can be massive, and this data has been isolated in individual research groups or institutes until now. Sharing the data will allow faster progress in the research area.

## FOR FURTHER INFORMATION

The American Association of Colleges of Pharmacy Libraries/Educational Resources Section's Basic Resources for Pharmacy Education (<http://www.aacp.org/governance/SECTIONS/libraryinformationscience/Pages/LibraryInformationscienceSpecialProjectsandInformation.aspx>) provides a benchmark to use in selecting many of the resources listed herein and is a good place to explore for more references in a specific pharmacy related field. An excellent book on pharmaceutical resources is Bonnie Snow's *Drug Information: A Guide to Current Resources*.<sup>56</sup>

**ACKNOWLEDGMENTS:** The previous version of this chapter was written by three colleagues at the University of the Sciences in Philadelphia: Leslie Ann Bowman, Mignon S. Adams and Amy Christopher. Although we have chosen to organize our material in our own way, reviewing their version has provided a valuable point of reference.

APPENDIX A 22

APPENDIX B 24

The aim of this chapter is to provide the pharmaceutical scientist with a general overview of the analytical testing that is performed in order to release a medicinal product for clinical or commercial use and specifications that ensure the quality and performance of the medicinal product being released.

### SPECIFICATIONS

The pharmaceutical manufacturer is responsible for ensuring the quality, purity, identity, and strength of each lot of drug product manufactured. One mandatory control strategy is to ensure that the lot “conforms to specification,” which means that the drug product (formulated preparation), when tested to the listed analytical procedures, will meet the listed acceptance criteria.<sup>1</sup> Specifications are critical quality standards.

A specification is a document that is defined as a list of tests, references to analytical procedures, and appropriate acceptance criteria (numerical range or limit).<sup>1</sup> The pharmaceutical manufacturer justifies the information on the specification, which is approved by regulatory authorities. Examples of specifications for hypothetical drug products are provided in Appendix A.

Specifications can be categorized in a couple of manners. One way is by the intended use of the product. For example, is the medicinal an investigational product intended for use in a clinical study, or is it a commercial product that will be marketed? Let's consider the evolution of a hypothetical oral drug product as it enters the clinic for single- and multiple-ascending dose safety studies during Phase 1 clinical studies, then multiple-ascending dose efficacy studies in Phase 2a, and confirmatory efficacy studies in Phase 2b and Phase 3. In order to enter the clinic rapidly, a simple drug product called a drug-in-capsule was chosen for Phase 1. This dosage form consists of neat drug (no excipients) that has been accurately weighed into gelatin capsules. The manufacturing process meets the volume demand for Phase 1, but the dosage form must be changed prior to scaling-up to Phase 2. Hence, the drug-in-capsule is a “lame duck” dosage form. Specifications for investigational products tend to have acceptance criteria that reflect the early life of the product. Here, the acceptance criteria for dissolution of our drug-in-capsule may be “record result.”

Now let's say that our drug-in-capsule drug product will be replaced with a dosage form that is manufactured using a scalable manufacturing process — a tablet for Phase 2. The tablet will first be used in Phase 2 ascending-dose clinical studies, so several dose strengths will need to be manufactured. Let's say that these dose strengths are 10, 25, and 100 mg. The acceptance criterion for the dissolution test may remain as “record result” because the dosage form is new, or the criterion may be a “disaster check” criterion. Although the analytical chemist may

not be able to assign a strict acceptance criterion because of the limited data, a slow-dissolving drug from an immediate-release tablet may jeopardize the interpretation of the clinical results. So a criterion like 70 percent of the drug dissolved after 60 minutes may be appropriate for the 100-mg tablet. The lower dose strengths are usually assigned the same acceptance criterion.

Finally, the tablet has entered late development and will be used for confirmatory studies. The dose ranging Phase 2a studies determined that the efficacious dose was 60 mg, so a new 60-mg tablet was developed for use in the Phase 3 studies. During Phase 3, a robust manufacturing process has been developed at suitable scale, a robust dissolution test also has been developed and validated, and many lots of tablets have been manufactured and analyzed. Now, a suitable acceptance criterion at the time of NDA or MAA submission may be 70 percent of the drug dissolved after 30 minutes.

Another common categorization involves using different acceptance criteria for release testing and stability testing in order to account for changes that may occur during the shelf life. For example, a topical cream may become less viscous upon storage at 25°C to 30°C for two years. The cream may be too fluid to apply when its viscosity is less than 1000 mPa·s. A suitable acceptance criterion for a stability specification may be 2000 mPa·s. Let's say that the development data indicate that in order to ensure a viscosity of 2000 mPa·s at the end of the shelf life, the cream must have a viscosity of 10,000 mPa·s at the time of release. Therefore, the acceptance criteria for the release and stability specifications would be not less than (NLT) 10,000 mPa·s and NLT 2000 mPa·s, respectively, in order to ensure a quality product for its entire shelf life.

### COMPENDIA

All drug products, whether commercial or investigational, must meet standards that have been established by Pharmacopoeial Conventions or Regulatory Agencies. The United States Pharmacopoeial (USP) Convention is a scientific nonprofit organization that sets standards for the quality, purity, identity, and strengths of medicines, food ingredients, and dietary supplements manufactured, distributed, and consumed worldwide.<sup>2-4</sup> USP drug standards are enforceable in the United States by the Food and Drug Administration, and these standards are developed and relied upon in more than 130 countries.<sup>2,4</sup>

The European Pharmacopoeia (Ph. Eur.) Commission establishes official standards that provide a legal and scientific basis for quality control during the development, production, and marketing of medicines in 37 signatory states of the convention.<sup>5,6</sup> In addition to the signatory states, which comprise 26 countries and the European Union, there are a large number

of observers of Ph. Eur. Twenty-two countries (including Australia, Brazil, Canada, China, the Russian Federation, and the United States) and the World Health Organization are listed as observers. Consequently, the standards developed by Ph. Eur. have an impact on the quality of medicines across the globe.<sup>5,6</sup>

The USP and Ph. Eur. publish books of pharmacopeial standards. The thirty-fourth revision of the USP and the twenty-ninth edition of the National Formulary, USP 34-NF29, became official on May 1, 2011. The USP-NF is continuously revised. Standard revisions are found in supplements to the USP-NF that are published twice yearly. Accelerated revisions are published in Pharmacopeial Forum (PF) and on the USP website, www.usp.org. A new edition of USP-NF becomes official each year on May 1. Chapters <1> through <999> are enforceable chapters, while Chapters <1000> through <1999> are informational chapters.<sup>3</sup>

The seventh edition of the *European Pharmacopoeia* (Ph. Eur. 7. 0) became official on January 1, 2011. This edition will be augmented with eight supplements over a three-year period.<sup>5</sup> The eighth edition of Ph. Eur. will become official on January 1, 2014. The *European Pharmacopoeia* is published in English and French.

The *British Pharmacopoeia* (BP) is the official collection of standards for UK medicinal products and pharmaceutical substances.<sup>7</sup> The standards are established by the *British Pharmacopoeia Commission*. Canada and Australia also use the BP as their official standards. The BP is recognized in over 100 countries as an internationally acceptable standard and remains an essential reference for all individuals and organizations working within pharmaceutical research, development, manufacture, and testing across the globe.<sup>8</sup> A new edition of the BP becomes official each year on January 1.

Japan's Ministry of Health, Labor, and Welfare (MHLW) publishes *The Japanese Pharmacopoeia* (JP), which provides an official standard to ensure the quality of medicines in Japan.<sup>9-11</sup> *The Japanese Pharmacopoeia, Sixteenth Edition* (JP 16) became official on April 1, 2011. JP 16 is printed in Japanese only at the time of publication of this chapter. JP 15, however, is available in English. Both editions can be found on *The Japanese Pharmacopoeia* website and are free of charge.

## MONOGRAPHS

A monograph is written after a drug product has been registered and established in the marketplace and usually before its patent expires. The USP defines a monograph as a written standard that describes an article (e.g., drug substance, drug product, excipient, compounded preparation).<sup>12</sup> A monograph published in any USP compendium provides the name of a substance; its definition; package, storage, and labeling requirement; and information on tests needed to ensure the substance is of the appropriate identity, strength, quality, and purity.<sup>3</sup> The later part of a monograph is similar in scope to a specification.

The monograph gives manufacturers, governments, and scientists a public standard by which to judge an article's quality. Monographs play an important role in meeting the USP's mission by providing standards for substances consumed in a global marketplace—standards that help maintain public health. The USP-NF comprises more than 4000 monographs.<sup>12</sup> The USP contains monographs for drug substances and preparations (drug products); excipient monographs are in the NF.

The *European Pharmacopoeia* contains more than 2000 general and specific monographs, including chemical substances, antibiotics, vaccines, dosage forms, herbal drugs, and homeopathic preparations.<sup>5</sup> One major difference between the Ph. Eur. and USP is illustrated by this example: the USP has monographs for tablets of a specific drug (e.g., amoxine), whereas Ph. Eur. will have only a general monograph for tablets. The BP and JP also contain monographs of drug substances and drug products. The BP, which contains over 3000 monographs, incorporates monographs of the *European Pharmacopoeia*.<sup>13</sup>

## RELEASE AND STABILITY TESTING

The release and stability testing can be classified in a couple of practical ways. One is by the nature of the testing performed: chemical, physical, and microbial. For example, the assay for the amount of active ingredient in a gel would be a chemical test, the viscosity measurement and the *in vitro* release test would be physical tests, and the microbial limits test would be a microbiological test. This classification system is often used in analytical laboratories that are specialized by the type of test being performed. The chapters in pharmacopeia are also organized by the nature of the test.<sup>3,5,9,10</sup>

Another classification system that is used is based on the attribute that is being tested. For example, the ICH Guidances and the USP provide two categories for the system: analytical tests and acceptance criteria for assessing (1) general quality attributes and (2) product performance.<sup>1,14-17</sup> Using the previous gel example, the assay, viscosity, and microbial limits tests would be examples of tests that assess general quality attributes while the *in vitro* release test would assess product performance.

## UNIVERSAL TESTS

There are four tests that are generally applicable to all drug products: description, identification, assay, and impurities.

### DESCRIPTION

This test is often called “appearance” on a specification and is a qualitative description of the dosage form. For example, the description of a tablet on a specification may read: white, round, biconvex, film-coated tablet, imprinted with “400” on one side.

### IDENTIFICATION

The purpose of an identification or identity test is to verify the identity of the active pharmaceutical ingredient(s) (API) in the dosage form. This test should be able to discriminate between compounds of closely related structure that are likely to be present. Infrared and Raman spectroscopy are commonly used techniques. A more practical technique, however, is high-performance liquid chromatography because the identity and assay can be determined using the same analytical method. The ICH Q6A Guidance, however, does not regard identification solely by a single chromatographic retention time as being specific, the definition of which is the ability of the method to assess unequivocally the analyte in the presence of the sample matrix (excipients, impurities, and degradation products). Thus, some laboratories will couple a diode array or mass spectrometric (MS) detector to the HPLC system. The diode array detector provides a UV spectrum of the drug; the MS detector gives the nominal mass of the drug.

### ASSAY

This test determines the strength or content of the API in the dosage form and is sometimes called a content test. The method should be stability-indicating, which means that the method is quantitative and specific and can detect chemical changes with respect to time, so that the quantity of the active ingredient(s) can be accurately and precisely measured in the presence of the sample matrix. HPLC is the most common technique used for stability-indicating methods.

### IMPURITIES

ICH Guidance Q6A defines an impurity in a drug product as any component that is not the API or an excipient. The most common type of impurities that are measured is related substances, which are process impurities from the new drug substance synthesis, degradation products of the API, or both. The test for related substances is often referred to as a purity test and must be stability indicating. The method can be the same as that used for assay, or it can be a different method that has been developed for measuring low-level impurities. An additional method

to measure chiral purity may be used to quantify enantiomeric impurities in the drug product. In cases in which an organic solvent is used during the manufacture of the drug product, a method for measuring residual solvents is also used.

## METHOD VALIDATION FOR UNIVERSAL TESTS

The objective of validation of an analytical method is to demonstrate that it is suitable for its intended purpose.<sup>3,5,18,19</sup> Therefore, the objective of the analytical method will govern the validation characteristics that need to be evaluated. Typical validation characteristics are specificity, accuracy, precision, linearity, range, robustness, detection limit, quantitation limit, and sample and standard stability. Well-characterized reference materials, with documented purity, should be used throughout the validation study.<sup>19</sup> A validation protocol that describes the validation experiments to be performed and their pre-determined validation performance criteria is required. In early development, a department Standard Operating Procedure (SOP) can be used instead of a protocol, provided that the SOP clearly outlines the validation experiments and validation performance criteria. Let's examine the characteristics evaluated for each of the four universal tests and typical acceptance criteria that accompany each test on the specification.

### ASSAY

#### Acceptance Criteria

The results from an assay are usually expressed as a percentage of the label claim with acceptance criteria that are typically in the range from 90.0 to 110.0 percent label claim. For example, a manufactured lot of 500-mg aspirin tablets with these acceptance criteria would have an average assay value between 450 and 550 mg. The width of these limits is to allow for manufacturing variability and shelf-life stability. In some cases, such as narrow-therapeutic drugs, the acceptance criteria may be from 95.0 to 105.0 percent label claim.

#### Validation Characteristics

Assay methods are validated for specificity, linearity, range, accuracy, precision, robustness, and sample and standard stability.<sup>18,19</sup> Validation of detection limit and quantitation limit is not needed unless the same method is used to quantify related substances.

#### SPECIFICITY

Most assays are performed using HPLC. Specificity can be demonstrated in a number of ways. A common approach is to spike each impurity and excipient into the analytical solution at an appropriate level and compare the results of the spiked samples against those of the unspiked samples to demonstrate that the presence of the impurities or excipients does not affect the assay result. Of course, this approach works only if authentic samples of the impurities are available.

If the impurities are not available, the API, or the dosage form, is subjected to forced degradation conditions, and the degradants and synthetic process impurities are separated from the API, using the method that is being validated, as well as other methods that make use of different stationary phases (chromatographic columns) and chromatographic conditions (mobile phase components and gradients, flow rate). Diode array or MS detection is often used. The goal here is to demonstrate that no impurity co-elutes with the API in the validated method.

The forced degradation conditions that are often used in the analytical laboratory for method development and validation are dissolving the API (with or without excipients) in an aqueous or aqueous-organic solvent and exposing the solution to acidic, basic, and nucleophilic and free radical oxidation conditions. It is important to control the degradation to less than about 10 percent in order to make the forced degradation

experiments representative of the degradation that might be seen during the shelf-life of the drug product and to decrease the probability of the degradants reacting with each other or degradants reacting with the API.

In addition, the API and the dosage form should be exposed to a variety of moderately stressed stability conditions, such as light and prudently selected combinations of heat and humidity in order to degrade the material "purposefully." Some common storage conditions for purposeful degradation of a solid-dosage form include 40°C and 75 percent relative humidity (40/75) in high-density polyethylene (HDPE) bottles, 40/75 in an open dish (containerless), 60/75 in HDPE bottles, and 60/75 in an open dish. Some pharmaceutical companies have formed purposeful-degradation groups that are tasked with identifying "soft spots" on API molecules, understanding the degradation chemistry, identifying impurities, conducting purposeful degradation studies, and proposing stabilization strategies to prevent or inhibit chemical degradation.<sup>20</sup>

If the API is volatile, gas chromatography (GC) can be used for the assay test. Just as with HPLC, more than one method should be used to demonstrate specificity. Gas chromatography with mass spectrometric detection (GC-MS) is useful to accomplish this goal. In cases in which a non-specific assay, such as titrimetry or UV spectrophotometry, is used, other supporting methods and knowledge of the degradation chemistry can be used to demonstrate overall specificity. The use of non-specific methods to determine assay, however, is not recommended, given the advances in chromatographic and detection technology. The USP is actively modernizing official USP-NF monographs for small-molecule API and their dosage forms that use outdated analytical technology or have non-specific identification and assay tests.<sup>21</sup>

#### LINEARITY AND RANGE

A linear relationship should be evaluated across the range of the analytical method. For a drug product that has assay acceptance criteria of 90.0 to 110.0 percent label claim, linearity is usually demonstrated minimally from 80.0 to 120.0 percent. Some companies have a policy to demonstrate linearity over an expanded range from 70.0 to 130.0 percent. The linearity can be demonstrated directly on the API or on separate weighings of API and excipient mixtures.

#### ACCURACY

The accuracy of an analytical method expresses the closeness of agreement between the value found using the method and either an accepted reference value or a conventional true value. Accuracy is also termed *trueness*. A common way that accuracy of a method is evaluated is by performing "spike and recovery" experiments. Here, a known quantity of drug substance is spiked into a placebo matrix and compared to a reference solution that contains a known amount of drug substance. The compatibility of the analyte with the filter used during sample preparation is often formally evaluated at this time. Another common way to validate the accuracy of a method is to compare the results obtained from the method being validated to those obtained from a second well-characterized procedure.

Accuracy should be assessed using at least nine determinations over a minimum of three concentration levels (three different concentrations with three replicates of each concentration) that cover the specified range.

Accuracy can be inferred once precision, linearity, and specificity have been established. This approach is more common in early development activities, such as IND-enabling toxicology studies or Phase 1 clinical studies.

#### PRECISION

The precision of an analytical method expresses the closeness of agreement between a series of measurements obtained from multiple samplings of the same homogeneous sample under the prescribed conditions.<sup>18,19</sup> The precision of a method is best

evaluated using authentic homogeneous samples. If authentic samples are not available, artificially prepared samples or a sample solution may be used.

Precision is considered at three levels: repeatability, intermediate precision, and reproducibility, which are intra-assay, within-laboratory, and inter-laboratory measurements, respectively. Repeatability is measured in one of two ways. One is to perform a minimum of six determinations at 100 percent of the test concentration. The other is to perform at least nine determinations over a minimum of three concentration levels (three different concentrations with three replicates of each concentration) that cover the specified range. Depending on company policy, repeatability and intermediate precision may be the only precision evaluation made in early development. Intermediate precision in its simplest sense is a comparison of results obtained by two analytical chemists from the same department (laboratory), preferably using two different chromatographic systems. Intermediate precision, however, can also be a design of experiments (DOE) in which variables such as analytical chemists, chromatographic systems, and days are examined.

Reproducibility is usually assessed prior to or during registration stability studies. A DOE is often used. Variable studies are similar to those used in intermediate precision, except that multiple analytical chemists and chromatographic systems are from two laboratories. These laboratories are often the laboratory that developed the method and the laboratory that will perform the release testing of the drug product.

### ROBUSTNESS

The robustness of an analytical method is evaluated prior to or during registration stability studies. The robustness evaluation shows the reliability of the method with respect to deliberate changes made to the method. For example, consider an HPLC assay method for which the pH of the aqueous buffer used in the mobile phase is 4.5. Experiments may be performed using buffers at pH 4.0 and 5.0 in order to evaluate the criticality of mobile phase pH on the assay results. Other variables that may be evaluated in robustness experiments for assay methods are flow rate, injection volume, column temperature, sample tray temperature, column manufacturer, mobile phase composition, extraction time for sample preparation, and solvent (diluent) composition for sample preparation. The numbers of variables can be large, and the variables may be interdependent, so a DOE approach to evaluate robustness is encouraged.

### SAMPLE AND STANDARD STABILITY

Regardless of the phase of development, the analytical samples and standards need to be stable for the duration of the analysis. This stability needs to be evaluated formally during method validation.

## IMPURITIES: RELATED SUBSTANCES

### Acceptance Criteria

The acceptance criteria for related substances on a drug product specification are expressed as less than or equal to a numerical value and are provided for individual impurities and total impurities. The purity results are reported as a percentage, with respect to either the peak area of the API in the drug product or the sum of the integrated peaks on the chromatogram. Purity methods must be stability-indicating. Related substances arising during drug product manufacturing and from the degradation of the drug substance must be monitored. Process impurities originating during the synthesis of the API are normally controlled during drug substance testing and are not listed on the drug product specification unless the synthesis impurity is also a degradation product in the drug product.

The magnitude of the acceptance criterion and how the impurity is listed on the specification are determined by the total daily dose, the dose at which the impurity was qualified in a toxicology study, manufacturing capability, and stability of the

drug product.<sup>22</sup> If the daily dose is not more than (NMT) 1.0g, impurities greater than 0.1 percent must be reported on the Certificate of Analysis (CofA). For daily doses greater than 1.0g, the impurities greater than 0.05 percent must be reported. The values for all of the reported impurities will be summed, and this sum must meet the acceptance criterion for total impurities.

Some individual impurities are listed on the specification and limited in order to ensure the quality of the drug product. These impurities are called specified impurities. If the level of a specified impurity exceeds the identification threshold listed in ICH Guidance Q3B, then this impurity must be identified using a combination of mass spectrometric and nuclear magnetic resonance (NMR) spectrophotometric techniques. Such impurities are called specified identified impurities. If the level of a specified impurity does not exceed the identification threshold, it does not have to be identified. This specified, unidentified impurity is listed on the specification by its relative retention time, which is calculated by dividing the retention of the impurity by the retention time of the API. Identification thresholds are determined by the maximum daily dose and the total daily intake of the impurity and are provided in Table 2-1. Two examples are provided to help interpret the use of this table.

- Example 1: Consider a tablet for which the maximum daily dose is 750 µg. One percent of the maximum daily dose is 7.5 µg, which is greater than the 5 µg total daily intake (TDI) limit. Therefore, any impurity greater than 5 µg or 0.67 percent must be identified.
- Example 2: Consider a tablet for which the maximum daily dose is 200 µg. One percent of the maximum daily dose is 2 µg, which is lower than 5 µg TDI. Therefore, any impurity greater than 1.0 percent must be identified.

If a specified, identified impurity exceeds the qualification thresholds provided in Table 2-2, the impurity must be qualified in a toxicology study. The qualification threshold calculations from the information in Table 2-2 are analogous to those performed for determining identification thresholds. The acceptance criterion for an individual impurity should not exceed the amount that has been qualified in a toxicology study.

How are meaningful limits set for each impurity? ICH Guidance Q6A recommends that the acceptance criteria be based on safety and efficacy data at hand at the time of filing. The Guidance recognizes that the amount of data batch history data at the time of filing is likely insufficient to assess manufacturing

**Table 2-1. Identification Thresholds**

Maximum Daily Dose	Threshold
< 1 mg	1.0% or 5 µg TDI, whichever is lower
≥ 1 mg and ≤ 10 mg	0.5% or 20 µg TDI, whichever is lower
> 1 mg and ≤ 2000 mg	0.2% or 2 mg TDI, whichever is lower
> 2000 mg	0.10%

**Table 2-2. Qualification Thresholds**

Maximum Daily Dose	Threshold
< 10 mg	1.0% or 50 µg TDI, whichever is lower
≥ 10 mg and ≤ 100 mg	0.5% or 200 µg TDI, whichever is lower
> 100 mg and ≤ 2000 mg	0.2% or 3 mg TDI, whichever is lower
> 2000 mg	0.15%

process capability and recommends that limits do not tightly encompass the batch data that are available at the time of filing.

The acceptance criteria for individual impurities that are degradation products are determined by extrapolating the stability data that are available at the time of filing and setting the limit using a statistical analysis that usually involves calculating the upper 95 percent confidence limit.

The acceptance criterion for total impurities is usually established by taking the acceptance criteria for individual impurities into account. If degradation does not occur in the drug product, acceptance criterion for total impurities is set at 2.0 or 3.0 percent. If degradation does occur, this acceptance criterion can be as high as 5.0 or 7.0 percent.

The Guidance, however, recognizes that the development stability data are incomplete at the time of filing and allows for the limit to be raised through a qualification toxicology study. Likewise, the limit can be lowered to a value that is less than the qualified amount if stability data indicate that a lower value is justifiable. As more batch history is obtained, process capability should be re-evaluated. The Guidance allows for the limits to be raised or lowered based on sufficient commercial batch history.

### Validation Characteristics

Impurity methods for related substances are validated for specificity, linearity, range, accuracy, precision, robustness, sample and standard stability, and quantitation limit.<sup>18,19</sup> Usually detection limit is also a validation characteristic that is also determined.

#### SPECIFICITY

The validation of a related substances impurity method is similar to that for an assay method, regardless if the method is combined with the assay method or a stand-alone impurity method. The USP is actively modernizing official USP-NF monographs for small-molecule API and their dosage forms that do not have a stability-indicating impurity method for related substances.

#### LINEARITY AND RANGE

A linear relationship should be evaluated across the range of the analytical method. For a drug product, linearity is assessed from the reporting level of an impurity to 120 percent of the specification limit.

#### ACCURACY

Accuracy of an impurity method is evaluated by performing “spike and recovery” experiments. If reference material for the impurities is not available, it is acceptable in early development to spike drug substance into a placebo matrix and compare the value obtained to a reference solution that contains a known amount of drug substance. The amount of drug substance or impurity reference material spiked should be representative of the expected range for the impurity. The compatibility of the analyte with the filter used during sample preparation is often formally evaluated at this time.

#### PRECISION

The precision of an impurity method is best evaluated using authentic homogeneous samples. If authentic samples are not available, artificially prepared samples or a sample solution may be used. If the impurity is not available in early development, the drug substance may be substituted. The manners in which repeatability, intermediate precision, and reproducibility are assessed are similar to those used for the assay test. It is important to conduct the evaluation at representative concentrations for the impurities.

#### ROBUSTNESS

Like the assay method, the robustness of an analytical method is evaluated prior to or during registration stability studies. The variables evaluated in robustness experiments for impurity

methods are often similar to those used for the assay method. A DOE approach to evaluate robustness is encouraged.

#### SAMPLE AND STANDARD STABILITY

Regardless of the phase of development, the analytical samples and standards need to be stable for the duration of the analysis. Drug substance can be substituted for impurity reference material during early development if no impurity reference material is available. Also, the stability of impurities in working standards can be evaluated as well.

#### LIMIT OF QUANTITATION (LOQ)

The LOQ for an impurity method can be calculated by measuring the signal-to-noise ratio. LOQ is defined as a signal-to-noise ratio of 10:1. Another way to calculate the LOQ is to measure the standard deviation of the responses and the slope of the calibration in the range examined. The LOQ can be calculated as follows:

$$\text{LOQ} = 10\sigma / s$$

where  $\sigma$  is the standard deviation of the responses and  $S$  is the slope of the calibration curve. A practical way to measure LOQ is to prepare a solution at 0.05 or 0.1 percent, which corresponds to the reporting threshold. Make six replicate injections; if the relative standard deviation is less than 20 percent, then the LOQ can be defined as the reporting threshold.

#### LIMIT OF DETECTION (LOD)

This validation characteristic is generally not required for quantitative impurity methods, but it is easily calculated once the LOQ is known:

$$\text{LOD} = \text{LOQ} / 3$$

### IMPURITIES: RESIDUAL SOLVENTS

#### Acceptance Criteria

Residual solvents are usually controlled by the drug substance specifications and usually do not appear on the drug product specification. Residual solvents in pharmaceuticals are defined as organic volatile chemicals that are used or produced in the manufacture of drug substances or excipients, or in the preparation of drug products. Solvents deliberately used as an excipient in a drug product are not considered residual.<sup>23</sup>

There are two cases that may require residual solvents to be controlled on the drug product specification.

Case 1—Cumulative method. Drug products should contain no higher levels of residual solvents than can be supported by safety data. A cumulative method may be used to calculate the residual solvent levels in the drug product from the levels in the ingredients (drug substance and excipients) used to produce the drug product. If the calculation results in a level equal to or below that recommended in ICH Guidance 3C<sup>23</sup>, no testing of the drug product for residual solvents is necessary. This calculation is usually performed in development to ensure that the calculated residual solvent levels are significantly lower than the safety limits. If, however, the calculated level is above the safety level, the drug product should be tested to determine whether the formulation process has reduced the relevant solvent level to within the acceptable amount. A method that is specific for each of the solvents of concern will need to be developed and validated. It is rare that the cumulative method results in having to list a residual solvent on the specification.

Case 2—Manufacturing. Drug product should also be tested if a solvent is used during its manufacture. Organic co-solvents, such as tetrahydrofuran (THF), are sometimes used to prepare spray-dried dispersions of low-soluble drugs. Most of the THF will evaporate during the manufacture of the dispersion, but residual THF is expected to be present. The THF can be controlled at the time of manufacture for the dispersion. If it is not,

then THF must be controlled in the drug product specification. THF is regarded as a Class 2 solvent, which means that the exposure to THF should be limited. A Class 2 solvent is considered a non-genotoxic animal carcinogen; a positive causative agent of other irreversible toxicity, such as neurotoxicity or teratogenicity; or an agent suspected of other significant but reversible toxicities. According to the ICH Guidance Q3C, the permitted daily exposure (PDE) for THF is 7.2 mg/day. There are two options to determine the acceptance criterion. Option 1 gives the limit as 720 ppm, which was calculated using the assumption that the product mass consumed each day does not exceed 10 g. Option 1 can be used provided that the total tablet mass consumed per day is less than 10 g and that all other excipients in the tablet also contain less than 720 ppm THF.

If the THF level in the tablet cannot be controlled to 720 ppm because the above conditions are not met or because the residual THF levels in the tablet are greater than 720 ppm, then Option 2 may be used to determine the acceptance criterion. Here the actual total tablet mass consumed each day is used in the calculation. Let's assume this value is 1.5 g. The limit can be calculated as follows:

$$\begin{aligned} \text{Acceptance criterion} &\leq (1000 \mu\text{g THF} / \text{mg THF}) \\ &\quad \times (7.2 \text{ mg THF} / \text{day}) / 1.5 \text{ g tablet} \\ &\leq 4800 \mu\text{g THF} / \text{g tablet} / \text{day} \\ &\leq 4800 \text{ ppm THF} / \text{day} \end{aligned}$$

Therefore, 4800 ppm THF can be used as the acceptance criterion. If manufacturing experience shows that the process capability is lower than 4800 ppm, then a lower acceptance criterion should be used.

### Validation Characteristics

Residual solvent analysis is usually determined by gas chromatography (GC) unless the solvent is high boiling. THF is suitable for headspace GC analysis. This method would be validated for specificity, linearity, range, accuracy, precision, robustness, sample and standard stability, and quantitation limit.

#### SPECIFICITY

Specificity is determined by comparing the chromatogram obtained from a diluted THF solution to that of the drug product matrix. The method is deemed specific if there are no interferences from the matrix observed.

#### LINEARITY AND RANGE

A linear relationship should be evaluated from 80.0 to 120.0 percent of the acceptance criterion. Some companies have a policy to demonstrate linearity over an expanded range from 70.0 to 130.0 percent.

#### ACCURACY

Accuracy of a residual solvent method is evaluated by performing "spike and recovery" experiments.

#### PRECISION

The manners in which repeatability, intermediate precision, and reproducibility are accessed are similar to those used for the impurity test for related substances.

#### ROBUSTNESS AND SAMPLE AND STANDARD STABILITY

The validation characteristics of a residual solvent method are evaluated in a similar manner to the previously discussed methods.

#### LIMIT OF QUANTITATION (LOQ)

The LOQ for a residual solvent method can be calculated using either of the two methods previously described. The LOQ

can be verified experimentally if the THF levels are very low by spiking the calculated LOQ amount into the drug product and matrix and measuring the precision of six replicate injections.

#### LIMIT OF DETECTION (LOD)

The LOD can be determined from the LOQ as previously discussed.

### IMPURITIES: ENANTIOMERIC PURITY

#### Acceptance Criteria

For simplicity, let's assume that the drug substance has only one chiral center and that the drug substance has been synthesized to afford a large enantiomeric excess. The opposite enantiomer is considered an impurity. The opposite enantiomer, however, is excluded from the identification and qualification thresholds to which the related substances are subjected because quantitation of the enantiomer at the threshold levels can be difficult.

The opposite enantiomer is quantified by HPLC using a different method than that used for related substances. The column must have a chiral stationary phase in order to separate the opposite enantiomer from the drug substance. As a result, the chiral purity test and acceptance criterion are separate entries on the drug product specification. In addition, the chiral purity result is usually not included in the calculation for total impurities for related substances.

The acceptance criterion for the amount of enantiomer in a drug product specification is usually the same as that given in the drug substance specification for drug products in clinical development unless there is potential evidence that racemization may occur in the drug product. In this case, the acceptance criterion for the drug product may be greater than that for the drug substance. It is the responsibility of the manufacturer, however, to control the amount of the other enantiomer in the drug product. It is not uncommon to have an acceptance criterion for the enantiomer as high as 1.0 to 2.0 percent, relative to the drug substance.

As development progresses or after registration, drug product release and stability data are used to establish the acceptance criterion. If racemization has been shown to be insignificant, the amount of the enantiomer does not need to be controlled in the drug product. Then the test is removed from the specification or sunsetted.

#### Validation Characteristics

Drug product enantiomeric purity methods are validated for specificity, linearity, range, accuracy, precision, robustness, sample and standard stability, and quantitation limit. Sometimes detection limit is also a validation characteristic that is determined.

#### SPECIFICITY

The method should be capable of separating the two enantiomers with baseline resolution and ensuring that there are no co-eluting peaks from other molecules present in the sample.

It should be noted that a stereospecific identity test for the drug substance is usually not needed in the drug product release specification. If drug product release and stability data indicate that racemization is insignificant, the stereospecific identity is more appropriately addressed as part of the drug substance specification. On the other hand, the enantiomeric impurity testing will serve as an identity test if racemization in the drug product is a concern.

#### LINEARITY AND RANGE

A linear relationship should be evaluated across the range of the analytical method. For a drug product, linearity is assessed from the LOQ to 120 percent of the specification limit. Some companies will assess linearity in the range from the LOQ to 2.0 percent (relative to the drug substance).

### ACCURACY

The accuracy of an impurity method is evaluated by performing “spike and recovery” experiments. If reference material for the impurities is not available, the accuracy is inferred from the linearity and the precision data.

### PRECISION

The precision of an enantiomeric purity method is usually evaluated using authentic homogeneous samples. If authentic samples are not available, artificially prepared samples may be used. The precision should be evaluated in the range of interest. The manners in which repeatability, intermediate precision, and reproducibility are accessed are similar to those used for the related substances impurity test.

### ROBUSTNESS AND SAMPLE AND STANDARD STABILITY

The validation characteristics of an enantiomeric purity method are evaluated in a similar manner to the previously discussed methods.

### LIMIT OF QUANTITATION (LOQ)

The LOQ for an enantiomeric purity method can be calculated using either of the two methods previously described. The LOQ can be verified experimentally by spiking the enantiomer into the drug product matrix at the calculated LOQ or at 0.05 percent, whichever is greater, and measuring the precision of six replicate injections.

### LIMIT OF DETECTION (LOD)

The LOD can be determined from the LOQ as previously discussed.

### IMPURITIES: ELEMENTAL IMPURITIES

The European Medicines Agency issued a draft guideline on the specification limits for residual metal in 2008.<sup>24</sup> This guideline applies to drug substances and new and existing drug products. Pharmaceutical companies, however, have been given up to five years for the implementation of the guideline to existing drug products. The USP has formed an Expert Panel to revise general chapters concerning elemental impurities.<sup>25,26</sup> Revised chapters appear in *Pharmacopeial Forum*.<sup>27,28</sup>

### IDENTIFICATION

#### Acceptance Criteria

The acceptance criteria for an identification test depend on the technique used. For chromatographic tests in which retention time of the sample is compared to that of a reference material, the acceptance criterion is usually given as a relative retention time (RRT), which is defined as the retention time of the standard divided by the retention time of the reference material. This criterion is commonly  $RRT = 1.00 \pm 0.05$ .

The acceptance criterion for a spectroscopic test is usually given as “consistent with reference standard.”

#### Validation Characteristics

Identification methods are not validated in the typical sense. Nevertheless, sound scientific judgment must be used. The chromatographic method, which is the same as that used for assay determination, has been shown to be free from interferences. A spectroscopic identification test must be consistent with the structure of the molecule, and the reference standard must have been fully characterized by MS and NMR spectroscopy.

### DESCRIPTION

Description is usually a visual test that is dependent on the physical appearance of the dosage form. Validation is not required. Examples of acceptance criteria for several dosage forms are given below.

*A capsule to be used in a clinical study:* Opaque, red, size 3 capsule

*A commercially available 10-mg capsule:* Blue and white, opaque capsules, imprinted with “ABC” on one half and “10 mg” on the other half in black ink

*A tablet to be used in a clinical study:* White to off-white, round, biconvex tablets

*A commercially available 500-mg tablet:* Off-white, film-coated tablets, ovaloid, biconvex with beveled edges, debossed with “500” on one side, with score on the other side, and “LL” on each side of the score

*A small-volume injectable solution:* Clear, colorless solution; free from particles or foreign matter

*Lyophilized drug for injection:* White to off-white cake or powder; free from particles or foreign matter

*Topical cream:* White to off-white cream with a uniform appearance

*Topical gel:* Clear, colorless to pale yellow gel

### TAXONOMY

The Dosage Forms Expert Committee of the USP developed a compendial taxonomy that was introduced in *Pharmacopeial Forum* 29(5) in 2002 in order to provide a uniform way of categorizing pharmaceutical dosage forms; a tool for finding information and linking specific dosage form monographs and general chapters; a rational linkage between dosage forms and their compendia specifications; and a linkage between dosage form drug substance(s) and their compendial use.<sup>29</sup> The Committee’s overall motivation was to give the manufacturer and the regulator clearer knowledge of the specifications generally needed to demonstrate compliance. The taxonomy is based on a tier concept.

Tier 1 delineates the dosage form according to the route of administration by which the drug substance is delivered. Five routes of administration have been identified:<sup>29,30</sup>

- Oral
- Parenteral
- Inhalation
- Transdermal/Topical
- Mucosal

The USP General Chapters—Dosage Forms Expert Committee has been tasked to update or write General Chapters for each route.<sup>30</sup>

Tier 2 is based on the general type of dosage form and its physical properties. For example, tablets and capsules are examples of oral drug products. USP Chapter <1151>, “Pharmaceutical Dosage Forms”, was rewritten to provide descriptions of dosage forms commonly used to administer the drug substance. A glossary is provided as a resource on nomenclature. USP Chapter <1151> gives general principles involved in the manufacture or compounding of these dosage forms and recommendations for proper use and storage. This informational chapter becomes official in USP 35-NF 30.<sup>14,15</sup>

Tier 3 gives the type of release pattern: immediate; extended; or delayed. Tablets, for example, can be subdivided into each of the three release patterns. Product performance tests may be different for each release pattern.

Product quality and performance tests for representative dosage forms are provided below. These tests are presented for pedagogical purposes. The reader is asked to consult *Pharmacopeial Forum* for in-process revisions of these chapters and the United States Pharmacopeia and European Pharmacopeia for official versions of the quality and performance tests for the various routes of delivery.

### DOSAGE FORMS—INJECTABLES

There are five general types of injectable presentations.<sup>31</sup>

1. [DRUG] Injection—Liquid preparations that are drug substances or solutions thereof.

- [DRUG] for Injection—Dry solids that, upon the addition of suitable vehicles, yield solutions conforming in all respects to the requirements for *Injections*.
- [DRUG] Injectable Emulsion—Liquid preparations of drug substances dissolved or dispersed in a suitable emulsion medium.
- [DRUG] Injectable Suspension—Liquid preparations of solids suspended in a suitable liquid medium.
- [DRUG] for Injectable Suspension—Dry solids that, upon the addition of suitable vehicles, yield preparations conforming in all respects to the requirements for *Injectable Suspensions*.

Product quality and performance tests for [Drug] Injection and [Drug] for Injection will be described below. Typical specifications for injectable dosage forms that are used in clinical development are provided in Tables A-1 and A-2, and representative monographs for these dosage forms are given in Appendix B.

## [DRUG] INJECTION

### Product Quality: Universal Tests

Appearance, identification, assay, and impurity (related substances) are universal product quality tests for this dosage form. If the drug substance is chiral, enantiomeric purity may be a universal product quality test if racemization has not been shown to be insignificant.

### Product Quality: Dosage Form Specific Tests

Tests that are specific for Injection solutions include pH, particulate matter, sterility, and endotoxin. All of these tests are compendial, so validation is not needed. The test should be verified using the drug product so that there is a degree of confidence in the results obtained from the compendial test and that the test has performed suitably as intended. USP-NF Chapter <1226>, “Verification of Compendial Procedures,” should be consulted for further information.<sup>32</sup>

#### pH

For compendial purposes, pH is defined as the value given by a suitable, properly standardized, potentiometric instrument (pH meter) capable of reproducing pH values to 0.02 pH unit using an indicator electrode sensitive to hydrogen activity, the glass electrode, and a suitable reference electrode. This definition indicates that pH is an experimental value.<sup>33</sup> (The theoretical definition of pH is negative 1 times the base ten logarithm of the hydrogen ion activity.)

The pH of the solution may affect the solubility and stability of the drug substance and may be a critical quality attribute that needs to be controlled. Specification will usually specify a pH range of 0.4 to 0.6 pH units, with the target pH in the middle of the range. See USP <791> and Pharm Eur 2.2.3 for further information on this test.<sup>33,34</sup>

#### PARTICULATE MATTER

Particulate matter in injections and parenteral infusions consists of extraneous mobile undissolved particles, other than gas bubbles, unintentionally present in the solutions.<sup>35</sup> The presence of visible particles will be determined from the Appearance Test. Two methods are used to test for subvisible particles and are provided in USP <788>, “Particulate Matter in Injections.” These tests are harmonized with those provided in the European Pharmacopeia and the Japanese Pharmacopeia.

Method 1, Light Obscuration Particle Count Test, is the preferred method for observing sub-visible particles. However, this method may not work for drug products for which clarity is reduced or viscosity is increased. Method 2, Microscopic Particle Count Test, provides an alternative procedure for these drug products. It may be necessary to run both methods on injection and infusion solutions in order to reach a conclusion on the conformance to the requirements. The acceptance criteria for these methods depend on the volume of the drug product.

#### STERILITY

The [DRUG] Injection must meet the requirements under sterility testing. A typical acceptance criterion is “no growth.” The ICH Steering Committee, based on the evaluation by the Q4B Expert Working Group (EWG), recommends that the official pharmacopoeial texts, Ph. Eur. 2.6.1. Sterility, JP 4.06 Sterility Test, and USP <71> Sterility Tests, can be used interchangeably in the ICH regions subject to the conditions detailed below.<sup>36</sup>

#### BACTERIAL ENDOTOXINS TEST

The Bacterial Endotoxins Test is a test to detect or quantify bacterial endotoxins from gram-negative bacteria using *Limulus Amebocyte Lysate* (LAL), obtained from the horseshoe crab. There are three types of techniques for this test, and any of them can be used to test for the presence of endotoxins:

- The gel-clot technique, which is based on gel formation;
- The turbidometric technique, based on the development of turbidity after cleavage of an endogenous substrate; and
- The chromogenic technique, which is based on the development of color after cleavage of a synthetic peptide-chromogen complex.

Proceed by any one of these techniques, unless otherwise indicated in the monograph. In case of dispute, the final decision is based on the gel-clot technique, unless otherwise indicated in the monograph.<sup>37</sup>

The endotoxin limit for parenteral drugs, defined on the basis of dose, equals K/M, where K is a threshold pyrogenic dose of 5 endotoxin units (EU) per kg of body weight, and M is equal to the maximum recommended bolus dose of product per kg of body weight. When the product is to be injected at frequent intervals or infused continuously, M is the maximum total dose administered in a single hour period. The endotoxin limit (acceptance criterion) for parenteral drugs is specified in drug product specification in units such as EU/mg of drug substance.<sup>37</sup>

#### UNIFORMITY OF DOSAGE FORMS

If the dose for the [DRUG] Injection is determined by the volume of solution delivered, a test for uniformity of the solution dosage form is not required. If the entire contents of the drug product are to be delivered, however, a uniformity test is needed. This test is a weight uniformity in which the weight of liquid in individual containers is weighed and an acceptance value is calculated.<sup>38–41</sup> The USP chapter for Uniformity of Dosage Form is not harmonized with the Uniformity of Dosage Forms chapter in the European Pharmacopeia.<sup>38–41</sup>

### Product Performance: Dosage Form Specific Tests

There are no performance tests for [DRUG] Injection dosage forms.

## [DRUG] FOR INJECTION

### Product Quality: Universal Tests

The universal tests for [DRUG] for Injection are identical to those for [DRUG] Injection. The acceptance criterion, however, is descriptive of a solid instead of a solution. For example, a typical acceptance criterion is “white to off-white cake or powder; free from particles or foreign matter.” If the drug substance is chiral, enantiomeric purity may be a universal product quality test if racemization has not been shown to be insignificant.

If a drug product exists in [DRUG] Injection and [DRUG] for Injection formats, different methods are often used for assay, impurity, and enantiometric purity. The chromatographic conditions and parameters will likely be identical, but the sample preparations are different because the physical forms of the two dosage forms are different.

## Product Quality: Dosage Form Specific Tests

### UNIFORMITY OF DOSAGE FORM

Uniformity of Dosage Forms is a product quality test for [DRUG] for Injection dosage forms. Weight uniformity may be used for single-dose containers; otherwise, a suitable analytical method must be used to determine uniformity of content.<sup>38–41</sup> Typically, an isocratic, non-stability-indicating method is used for content uniformity. The method is validated for specificity, accuracy, precision, linearity, and sample and standard stability. The performance criteria for accuracy and precision are less stringent for this method than performance criteria for assay and purity methods. The European and United States Pharmacopeias, procedures for the Uniformity of Dosage Forms Test are harmonized for this dosage form.

### WATER DETERMINATION

The product quality tests for [DRUG] for Injection may include water determination if water content is a critical quality attribute. Karl Fischer titrations and loss on drying are common techniques to determine moisture content.<sup>42</sup>

## Product Performance: Dosage Form Specific Tests

### RECONSTITUTION TIME

A common performance test for [DRUG] for Injection dosage forms is reconstitution time. Here, the time to dissolve the powder in a specified volume of diluent is measured by a stopwatch. The vial is vigorously shaken after the addition of the diluent and observed every 5 to 10 seconds. The time for which the solid contents take to dissolve is recorded and must be less than the acceptance criterion.

## Product Quality: Dosage Form Specific Tests— Reconstituted Drug Product

Appearance, pH, and particulate matter are typical quality tests for reconstituted solutions. The acceptance criteria for these tests are similar for a [DRUG] for Injection and [DRUG] Injection dosage forms.

## DOSAGE FORMS—ORAL DRUG PRODUCTS

There are many types of oral dosage forms: tablets, capsules, powders, granules, medicated gums, solutions, and suspensions are common dosage forms that are available by prescription or over-the-counter.<sup>14,15,43</sup> An example of a specification for an immediate-release tablet that is used in clinical development is given in Table A-3. Representative monographs for immediate-, delayed-, and extended-release tablets are provided in Appendix B. The product quality and performance tests for these types of tablets are discussed below.

### IMMEDIATE-RELEASE TABLETS

#### Product Quality: Universal Tests

The universal tests for an immediate-release tablet are identical to those for injectable dosage forms. The acceptance criterion, however, is descriptive of a solid unit-dose. For example, a typical acceptance criterion is “white to off-white round convex tablets.” If the drug substance is chiral, enantiomeric purity may be a universal product quality test if racemization has not been shown to be insignificant.

#### Product Quality: Dosage Form Specific Tests

Tests that are specific for immediate-release tablets include uniformity of dosage forms, tablet friability, tablet breaking force, water determination, X-ray powder diffraction, microbial enumeration tests, and tests for specified microorganisms.

### UNIFORMITY OF DOSAGE FORM

Each tablet should have a drug substance content within a narrow range around the label claim (LC). The magnitude of this

range is governed by an acceptance limit, which is designed to provide within a stated probability that a single tablet taken from an entire manufacturing lot would pass the content uniformity test. Details on how to calculate the acceptance value (AV) are provided in the United States Pharmacopeia<sup>38</sup> and the European Pharmacopeia.<sup>39</sup>

In most cases,<sup>38,39,44</sup> the content of the tablet is measured using an appropriate analytical method, such as an isocratic non-stability-indicating HPLC method. First, 30 tablets from a manufacturing lot are randomly selected. Ten of these tablets are individually tested. The average ( $\bar{M}$ ) and standard deviation ( $s$ ) are calculated from the results.

The acceptance value and  $\bar{M}$  are typically calculated as follows:  $AV = \bar{M} + 2.4s$

$$\begin{aligned} \bar{M} &= \bar{X} && \text{if } \bar{X} < 98.5\% \text{ LC;} \\ \bar{M} &= 98.5 - \bar{X} && \text{if } 98.5 \leq \bar{X} \leq 101.5\% \text{ LC;} \text{ and} \\ \bar{M} &= \bar{X} - 101.5 && \text{if } \bar{X} > 101.5\% \text{ LC.} \end{aligned}$$

If AV is less than or equal to 15.0, which is called L1, the lot of tablets passes the uniformity of dosage form test. If AV is greater than L1, then 20 more tablets must be individually tested. The average and standard deviation for all 30 tablets are calculated. The AV for the 30 tablets is calculated:  $AV = \bar{M} + 2.0s$ . The equations to calculate  $\bar{M}$  are given above. The lot passes the uniformity of dosage form test if the AV for the 30 tablets is less than or equal to 25.0 (L2), if no individual tablet content is less than 0.75 $\bar{M}$ , and if no individual tablet content is greater than 1.25 $\bar{M}$ .

The USP allows for a weight variation test to be substituted for a content uniformity assay for uncoated or film-coated tablets if the tablet label claim is not less than 25 mg of active ingredient and if the drug load is not less than 25 percent.<sup>38</sup> Drug load is defined as the weight percent of the tablet composition that is an active substance.

### UNIFORMITY OF CONTENT AND UNIFORMITY OF MASS

The general monograph for tablets in the European Pharmacopeia (01/2008:0478) requires compliance to two additional quality tests: uniformity of content and uniformity of mass.<sup>45</sup> The uniformity of content test<sup>41</sup> applies only to tablets with less than 2 mg of active substance or less than 2 percent drug load. The lot passes this test if the individual content of each of 10 tablets measured in the uniformity of dosage forms test is between 85 and 115 percent of the average content. If this criterion is not met and if the individual content of each of the 10 tablets is between 75 and 125 percent of the average, the content of 20 additional tablets is measured. If the individual contents of all 30 tablets are between 75 and 125 percent of the average, and if the content of 29 of the 30 tablets is between 85 and 115 percent of the average, then the lot passes the uniformity of content test.

The uniformity of mass test<sup>40</sup> is performed by weighing 20 tablets individually. An average mass,  $\bar{M}$ , is calculated. The acceptance limits for this test are determined from the value of  $\bar{M}$ .

If $\bar{M} \leq 80$ mg	All tablet masses must be between $0.8\bar{M}$ and $1.2\bar{M}$ and at least 18 of the individual masses must be between $0.9\bar{M}$ and $1.1\bar{M}$ .
If $\bar{M} \leq 80$ –250 mg	All tablet masses must be between $0.85\bar{M}$ and $1.15\bar{M}$ and at least 18 of the individual masses must be between $0.925\bar{M}$ and $1.075\bar{M}$ .
If $\bar{M} \geq 250$ mg	All tablet masses must be between $0.9\bar{M}$ and $1.1\bar{M}$ and at least 18 of the individual masses must be between $0.95\bar{M}$ and $1.05\bar{M}$ .

### TABLET FRIABILITY

The tablet friability<sup>46</sup> test usually does not appear in a specification or monograph. It is, however, an important test that is performed during development of the tablet to ensure that the tablet will not break or chip during coating, packaging, or routine handling during distribution to the patient. The test is harmonized across the European, Japanese, and United States Pharmacopeia and is described in detail in their chapters. Ten tablets or 650 g of tablets, whichever is greater, are placed in a tablet friability apparatus and rotated 100 times at 25 rpm. The lot passes the test if no tablet breaks and if the total weight loss after tumbling is less than the acceptance limit for the product. This limit is usually not more than 1.0 percent weight loss, but it varies depending on the nature of the product. Tablet friability is monitored during the tablet compression operation in manufacturing.

### TABLET BREAKING FORCE

The tablet breaking force test,<sup>47</sup> or tablet hardness test as it is sometimes called, is often found on a specification during development to ensure that proper control during manufacturing exists. Variation in tablet hardness can affect *in vitro* and *in vivo* performance because tablet disintegration and dissolution may vary. The test is often performed during developmental stability studies and as an in-process control during the tablet compression operation in manufacturing.

### WATER DETERMINATION

The product quality tests for a tablet may include water determination if water content is a critical quality attribute. Karl Fischer titrations and loss on drying are common techniques to determine moisture content.<sup>42</sup>

### X-RAY POWDER DIFFRACTION

The crystal form or polymorph of the drug may affect the solubility, dissolution rate, and bioavailability of the drug. X-ray diffraction is often performed to ensure that the crystal form has not changed during manufacturing or storage of the tablet.<sup>48</sup> If a tablet is made using an amorphous dispersion of the drug substance, X-ray diffraction is performed to ensure that the drug has not crystallized. An example of the impact of crystal form on product performance was observed in 1998 for Norvir (ritonavir) soft gelatin capsules.<sup>49</sup>

### MICROBIAL ENUMERATION TESTS AND TESTS FOR SPECIFIED MICROORGANISMS

Typical microbiological tests that appear in an oral solid-dosage form specification include total aerobic microbial count (TAMC), total yeast and molds count (TYMC), and the absence of *E. coli*. The tests are described in detail in the United States Pharmacopeia<sup>50,51</sup> and the European Pharmacopeia.<sup>52,53</sup> Although these tests appear in a specification, they are generally not included in a monograph.

## Product Performance: Dosage Form Specific Tests

There are two performance tests for immediate-release tablets: dissolution and disintegration.

### DISSOLUTION

A dissolution test is performed by monitoring the amount of drug dissolved as a function of time. Usually the test is performed using Apparatus 1 or Apparatus 2.<sup>54,55</sup> When Apparatus 1 is used, the dosage form is placed in a basket, which is lowered into a specified volume (usually 500 or 900 mL) of medium equilibrated at  $37.0 \pm 0.5^\circ\text{C}$ . The medium is chosen so the solubility of the active ingredient is about 3 to 4 times greater than the concentration of the drug in medium after complete dissolution of the active substance has occurred.<sup>56</sup> The dosage form is rotated at a pre-determined speed, usually between 50 and 75 rpm. Six dosage forms are tested simultaneously. Apparatus 1 is

usually used for capsules. Apparatus 2, usually used for tablets, makes use of a paddle to create hydrodynamic flow over the tablet, which rests at the bottom of the dissolution flask.

During tablet development when a dearth of release and stability data exist and when the formulation or manufacturing process is subject to change, it is common to record the entire dissolution profile or the amount of drug dissolved at specified intervals, such as 10, 20, 30, 40, 50, and 60 minutes or 15, 30, 45, and 60 minutes. An isocratic, non-stability-indicating HPLC method or a UV-Vis spectrophotometric method is often used to measure the drug dissolved. Prior to registration, dissolution for an immediate-release tablet becomes a single-point test. The acceptance criterion for this test is a function of Q, which is expressed as percent label claim of drug dissolved at the specified time.<sup>54,55</sup>

Like the Uniformity of Dosage Forms Test, the dissolution test is a staged test. There are three levels. In the first level of testing called S1, six tablets are tested. Each tablet must be  $Q + 5$  percent (absolute percentage points) dissolved at a specified time.<sup>54,55</sup> In the USP monograph for capecetabine tablets, the Q value is specified as 80 percent and the time point is 30 minutes. Here, 85 percent of the capecetabine in each tablet must be dissolved at 30 minutes.

If this criterion is not met, then six additional tablets are tested in level 2 (S2). In order to pass the S2 acceptance criteria, the average of all 12 tablets must be equal to or greater than Q (80 percent LC for capecetabine tablets), and no tablet has less than  $Q - 15$  percent (65 percent LC for capecetabine tablets).<sup>54,55</sup>

If these criteria are not met, then Level 3 or S3 testing must be performed by testing 12 additional tablets. To pass S3, the average of all 24 tablets must be equal to or greater than Q (80 percent LC for capecetabine tablets). Two additional criteria must be met as well: no more than 2 tablets are less than  $Q - 15$  percent (65 percent LC for capecetabine tablets), and no tablet is less than  $Q - 25$  percent dissolved (55 percent LC for capecetabine tablets).<sup>54,55</sup>

### DISINTEGRATION

One tablet is placed in each of six tubes of a basket rack assembly for a disintegration apparatus and immersed in a specified medium equilibrated at  $37 \pm 2^\circ\text{C}$ . The basket is raised and lowered a distance of  $55 \pm 2$  mm at a rate of 29 to 32 cycles per minute for a defined period of time, usually 15 minutes for uncoated tablets and 30 minutes for coated tablets. The lot passes the test if all of the tablets disintegrate completely at the end of the specified time. If one or two of the tablets fail to disintegrate completely, the test is repeated on 12 additional tablets. The disintegration test is passed if at least 16 of the 18 tablets have disintegrated completely.<sup>57,58</sup> Automated disintegration apparatuses exist to record the exact time that each tablet disintegrated and are often used during tablet development and optimization and during release and stability testing.

Disintegration may not be included in a specification or monograph if dissolution is performed. Disintegration, however, is frequently performed as an in-process control during tablet manufacturing. A disintegration test may be used in place of a dissolution test when a drug is rapidly dissolving.<sup>1</sup>

## DELAYED-RELEASE TABLETS

### Product Quality: Universal Tests and Dosage Form Specific Tests

A delayed-release tablet is designed to release the drug after the tablet leaves the acidic environment of the stomach. The quality tests for a delayed-release tablet are identical to those for an immediate-release tablet. Tablet friability and tablet breaking force are usually controlled on the tablet core prior to the coating operation. Hardness may also be tested on the enteric-coated tablet.

## Product Performance: Dosage Form Specific Tests

### DISSOLUTION

A dissolution test is a two-part test. First, the tablets are exposed to an acid medium that is followed by exposure to a buffer medium. The medium used for an acid stage is 0.1N HCl, and the duration of this stage is 2 hours. The tablets are transferred to a buffer medium, usually 0.2M phosphate buffer at pH 6.8, but other buffers and pH targets may be used if justified. The duration of the buffer stage is usually 45 minutes, but this duration may vary depending on the product.<sup>54,55</sup>

An aliquot of the acid medium from each vessel is analyzed. The acceptance criteria for the acid stage are as follows and there are three levels:

Level 1 (A1) testing is passed if no individual value exceeds 10 percent dissolved. If the A1 criteria are not met, then the dissolution test is performed on 6 additional tablets for Level 2 (A2) testing. Level A2 criteria are passed if the average of all 12 tablets in the acid stage is not more than 10 percent dissolved and if no individual tablet is greater than 25 percent dissolved.<sup>54,55</sup>

Level 3 testing is performed if the A2 criteria are not met. The A3 criteria are passed if the average of all 24 tablets in the acid stage is not more than 10 percent dissolved and if no individual tablet is greater than 25 percent dissolved.<sup>54,55</sup>

The acceptance criteria for the buffer stage are based on a Q value at a specified time. The B1, B2, and B3 criteria are identical to those for the immediate release S1, S2, and S3 criteria.<sup>54,55</sup>

### DISINTEGRATION

For enteric-coated tablets, disintegration is performed on six tablets for one hour using simulated gastric fluid or 0.1 N HCl as the immersion medium. The tablets are observed for no evidence of disintegration, cracking, or softening. The test is repeated on the same tablets using simulated intestinal fluid or a phosphate buffer as the immersion medium. The duration in the medium varies but is usually between 15 and 60 minutes. The same acceptance criteria apply to immediate- and delayed-release tablets.<sup>57,58</sup> Disintegration is usually performed as an in-process test on the cores during manufacturing.

## EXTENDED-RELEASE TABLETS

### Product Quality: Universal Tests and Dosage Form Specific Tests

An extended-release or prolonged-release tablet is designed to release the drug over a defined time period, usually 4 to 12 hours. The quality tests for an extended-release tablet are identical to those for an immediate- or delayed-release tablet.

### Product Quality: Dosage Form Specific Tests

Dissolution is the only performance test for extended-release tablets. Disintegration is usually not performed.

### DISSOLUTION

A dissolution test is generally the same as that used for an immediate-release tablet, except that three time points are specified. The time points used for acetaminophen extended-release tablets that are 30 minutes, 90 minutes, and 4 hours. The acceptance ranges are as follows:

Between 40 and 60 percent acetaminophen dissolved at 30 minutes;

Between 55 and 85 percent acetaminophen dissolved at 90 minutes; and

Not less than 80 percent acetaminophen dissolved at 4 hours.

Six tablets are analyzed in Level 1 (L1); acceptance criteria are met if no individual value lies outside each of the stated ranges and no individual value is less than the final time period.<sup>54,55</sup> If the L1 criteria are not met, then six additional tablets are analyzed in Level 2 (L2). The L2 criteria are met if these three conditions are met:

1. The average values of the 12 tablets lies within each of the stated ranges and is not less than the stated range of the final time point;
2. None is more than 10 percent of labeled content outside each of the stated ranges; and
3. None is more than 10 percent of the labeled content below the stated amount at the final test time.<sup>54,55</sup>

If the L2 criteria are not met, then 12 additional tablets are tested in Level 3 (L3). The L3 criteria are met if these five conditions are met:

1. The average values of the 24 tablets lies within each of the stated ranges and is not less than the stated range of the final time point;
2. Not more than 2 of the 24 tablets are more than 10 percent of labeled content outside each of the stated ranges;
3. Not more than 2 of the 24 tablets are more than 10 percent of the labeled content below the stated amount at the final test time;
4. None of the 24 tablets is more than 20 percent of labeled content outside each of the stated ranges; and
5. None of the 24 tablets is more than 20 percent of the labeled content below the stated amount at the final test time.<sup>54,55</sup>

## ADDITIONAL DOSAGE FORMS

The product quality and performance tests for many dosage forms are summarized in “Chart 4: Non Complex Active Drug Products” in the Guide to General Chapters to USP 34,<sup>59</sup> USP <1151>,<sup>14,15</sup> and the Dosage Forms chapter of the European Pharmacopeia.<sup>43</sup>

The USP General Chapters-Dosage Forms Expert Committee is charged to revise product quality chapters for five routes of administration.<sup>30</sup> These General Chapters have been recently or are in the process of being revised:

- <2> Oral Drug Products—Product Quality Tests<sup>30</sup>
- <3> Topical and Transdermal Drug Products—Product Quality Tests<sup>16,17,30,62</sup>
- <725> Topical and Transdermal Drug Products—Product Performance Tests<sup>30,60,62</sup>
- <1724> Topical and Transdermal Drug Products—Product Performance Tests<sup>30,61,62</sup>
- <5> Inhalation and Nasal Drug Products—General Information and Product Quality Tests<sup>30,63,65</sup>
- <601> Aerosols, Nasal Sprays, Metered-Dose Inhalers, and Dry Powder Inhalers<sup>30,64,65</sup>

## FUTURE DIRECTION

The biggest change in the analysis of medical products in the coming years will likely be in the implementation of the Quality by Design (QbD) paradigm and corresponding ICH Guidelines<sup>66-69</sup> into everyday pharmaceutical development. The information and knowledge gained from pharmaceutical development studies and manufacturing experience provide scientific understanding to support the establishment of the design space, specifications, and manufacturing controls. The use of meaningful analytical methods and specifications will be an integral part of QbD because quality is expected to be built into the design of the product. Analytical tests, especially those that test product performance, will be expected to be discriminating. For example, dissolution tests will be expected to tell when a manufacturing or formulation change will affect the product performance.

## APPENDIX A EXAMPLE SPECIFICATIONS

**Table A-1. ABC1234 Injection Specifications**

Attribute	Method	Acceptance Criteria
Appearance	Visual	Clear, colorless solution and essentially free of particles or foreign matter
Identification	Reversed-phase HPLC Method ABC-2012-0001	Conforms to Reference Standard (RRT 1.00 ± 0.05)
Assay	Reversed-phase HPLC Method ABC-2012-0001	90.0–110.0% of label claim
Impurities	Reversed-phase HPLC Method ABC-2012-0001	<p><b>Specified Identified Impurities</b>            ABC0001 (RRT ~ 0.37): ≤ 0.30% area            ABC0002 (RRT ~ 1.15): ≤ 1.00% area            ABC0003 (RRT ~ 1.58): ≤ 3.00% area</p> <p><b>Specified Unidentified Impurities</b>            RRT ~ 1.08: ≤ 0.20% area</p> <p><b>Unspecified Unidentified Impurities</b>            Any other individual Impurity ≤ 0.10% area</p> <p><b>Total Impurities</b>            ≤ 4.00% area</p>
Enantiomeric purity	Chiral HPLC Method ABC-2012-0002	≤ 1.00% area
pH	USP <791>	5.5 ± 0.3
Particulate matter	USP <788>	<p><b>Light Obscuration Particle Count</b>            particles per container ≥10 µm: ≤ 6000            particles per container ≥25 µm: ≤ 600</p> <p><b>Microscopic Particle Count<sup>a</sup></b>            particles per container ≥10 µm: ≤ 3000            particles per container ≥25 µm: ≤ 300</p>
Sterility	USP <71>	No Growth
Endotoxin	USP <85>	< 3.5 EU/mg of ABC1234

<sup>a</sup>Microscopic particle count will be performed only if the light obscuration particle count exceeds the acceptance criteria.

**Table A-2. ABC1234 Injection Specifications**

Attribute	Method	Acceptance Criteria
Appearance	Lyophilized Cake Visual	White to off-white cake or powder, essentially free of foreign matter
Identification	Reversed-phase HPLC Method ABC-2012-0003	Conforms to Reference Standard (RRT 1.00 ± 0.05)
Assay	Reversed-phase HPLC Method ABC-2012-0003	90.0–110.0% of label claim (5.0 mg ABC1234/vial)
Impurities	Reversed-phase HPLC Method ABC-2012-0003	<p><b>Specified Identified Impurities</b>            ABC0001 (RRT ~ 0.37): ≤ 0.30% area            ABC0002 (RRT ~ 1.15): ≤ 1.00% area            ABC0003 (RRT ~ 1.58): ≤ 2.00% area</p> <p><b>Specified Unidentified Impurities</b>            RRT ~ 1.08: ≤ 0.20% area</p> <p><b>Unspecified Unidentified Impurities</b>            Any other individual impurity ≤ 0.10% area</p> <p><b>Total Impurities</b>            ≤ 3.00% area</p>
Enantiomeric purity	Chiral HPLC Method ABC-2012-0004	≤ 1.00% area
Moisture content	USP <921>	Record result
Content uniformity	USP <905>; Reversed-phase HPLC Method ABC-2012-0005	Conforms to USP and Ph. Eur. requirements

Attribute	Method	Acceptance Criteria
Sterility	USP <71>	No Growth
Endotoxin	USP <85>	< 3.5 EU/mg of ABC1234
Reconstitution time	Visual	≤ 120 seconds
<b>Reconstituted Solution</b>		
Appearance	Visual	Clear, colorless solution, essentially free of particles and foreign matter
pH	USP <791>	5.0 ± 0.3
Particulate matter	USP <788>	<b>Light Obscuration Particle Count</b> particles per container ≥10 µm: ≤ 6000 particles per container ≥25 µm: ≤ 600 <b>Microscopic Particle Count<sup>a</sup></b> particles per container ≥10 µm: ≤ 3000 particles per container ≥25 µm: ≤ 300

<sup>a</sup>Microscopic particle count will be performed only if the light obscuration particle count exceeds the acceptance criteria.

**Table A-3. ABC5678 Tablet (10- and 100-mg) Specifications**

Attribute	Method	Acceptance Criteria
Appearance	Visual	White to off-white round convex tablets
Identification	Reversed-phase HPLC Method ABC-2012-0006	Conforms to Reference Standard (RRT 1.00 ± 0.05)
Assay	Reversed-phase HPLC Method ABC-2012-0006	90.0–110.0% of label claim
Impurities	Reversed-phase HPLC Method ABC-2012-0006	<b>Specified Identified Impurities</b> ABC0001 (RRT ~ 0.37): ≤ 0.30% area ABC0002 (RRT ~ 1.15): ≤ 1.00% area ABC0003 (RRT ~ 1.58): ≤ 1.50% area <b>Specified Unidentified Impurities</b> RRT ~ 1.08: ≤ 0.20% area <b>Unspecified Unidentified Impurities</b> Any other individual impurity ≤ 0.10% area <b>Total Impurities</b> ≤ 3.00% area
Enantiomeric purity	Chiral HPLC Method ABC-2012-0007	≤ 1.00% area
Content uniformity	USP <905>; Reversed-phase HPLC Method ABC-2012-0008	Conforms to USP and Ph. Eur. requirements
Dissolution	USP <711>; Reversed-phase HPLC Method ABC-2012-0009	Record result
Moisture content	USP <901>	Record result
Tablet breaking force	USP <1217>	Record result
X-ray powder diffraction	USP <941>	Consistent with a reference pattern
Microbial Enumeration Tests	USP <61> or Ph. Eur. 2.6.12	Total Aerobic Microbial Count ≤ 10 <sup>3</sup> CFU/g Total Yeast and Molds Count ≤ 10 <sup>2</sup> CFU/g
Microbial Specified Microorganisms Test	USP <62> or Ph. Eur. 2.6.13	Absence of <i>E. coli</i>

## Appendix B Sample Monographs

### NAFCILLIN INJECTION<sup>70</sup>

Nafcillin Injection is a sterile isoosmotic solution of Nafcillin Sodium and one or more buffer substances in Water for Injection. It contains dextrose as a tonicity-adjusting agent. It contains an amount of nafcillin sodium equivalent to not less than 90.0 percent and not more than 120.0 percent of the labeled amount of nafcillin ( $C_{21}H_{22}N_2O_5S$ ). It contains no antimicrobial preservatives.

#### PACKAGING AND STORAGE

Preserve in *Containers for Injections* as described under *Injections* <1>. Maintain in the frozen state.

#### LABELING

It meets the requirements for *Labeling* under *Injections* <1>. The label states that it is to be thawed just prior to use, describes conditions for proper storage of the resultant solution, and directs that the solution is not to be refrozen.

#### USP REFERENCE STANDARDS <11>

USP Endotoxin RS  
USP Nafcillin Sodium RS

#### IDENTIFICATION

The retention time of the major peak for nafcillin in the chromatogram of the *Assay preparation* corresponds to that in the chromatogram of the *Standard preparation*, as obtained in the *Assay*.

#### BACTERIAL ENDOTOXINS <85>

It contains not more than 0.13 USP Endotoxin Unit per mg of nafcillin.

#### STERILITY <71>

It meets the requirements when tested as directed for *Membrane Filtration* under *Test for Sterility of the Product to be Examined*.

**pH** <791>: between 6.0 and 8.5.

**Particulate matter** <788>: meets the requirements for small-volume injections.

#### ASSAY

*Acetic acid solution, 0.05 M Sodium acetate, Diluent, Mobile phase, Standard preparation, Resolution solution, and Chromatographic system*—Proceed as directed in the *Assay* under *Nafcillin Sodium*.

#### Assay preparation

Allow one container of Injection to thaw, and mix. Transfer an accurately measured volume of Injection, equivalent to about 40 mg of nafcillin, to a 100-mL volumetric flask, dilute with *Diluent* to volume, and mix.

#### Procedure

Proceed as directed for *Procedure* in the *Assay* under *Nafcillin Sodium*. Calculate the quantity, in mg, of nafcillin ( $C_{21}H_{22}N_2O_5S$ ) in each mL of the Injection taken by the formula:

$$0.1(C/V)(r_u/r_s)$$

in which *C* is the concentration, in  $\mu\text{g}$  per mL, of nafcillin in the *Standard preparation*; *V* is the volume, in mL, of Injection taken to prepare the *Assay preparation*; and  $r_u$  and  $r_s$  are the nafcillin peak responses obtained from the *Assay preparation* and the *Standard preparation*, respectively.

### NAFCILLIN FOR INJECTION<sup>71</sup>

Nafcillin for Injection contains an amount of Nafcillin Sodium equivalent to not less than 90.0 percent and not more than 120.0 percent of the labeled amount of nafcillin ( $C_{21}H_{22}N_2O_5S$ ).

#### PACKAGING AND STORAGE

Preserve in *Containers for Sterile Solids* as described under *Injections* <1>.

#### USP REFERENCE STANDARDS <11>

USP Endotoxin RS  
USP Nafcillin Sodium RS

#### CONSTITUTED SOLUTION

At the time of use, it meets the requirements for *Constituted Solutions* under *Injections* <1>.

#### IDENTIFICATION

The retention time of the major peak for nafcillin in the chromatogram of the *Assay preparation* corresponds to that in the chromatogram of the *Standard preparation*, as obtained in the *Assay*.

#### BACTERIAL ENDOTOXINS <85>

It contains not more than 0.13 USP Endotoxin Unit per mg of nafcillin.

#### STERILITY <71>

It meets the requirements when tested as directed for *Membrane Filtration* under *Test for Sterility of the Product to be Examined*.

**pH** <791>: between 6.0 and 8.5, in the solution constituted as directed in the labeling.

**Water, Method I** <921>: between 3.5 percent and 5.3 percent.

**Particulate matter** <788>: meets the requirements for small-volume injections.

#### OTHER REQUIREMENTS

It meets the requirements for *Uniformity of Dosage Units* <905> and *Labeling* under *Injections* <1>.

#### ASSAY

*Acetic acid solution, 0.05 M Sodium acetate, Diluent, Mobile phase, Standard preparation, Resolution solution, and Chromatographic system*—Proceed as directed in the *Assay* under *Nafcillin Sodium*.

#### Assay preparation 1

(where it is represented as being in a single-dose container)—Constitute Nafcillin for Injection in a volume of water, accurately measured, corresponding to the volume

of solvent specified in the labeling. Withdraw all of the withdrawable contents, using a suitable hypodermic needle and syringe, and dilute quantitatively with *Diluent* to obtain a solution having a concentration of about 0.4 mg of nafcillin ( $C_{21}H_{22}N_2O_5S$ ) per mL.

### Assay preparation 2

(where the label states the quantity of nafcillin in a given volume of constituted solution)—Constitute Nafcillin for Injection in a volume of water, accurately measured, corresponding to the volume of solvent specified in the labeling. Dilute an accurately measured volume of the constituted solution quantitatively with *Diluent* to obtain a solution having a concentration of about 0.4 mg of nafcillin ( $C_{21}H_{22}N_2O_5S$ ) per mL.

### Procedure

Proceed as directed for *Procedure* in the *Assay* under *Nafcillin Sodium*. Calculate the quantity, in mg, of nafcillin

( $C_{21}H_{22}N_2O_5S$ ) in the portion of constituted Nafcillin for Injection taken by the formula:

$$(C / 1000)(L / D)(r_u / r_s)$$

In which *L* is the labeled quantity, in mg, of nafcillin in the portion of Nafcillin for Injection taken; *D* is the concentration, in mg per mL, of nafcillin in *Assay preparation 1* or *Assay preparation 2*, as appropriate, based on the volume of constituted Nafcillin for Injection taken and the extent of dilution; and the other terms are as defined therein.

Perform the above procedure on ten containers where it is represented as being in a single-dose container and, if necessary, on ten containers where the label states the quantity of nafcillin in a given volume of constituted solution. Use the individual results to determine the *Uniformity of dosage units* and the average thereof as the *Assay* value.

## CAPECITABINE TABLETS<sup>72</sup>

### DEFINITION

Capecitabine Tablets contain NLT 93.0 percent and NMT 105.0 percent of the labeled amount of capecitabine ( $C_{15}H_{22}FN_3O_6$ ).

### IDENTIFICATION

- **A. INFRARED ABSORPTION <197K>**  
Analytical wave number: 1500–1760  $cm^{-1}$   
Sample: Grind 1 tablet to a fine powder with a mortar and pestle. Mix 1 mg of this sample with 300 mg of potassium bromide.
- **B.** The retention time of the major peak of the *Sample solution* corresponds to that of the *Standard solution*, as obtained in the *Assay*.

### ASSAY

#### PROCEDURE

- **Diluent:** Methanol, acetonitrile, and water (7:1:12)
- **Solution A:** 0.1 percent mixture of glacial acetic acid in water
- **Solution B:** Methanol, acetonitrile, and *Solution A* (7:1:12)
- **Solution C:** Methanol, acetonitrile, and *Solution A* (16:1:3)
- **Mobile phase:** See the gradient table below.

Time (min)	Solution B b>(% )	Solution C (%)
0	100	0
5	100	0
20	49	51
30	49	51
31	100	0
40	100	0

[NOTE—The following solutions may be sonicated as necessary.]

**System suitability solution:** Includes 0.6  $\mu g/mL$  of USP Capecitabine RS, 0.6  $\mu g/mL$  of USP Capecitabine Related Compound A RS, 0.6  $\mu g/mL$  of USP Capecitabine Related Compound B RS, and 0.6  $\mu g/mL$  of USP Capecitabine Related Compound C RS in *Diluent*

**Standard solution:** 0.6  $mg/mL$  of USP Capecitabine RS in *Diluent*

**Sample solution:** Equivalent to 0.6  $mg/mL$  of capecitabine, from powdered tablets (NLT 20), in *Diluent*. [NOTE—Pass through a PVDF membrane filter of 0.45- $\mu m$  pore size, and use the filtrate.]

### Chromatographic system

(See *Chromatography* <621>, *System Suitability*.)

- **Mode:** LC
- **Detector:** UV 250 nm
- **Column:** 4.6-mm x 25-cm; 5- $\mu m$  packing L1
- **Column temperature:** 40°
- **Autosampler temperature:** 5°
- **Flow rate:** 1 mL/min
- **Injection size:** 10  $\mu L$

### System suitability

**Samples:** *System suitability solution* and *Standard solution* [NOTE—For the purpose of peak identification, the approximate relative retention times are given in *Impurity Table 1*. The relative retention times are measured with respect to capecitabine.]

### Suitability requirements

**Resolution:** NLT 1.0 between Capecitabine Related Compound A and Capecitabine Related Compound B, *System suitability solution*

**Tailing factor:** NMT 1.5, *Standard solution*

**Relative standard deviation:** NMT 2.0 percent, *Standard solution*

### Analysis

**Samples:** *Standard solution* and *Sample solution*. Calculate the percentage of  $C_{15}H_{22}FN_3O_6$  in the portion of tablets taken:

$$\text{Result} = (r_u / r_s) (C_s / C_u) 100$$

- $r_u$  = peak response from the *Sample solution*
- $r_s$  = peak response from the *Standard solution*
- $C_s$  = concentration of USP Capecitabine  $R_s$  in the *Standard solution* ( $mg/mL$ )
- $C_u$  = nominal concentration of capecitabine in the *Sample solution* ( $mg/mL$ )
- **Acceptance criteria:** 93.0 percent–105.0 percent

## PERFORMANCE TESTS

- **DISSOLUTION <711>**  
**Medium:** Water; 900 mL, degassed  
**Apparatus 2:** 50 rpm  
**Time:** 30 min

## STANDARD SOLUTIONS

For tablets labeled to contain 150 mg: 17 mg of USP Capecitabine RS in 100 mL of *Medium*

For tablets labeled to contain 500 mg: 28 mg of USP Capecitabine RS in 50 mL of *Medium*

**Sample solution:** Pass a portion of the solution under test through a fiberglass filter of 0.45- $\mu$ m pore size.

**Analysis:** Determine the amount of  $C_{15}H_{22}FN_3O_6$  dissolved by selecting a wavelength with appropriate sensitivity between 300 and 330 nm on portions of the *Sample solution*, suitably diluted with *Medium*, if necessary, in comparison with the appropriate *Standard solution*, using a 1-mm quartz cell. Calculate the percentage of  $C_{15}H_{22}FN_3O_6$  dissolved in each tablet:

$$\text{Result} = (A_u / A_s) C_s (V/L) 100$$

- $A_u$  = absorbance of the *Sample solution*
- $A_s$  = absorbance of the *Standard solution*
- $C_s$  = concentration of capecitabine in the *Standard solution* (mg/mL)
- $V$  = volume of medium, 900 mL
- $L$  = Tablet label claim (mg)

**Tolerances:** NLT 80 percent (Q) of the labeled amount of  $C_{15}H_{22}FN_3O_6$  is dissolved.

Uniformity of Dosage Units <905>: Meet the requirements.

## IMPURITIES

### ORGANIC IMPURITIES

- **PROCEDURE**  
**Diluent, Solution A, Solution B, Solution C, Mobile phase, System suitability solution, Standard solution, Sample solution, and Chromatographic system:**

Proceed as directed in the *Assay*.

## ANALYSIS

**Samples:** *Standard solution* and *Sample solution*. Calculate the percentage of each impurity in the portion of tablets taken:

$$\text{Result} = (r_u / r_s) (C_s / C_u) 100 / F$$

- $r_u$  = peak response for each impurity from the *Sample solution*
- $r_s$  = peak response for capecitabine from the *Standard solution*
- $C_s$  = concentration of USP Capecitabine RS in the *Standard solution* (mg/mL)
- $C_u$  = nominal concentration of capecitabine in the *Sample solution* (mg/mL)
- $F$  = relative response factor for each impurity, from *Impurity Table 1*

## ACCEPTANCE CRITERIA

**Individual impurities:** See *Impurity Table 1*

**Total degradation products:** NMT 2.0 percent

## ADDITIONAL REQUIREMENTS

- **PACKAGING AND STORAGE:** Preserve in tight containers. Store at controlled room temperature.
- **USP REFERENCE STANDARDS <11>**  
 USP Capecitabine RS  
 USP Capecitabine Related Compound A RS  
 5'-Deoxy-5-fluorocytidine.

$C_9H_{12}FN_3O_4$  245.21 USP Capecitabine Related Compound B RS

5'-Deoxy-5-fluorouridine.

$C_9H_{11}FN_2O_5$  246.19 USP Capecitabine Related Compound C RS

2',3'-O-Carbonyl-5'-deoxy-5-fluoro-N<sup>4</sup>-(pentyloxycarbonyl)cytidine.

$C_{16}H_{20}FN_3O_7$  385.34.

**Table B-1. Impurity Table 1**

Name	Relative Retention Time	Relative Response Factor	Acceptance Criteria, NMT (%)
Capecitabine Related Compound A	0.18	1.05	1.0
Capecitabine Related Compound B	0.19	0.81	1.0
2',3'-Di-O-acetyl-5'-deoxy-5-fluorocytidine*	0.36	0.89	—
5'-Deoxy-5-fluoro-N <sup>4</sup> -(2-methyl-1-butyloxycarbonyl)cytidine + 5'-Deoxy-5-fluoro-N <sup>4</sup> -(3-methyl-1-butyloxycarbonyl)cytidine*	0.95	1.01	—
Capecitabine	1.00	1.00	—
[1-[5-Deoxy-3-O-(5-deoxy- $\beta$ -D-ribofuranosyl)- $\beta$ -D-ribofuranosyl]-5-fluoro-2-oxo-1,2-dihydropyrimidin-4-yl]-carbamic acid pentyl ester*	1.06	1.00	—
[1-[5-Deoxy-2-O-(5-deoxy- $\beta$ -D-ribofuranosyl)- $\beta$ -D-ribofuranosyl]-5-fluoro-2-oxo-1,2-dihydropyrimidin-4-yl]-carbamic acid pentyl ester*	1.09	1.00	—
Capecitabine Related Compound C	1.11	0.91	0.5
[1-[5-Deoxy-3-O-(5-deoxy- $\alpha$ -D-ribofuranosyl)- $\beta$ -D-ribofuranosyl]-5-fluoro-2-oxo-1,2-dihydropyrimidin-4-yl]-carbamic acid pentyl ester*	1.20	1.00	—
2',3'-Di-O-acetyl-5'-deoxy-5-fluoro-N <sup>4</sup> -(pentyloxycarbonyl)cytidine*	1.37	0.85	—
Individual unspecified degradation product	—	1.00	0.1

\*These impurities are process impurities and are not included in the total degradation products.

## NAPROXEN DELAYED-RELEASE TABLETS<sup>73</sup>

Naproxen Delayed-Release Tablets contain not less than 90.0 percent and not more than 110.0 percent of the labeled amount of naproxen ( $C_{14}H_{14}O_3$ ).

### PACKAGING AND STORAGE

Preserve in well-closed containers, and store at controlled room temperature.

### USP REFERENCE STANDARDS <11>

USP Naproxen RS

### IDENTIFICATION

A: *Ultraviolet Absorption* <197U>

### Test solution

Use the solution under test as obtained in the *Buffer stage* of the *Dissolution* test.

### Standard solution

Use the Standard solution prepared as directed in the *Buffer stage* of the *Dissolution* test.

B: The retention time of the major peak in the chromatogram of the *Assay preparation* corresponds to that in the chromatogram of the *Standard preparation*, as obtained in the *Assay*.

**Dissolution**, *Delayed-Release Dosage Forms, Method B* <711>

### ACID STAGE

*Acid stage medium*: 0.1 N hydrochloric acid; 1000 mL.

*Apparatus 2*: 50 rpm.

*Time*: 2 hours.

### Procedure

Determine the amount of  $C_{14}H_{14}O_3$  dissolved by employing UV absorption at the wavelength of maximum absorbance at about 332 nm on filtered portions of the solution under test, suitably diluted with *Acid stage medium*, if necessary, in comparison with a Standard solution having a known concentration of USP Naproxen RS in the same *Acid stage medium*.

### Tolerances

Not more than 10 percent (*Q*) of the labeled amount of  $C_{14}H_{14}O_3$  is dissolved in 2 hours.

### BUFFER STAGE

*Buffer stage medium*: 0.2 M phosphate buffer, pH 6.8; 1000 mL.

*Apparatus 2*: 50 rpm.

*Time*: 45 minutes.

### Procedure

Determine the amount of  $C_{14}H_{14}O_3$  dissolved by employing UV absorption at the wavelength of maximum absorbance at about 332 nm on filtered portions of the solution under test, suitably diluted with *Buffer stage medium*, if necessary, in comparison with a Standard solution having a known concentration of USP Naproxen RS in the same *Buffer stage medium*.

### Tolerances

Not less than 80 percent (*Q*) of the labeled amount of  $C_{14}H_{14}O_3$  is dissolved in 45 minutes.

**Uniformity of dosage units** <905>: meet the requirements.

## PROCEDURE FOR CONTENT UNIFORMITY

### Mobile phase, Diluent A, Diluent B, and Chromatographic system

Proceed as directed in the *Assay*.

### Standard solution

Transfer about 12.5 mg of USP Naproxen RS, accurately weighed, to a 50-mL volumetric flask, dilute with *Diluent A* to volume, and mix well. Transfer 10 mL of this solution to a 25-mL volumetric flask, dilute with *Diluent B* to volume, and mix.

### Test solution

Transfer 1 tablet to a 200-mL volumetric flask, and add about 140 mL of *Diluent B*. Shake by mechanical means for 15 minutes, sonicate for 15 minutes, dilute with *Diluent B* to volume, and mix. Pass a portion of this solution through a filter having a porosity of 0.45  $\mu\text{m}$ , pipet 2.0 mL of the filtrate for a 500-mg tablet and 2.5 mL for a 375-mg tablet into a 50-mL volumetric flask, dilute with *Mobile phase* to volume, and mix.

### ASSAY

#### Mobile phase

Prepare a filtered and degassed mixture of 1 percent acetic acid solution and acetonitrile (11 : 9).

#### Diluent A

Use acetonitrile and water (9 : 1).

#### Diluent B

Use acetonitrile and water (1 : 1).

#### Standard stock preparation

Transfer about 12.5 mg of USP Naproxen RS, accurately weighed, to a 25-mL volumetric flask. Dissolve in and dilute with *Diluent A* to volume, and mix.

#### Standard preparation

Accurately transfer 10.0 mL of the *Standard stock preparation* into a 50-mL volumetric flask, and dilute with *Mobile phase* to volume, and mix.

#### Assay preparation

Weigh and powder 20 tablets. Accurately weigh an amount of the powder, equivalent to about 250 mg of naproxen, into a 100-mL volumetric flask, and add about 70 mL of *Diluent B*. Shake by mechanical means for 15 minutes, sonicate for 15 minutes, dilute with *Diluent B* to volume, and mix. Pass this solution through a filter having a porosity of 0.45  $\mu\text{m}$ , transfer 2.0 mL of the filtrate into a 50-mL volumetric flask, dilute with *Mobile phase* to volume, and mix.

*Chromatographic system* (see *Chromatography* <621>—The liquid chromatograph is equipped with a 254-nm detector and a 4.6-mm  $\times$  25-cm column that contains 5- $\mu\text{m}$  packing L1. The flow rate is about 1.0 mL per minute. Chromatograph the *Standard preparation*, and record the peak responses as directed for *Procedure*: the tailing factor of the naproxen peak is not more than 1.5, and the relative standard deviation for replicate injections of the *Standard preparation* is not more than 2.0 percent.

### Procedure

Separately inject equal volumes (about 50  $\mu\text{L}$ ) of the *Standard preparation* and the *Assay preparation* into the chromatograph, record the chromatograms, and measure the responses for the naproxen peak. Calculate the quantity, in mg, of naproxen ( $C_{14}H_{14}O_3$ ) in the portion of tablets taken by the formula:

$$2500(r_u/r_s)$$

in which *C* is the concentration, in mg per mL, of USP Naproxen RS in the *Standard preparation*; and  $r_u$  and  $r_s$  are

the peak responses obtained from the *Assay preparation* and the *Standard preparation*, respectively.

## ACETAMINOPHEN EXTENDED-RELEASE TABLETS<sup>74</sup>

Acetaminophen Extended-Release Tablets contain not less than 90.0 percent and not more than 110.0 percent of the labeled amount of acetaminophen ( $C_8H_9NO_2$ ).

### PACKAGING AND STORAGE

Preserve in tight containers.

### LABELING

Where the tablets are gelatin-coated, the label so states. When more than one *Dissolution* test is given, the labeling states the *Dissolution* test used only if *Test 1* is not used.

### USP REFERENCE STANDARDS <11>

#### USP Acetaminophen RS Identification

**A:** *Infrared Absorption* <197K>—Use a portion of powdered tablets.

**B:** The retention time of the major peak in the chromatogram of the *Assay preparation* corresponds to that in the chromatogram of the *Standard preparation*, as obtained in the *Assay*.

### DISSOLUTION <711>

#### TEST 1

*Medium:* simulated gastric fluid TS (without enzyme); 900 mL.

*Apparatus 2:* 50 rpm.

*Times:* 15 minutes, 1 hour, and 3 hours.

#### Procedure

Determine the amount of  $C_8H_9NO_2$  dissolved from UV absorbances at 280 nm, using a filtered portion of the solution under test in comparison with a Standard solution having a known concentration of USP Acetaminophen RS in the same *Medium*.

#### Tolerances

The percentages of the labeled amount of  $C_8H_9NO_2$  dissolved at the times specified conform to *Acceptance Table*.

Time	Amount dissolved
15 minutes	between 45% and 65%
1 hour	between 60% and 85%
3 hours	not less than 85%

### FOR GELATIN-COATED TABLETS

#### Medium, Apparatus, and Procedure

Proceed as directed above.

*Times:* 30 minutes, 90 minutes, and 4 hours.

#### Tolerances

The percentage of the labeled amount of  $C_8H_9NO_2$  dissolved at the times specified conform to *Acceptance Table*.

Time	Amount dissolved
30 minutes	between 40% and 60%
90 minutes	between 55% and 85%
4 hours	not less than 80%

### TEST 2

If the product complies with this test, the labeling indicates that it meets USP *Dissolution Test 2*.

#### Medium, Apparatus, and Procedure

Proceed as directed for *Test 1*.

#### Tolerances

The percentages of the labeled amount of  $C_8H_9NO_2$  dissolved at the times specified conform to *Acceptance Table*.

Time	Amount dissolved
15 minutes	between 40% and 60%
1 hour	between 55% and 75%
3 hours	not less than 80%

**Uniformity of dosage units** <905>: meet the requirements.

### ASSAY

#### Mobile phase

Prepare a mixture of water and phosphoric acid (9 : 1). Combine 1 mL of this solution with a mixture of water and methanol (700 : 300). Filter and degas. Make adjustments if necessary. See *System Suitability* under *Chromatography* <621>.

#### Standard preparation

Dissolve an accurately weighed quantity of USP Acetaminophen RS in methanol, and dilute quantitatively, and stepwise if necessary, with *Mobile phase* to obtain a solution having a known concentration of about 0.65 mg per mL.

#### Assay preparation

Transfer 10 tablets into a 250-mL volumetric flask containing 50 mL of water and a magnetic stir bar. Stir at least 30 minutes or until the coating has dissolved. Add 150 mL of methanol, and stir for 45 minutes. Tablet cores should be disintegrated at least 15 minutes prior to ending the stirring. Remove the magnetic stir bar and rinse into the flask with methanol. Dilute with methanol to volume, mix well, and centrifuge. Transfer 5 mL of the clear supernatant to a 200-mL volumetric flask, dilute with *Mobile phase* to volume, and mix well.

*Chromatographic system* (see *Chromatography* <621>—The liquid chromatograph is equipped with a 295-nm detector and a 3.9-mm x 15-cm column that contains packing L1. The flow rate is about 2.0 mL per minute. Chromatograph the *Standard preparation*, and record the peak responses as directed for *Procedure*: the tailing factor is not more than 3.0, and the relative standard deviation for replicate injections is not more than 2.0 percent.

#### Procedure

Separately inject equal volumes (about 20  $\mu$ L) of the *Standard preparation* and the *Assay preparation* into the chromatograph, record the chromatograms, and measure the responses for the major peaks. Calculate the quantity, in mg, of acetaminophen ( $C_8H_9NO_2$ ) in each tablet taken by the formula:

$$1000C(r_u/r_s)$$

In which  $C$  is the concentration, in mg per mL, of USP Acetaminophen RS in the *Standard preparation*; and  $r_u$  and  $r_s$  are the acetaminophen peak responses obtained from the *Assay preparation* and the *Standard preparation*, respectively.

# Chapter 3

## Quality Assurance and Control

John H. Parker, PhD and John E. Enders, PhD, MBA

QA AND QC: ORGANIZATION/RESPONSIBILITIES 29

QUALITY BY DESIGN 30

DOCUMENTATION 31

QUALITY IN PHARMACEUTICAL BIOTECHNOLOGY 31

CONTEMPORARY ISSUES 32

FDA MODERNIZATION 32

APPENDIX A 34

The pharmaceutical industry, as a vital segment of the healthcare system, conducts research and manufactures and markets pharmaceutical and biological products and medical devices used for the acute/chronic treatment and diagnosis of disease. Recent advances in drug discovery, primarily in the field of biotechnology and in the required controls over manufacturing processes, are presenting new challenges to the control of quality and to the systems that operate internally in the industry. The external regulations established by the federal Food and Drug Administration (FDA) and other regulatory bodies also add to these challenges. The evolving role of the industrial quality professional requires more extensive education including food and drug law, business, as well as the traditional science/technology coursework.

The pursuit of quality is being approached through the application of quality systems including risk-based assessment and continuous improvement, whereby management and labor join forces to build quality into products while helping to ensure the company's financial success. This changed emphasis is directed toward defect prevention (proactive) rather than defect detection (after the fact).

Quality assurance (QA) and quality control (QC) departments develop and follow standard internal operating procedures directed toward assuring the quality, safety, purity, and effectiveness of drug products. The FDA has issued a primary regulation to the industry entitled *Current Good Manufacturing Practice for Finished Pharmaceuticals* (commonly referred to as the cGMPs or GMPs) (see Appendix). Numerous guidelines have been issued relative to specific dosage forms and operations such as aseptic manufacturing, validation and stability testing, etc., which impose significant compliance requirements. These guidelines also serve as the basis for compliance investigations conducted by the FDA and are used in regulatory agency inspections of facilities and operations. Emphasis is being placed on the inspection of quality systems as part of the regulatory pre-approval program when reviewing New Drug Applications (NDAs) and Biological License Applications (BLAs).

### QA AND QC: ORGANIZATION/RESPONSIBILITIES

Industry, to ensure compliance with these government regulations and with their own internal policies and procedures, has developed very sophisticated quality organizations with well-defined responsibilities. It has been accepted that QA and QC have different functions within an organization; although both are considered part of the Quality Unit as identified in 21 CFR (see Appendix). QC most commonly functions to test and measure material and product. QA establishes systems for ensuring the quality of the product. Firms must decide upon the exact roles they wish QC and QA to perform in operations and put these definitions in writing.

### QA FUNCTIONS AND RESPONSIBILITIES

The QA department within any organization, because of its responsibilities, normally will report to a relatively high-level

administrator within a company, depending on its size. In smaller companies they may report to the chief executive officer or the president. In larger corporations, they will sometimes report to the president or executive vice-president or chief of operations. In any case, however, responsibility for quality, as currently dictated by FDA, ultimately resides with top management which has responsibility for ensuring that appropriate resources are provided to meet all quality and compliance requirements. In all cases, the QA department will be independent of the economic issues associated with manufacturing and distribution of the product.

The QA department is responsible for ensuring that the quality policies adopted by a company are followed. In some organizations, QA serves as the primary contact with regulatory agencies and is the final authority for product acceptance (release) or rejection. It is customary for QA to play a major role in the identification and preparation of the necessary policies and standard operating procedures (SOPs) relative to the control of quality. Where QA has responsibility for final product release, it must determine that the product meets all the applicable specifications and that it was manufactured according to internal standards and cGMPs. QA departments now tend to work as a team member with the other functional groups within the firm rather than simply to serve a police function, a largely outdated role of QA.

A second major responsibility of the QA department is the quality monitoring or audit function. Through this activity, it is able to determine if operations have adequate systems, facilities, and written procedures to control the quality of products produced. Thus, the QA function not only determines that the procedures are current and correct, but that properly trained operators are following them. Combining this review of SOPs with an audit of facilities and operations, including those of contract manufacturing and testing subcontractors, will give company management an inside report on its level of compliance and will allow the necessary changes and/or corrections to be made prior to a product failure or being reported as a deficiency during an inspection by an FDA investigator. This is consistent with the top-level management review component of the quality systems approach currently emphasized by FDA during inspections. Senior management of a company looks to the QA function to assess operations continually and to advise and guide them toward full compliance with all applicable internal and external regulations. Organizationally, the Quality department(s) should report, as directed by the GMPs, to someone other than the person responsible for production.

### QC FUNCTIONS AND RESPONSIBILITIES

Quality Control is responsible for the day-to-day control of quality within a company. This department is staffed with scientists and technicians responsible for the sampling and analytical testing of incoming raw materials and inspection of packaging components, including labeling. QC conducts in-process testing when required, performs environmental monitoring, inspects operations for compliance, and conducts the required release

tests on finished dosage form. Finally, QC is responsible for monitoring product quality through distribution, including testing of product complaint samples, evaluating product stability, and so on.

Many companies have the heads of QC and production report to a common higher level of management, but with QC being independent of production. This higher-level management may be the same or different individuals, but it allows independent operation of both functions without direct conflict arising when reaching a final decision on the acceptability of final products.

The analytical control laboratory must be staffed with persons who are trained academically and are, through experience, capable of performing the often complex analyses used to evaluate the acceptability of the materials tested. The equipment and instrumentation in the laboratory must be suitable for performing the testing in an accurate and efficient manner. Detailed specifications must be available, as well as validated test methods against which products and raw materials will be evaluated. The specifications detail the limits for acceptance of the article, based on identified critical parameters.

The testing and acceptance of only high-quality raw materials is essential for the production of uniformly acceptable products. Quality Control plays a major role in the selection and qualification of vendors from whom these materials are purchased. Testing of representative samples is required, and in many cases, an audit of the vendor's operation is necessary to determine their suitability and degree of compliance with GMPs and other relevant standards prior to their being approved. The vendor audit frequently is organized by QA, with technical support from research, QC, and manufacturing.

At various critical in-process steps in production, it may be necessary to sample and test product against criteria previously established. Often, in-process alert or action levels will be identified for the critical in-process parameters as a means of process control. These alert or action levels are normally set such that they are more restrictive than the final acceptance limits, but serve as an in-process control by providing early warnings of conditions that could lead to an out-of-control situation and thus will allow timely corrective action before such conditions occur. The acceptance criteria for such testing are established using Quality by Design (QBD) approaches which identify the Design Space within which the process will perform satisfactorily. Trending of analytical data is also useful in providing early warning signals that the process is moving out of control. It should be noted, however, that materials, which have reached the alert or action level criteria, are still acceptable for use in manufacturing, since they have not exceeded an out-of-limit rejection level.

Quality Control is responsible, as part of its testing and inspection functions, for monitoring the environmental conditions under which products are manufactured and/or held. Different levels of control are established depending on the intended use of the dosage form. Parenteral and ophthalmic products must be produced in a controlled environment that is designed to ensure their sterility. Monitoring of air and water systems is critical in confirming that they are being controlled and that the levels of particulates, microbial matter, and other contaminants are within pre-established limits. The United States Pharmacopeia (USP) contains monographs and specifications on Water Used for Pharmaceutical Purposes. Formerly, the Federal Government Standard 209E, *Airborne Particulate Cleanliness Classes in Cleanrooms and Clean Zones*, established acceptable limits for particulates in a controlled environment, but it is no longer considered applicable to the pharmaceutical industry, having been replaced by international standards. Federal standards are currently not enforced for environmental quality, but guidance is available in the FDA Concept Paper, *Sterile Drug Products Produced by Aseptic Processing*, published in September 2004.<sup>1</sup> In addition, reference is made to the Baseline Pharmaceutical Engineering Guide, Vol. 3, *Sterile Manufacturing Facilities*, published by the International Society

of Pharmaceutical Engineering (ISPE) in partnership with the FDA, in June 2000.<sup>2</sup> Generally, conditions listed as Class ISO 5 (formerly Class 100) (or equivalent) are maintained in areas where parenteral products are filled into clean, sterile containers. The ISO 5 classification is defined as an area that can be controlled to contain fewer than 100 particles, 0.5 microns and larger, per cubic foot of air. In addition, manufacturers must establish limits for the presence of viable microorganisms in the environment and appropriately monitor the air quality in the filling area.

Another major element of control is the environmental monitoring of the areas in which nonsterile products are manufactured, such as liquids, tablets, and capsules. The objective here is first to determine an acceptable level of particulates and microbial contaminants and then to control them to this level. If particulate levels are found to be excessive, steps must be taken to bring them within acceptable limits so as not to compromise the quality of the product. This monitoring and control of the environment will further ensure the quality and stability of the product by preventing the products from being exposed to a hostile environment.

Control of packaging components, especially those that come into direct contact with a product, is required. These materials must be inspected and tested against rigid specifications to ensure that they meet predetermined functional standards. This includes evaluation of compatibility of the product with the packaging materials. Labeling is understandably a critical component, not just in its original design and acceptance, but also with regard to secure storage and issuance to ensure accountability. Furthermore, final product labeling must be 100% inspected to ensure that it is correct. Often automated imaging methods are employed to conduct these inspections.

## QUALITY BY DESIGN

The production of quality pharmaceutical products requires embracing the principles of Total Quality Management (TQM). Although the term TQM has fallen out of favor in recent years and has been replaced by other, though similar designations, such as Total Product Quality (TPQ), the principles of TQM will serve to improve productivity and customer satisfaction. The quality function is part of a team composed of research, production, marketing/sales, and customer service. In the competitive markets of today, it is critical to improve quality and service continually while minimizing costs and maximizing resource utilization to help contain overall healthcare costs. The concept of TQM requires the total commitment of senior-level management and supervision of all departments, operators, suppliers, and customers. Its basic principle is one of continually striving for process improvement that begins with product development and only concludes when feedback and follow-up have been completed on customer complaints and suggestions. In many firms the QA department has the responsibility to organize and implement programs with these objectives in mind.

Quality must be designed into products, beginning with research and development phases. Quality by Design as described in the International Committee on Harmonization (ICH) Q8 (R2) Guidance for Industry<sup>3</sup> is becoming more common in the development of products and processes. Product quality criteria are established, and detailed specifications are written. Meticulous, written procedures must be prepared for production and control, and processes must be rigorously validated. Raw materials must be characterized and then purchased from reputable, approved suppliers to ensure that, when the materials are incorporated into the finished dosage form, they will provide products of uniformly high quality. Facilities must be designed, constructed, and controlled to provide the proper stable environment for protecting the integrity of products. Equipment must be selected that is efficient and can be cleaned readily and sanitized, to aid in preventing cross-contamination of one product with another. Single use equipment is commonly used in

the industry, particularly in manufacture of biological products. Product contact components are discarded after use. Personnel must be trained properly so that their personal habits, clothing, and job performance do not compromise product quality. The directions that they use must be in writing, approved by responsible individuals, and strictly followed. Training programs must be thoroughly documented and include an evaluation of mastery of the procedures employed.

Distribution departments are responsible for controlling the shipping and handling of products, using inventory-control systems most often based on the *first in–first out* principle. They select modes of distribution that will protect products from adverse handling or environmental conditions while in transit to distribution points and to customers. Products that require shipment under refrigerated or frozen conditions also require that validation of shipping conditions be rigorously completed. Furthermore, they must maintain accurate records of distribution to ensure that any product recall, if required, will be effectively and thoroughly conducted.

The marketing department must be sensitive to the customer's needs and be responsive to complaints. The quality department should be kept informed of real or potential problems as reported from the marketplace so that they may conduct investigations of product complaints, as appropriate, to determine the cause of the condition described in the complaint.

Involved with each of the operations described above, QA is ever present and gives approval only after assessing and being assured that the entire production process has been completed satisfactorily and that all the aspects of the GMPs have been satisfied.

In the pharmaceutical industry, QBD or the equivalent system, therefore, can be looked upon as a combined team effort to develop, produce, market, distribute, and control products that are safe and will be effective for the time they remain in the marketplace. Such a program ultimately will assure the professional dispenser and the final consumer that each lot of every product conforms to certain specifications and that each unit has met all the requirements, both internal and external, of the industry and will fulfill the declarations made in its labeling.

## DOCUMENTATION

The saying, "If it wasn't documented, it wasn't done," describes the linkage between written records of action taken and the quality operation. These written documents include those found in the product development phase as well as those associated with the actual manufacture and testing of individual batches. The former will consist of research and development reports, technology transfer reports, nonclinical and clinical study reports, and the validation records required when the FDA conducts its pre-approval investigations. Elements of these documents will include raw material and final product specifications along with appropriate validated test methods, technology-transfer documents, and production scale-up support data as well as stability study reports. Specific critical pieces of equipment must be identified along with the process and product qualification/validation records. The *Master Production Batch Record* (MPBR) is often the document that facilitates the orderly transition from product and process development to commercial-scale production, since it is the document that captures the process as described by the product development documentation.

The *Production Batch Record* (PBR), an exact copy of the approved MPBR, is used along with written SOPs to produce individual batches of product that are assigned specific code or lot numbers. The PBR provides a historical record of every step, beginning with the receipt of raw materials and package components and continuing through each phase of production. Recording charts or computer printouts of significant operations such as autoclaving, drying, air-particulate monitoring, lyophilizing, and so on, become part of the batch history. More and more companies are using electronic PBRs to capture the

data collected during the production process. After a batch has been completed, including final analytical and physical testing, there is one final additional step that must be completed prior to approving the batch for distribution. All documentation relating to the production of the specific batch is given a final review. This is often a two-step process in which each of the required documents is checked for accuracy and completeness by manufacturing. Any discrepancy must then be investigated and a written explanation made. This is followed by a final review by QA to ensure that all documents are complete and that all issues have been appropriately resolved. Only after this final review by QA has been completed satisfactorily may the batch be approved for release. Once the batch has been approved, accurate distribution records are required to trace the batch in the marketplace, which would facilitate, if the need arose, recalling the batch.

## QUALITY IN PHARMACEUTICAL BIOTECHNOLOGY

Because of the physical/chemical nature of the proteinaceous products derived from pharmaceutical biotechnology, unique quality considerations prevail that are associated with early research and development synthesis, clinical product scale-up, and commercial manufacture. This is particularly challenging for QC departments due to some gross differences between biological therapeutic agents and chemical drug products. In contrast to small-molecule pharmaceuticals, biotechnology-derived drugs are obtained from living organisms and often consist of complex mixtures of protein and other substances, frequently are heat labile, and, finally, are highly susceptible to microbiological contamination. In the context of this discussion, pharmaceutical biotechnology products are defined to include proteins and peptides produced by recombinant DNA (rDNA) techniques and monoclonal anti-body/hybridoma (MAb) technology. The former refers to the fact that these products are often produced by microorganisms or mammalian cells containing hybrid DNA, most often produced by joining pieces of DNA from different sources to gain the appropriate expressed product; the latter involves production of a single clone from hybrid cells, using hybridoma technology that fuses different cells to make the desired antibody. Currently, many MAb products are produced by mammalian cell culture in which the product of interest is expressed in large quantities. These MAb products are often human protein molecules in highly purified and well-characterized form. See also Chapter 34, *Biotechnology and Drugs*. In general, the objective of the pharmaceutical biotechnology manufacturing process is to produce a product essentially free of contamination. The attributes that the product should possess are sterility and the absence of pyrogens, unwanted organisms, by-products of the manufacturing process, and degradation by-products. The same requirements for adherence to cGMPs exist throughout the production process for recombinant proteins and monoclonal antibodies as apply to other pharmaceutical products.

Consideration must also be given to the design of the delivery system for the biotechnology-derived drug, especially because of the lability of many of these products. In accomplishing this task, often the more conventional manufacturing processes may be employed such as sterile filtration, aseptic handling, and, in some instances, lyophilization. However, for many of these products, new delivery systems are being evaluated as described below.

Characterization of the products produced by pharmaceutical biotechnology is a rapidly changing technical challenge, but tremendous advances have been made in the past decade. The FDA considers most of these products (other than some of the vaccines) to be well characterized and has changed the approach to license approval with this improved understanding of product specifications in mind. Guidance documents in the ICH Q5 series and ICH Q10 outline QC or testing considerations that address the structure, potency, and purity of proteins and

the analysis of contaminants resulting from the manufacturing process or degradation. Full characterization includes physical and chemical stability. Satisfactory stability of the product is a requirement for controlled manufacture and an acceptable shelf life following distribution. Because many of these products are temperature labile, the maintenance of cold chain shipping conditions is a challenge that must be addressed during the distribution and handling processes.

## CONTEMPORARY ISSUES

As a demonstration of the pace of change in the pharmaceutical industry, technologies that were on the cutting edge as recently as 10 years ago have become rather commonplace, as organizations routinely employ them to increase productivity and reduce costs while maintaining product quality. Statistical process control based on an understanding of process design space permits improved real-time control, thereby reducing end-product failures. Qualification and potential certification of suppliers of goods and services adds to the thrust of building in quality and allows the reduction in inventory costs by following just-in-time purchasing and receipt principles. Finally, in practically all facets of research, development, and operations, automation and computerization, including robotics, are work methods that have an impact on our daily lives by increasing productivity and raising the standards of quality by enhancing reproducibility. This application of computerized manufacturing and control has led to increasingly rigorous requirements for the appropriate design and validation of computer-controlled processes. This is evident in the publishing of 21 CFR Part 11 and Good Automated Manufacturing Practice (GAMP) 4, which describe the requirements for electronic records and signatures and validation respectively (see Appendix).

Today, the pace of change in the pharmaceutical industry continues unabated. There is increased emphasis on analytical chemistry as it relates to the entire drug discovery, development, and manufacturing sequence. This, coupled with new clues as to potential drug targets uncovered through the Human Genome Project, new histochemical methods to identify targets at a cellular level, and new approaches to computer modeling of potential drug compounds has led to many new candidates for development. This is evident in the new drug submissions made by industry to the FDA and in the depth and complexity of the review process associated with these new compounds. More technically sophisticated instrumental methods of analysis, assisted by computer interfacing, provide greater sensitivity along with the ability to analyze the results more efficiently and effectively. From these advances flows the requirement for more stability-indicating assay methods as well as increased emphasis on the impurities in drug substances and products, such as organic volatile impurities and even ordinary impurities derived from raw materials used in production. Taken as a whole, accurate mass balance of the parent compound, degradants, and impurities is an expectation. Compendia such as the USP and ICH guidance are including these concepts in general chapters and individual drug monographs. The evolution of high performance liquid chromatography (HPLC) methods, often coupled with mass spectrometry, and other even more sensitive technologies, and the wide acceptance of these techniques has increased the trend toward painstakingly thorough characterization of products, so that it is becoming the exception rather than the rule. Additionally, HPLC facilitates the recent focus on optical purity through chiral separation to support improvements in asymmetric synthesis, with the intent of producing the single, therapeutically active compound.

The move toward the elimination of tests that require animals is exemplified first by the replacement of the rabbit pyrogen test some 15 years ago with the bacterial endotoxin (LAL) method and the move, particularly in the EU, to using only a single species in nonclinical toxicology testing. It may be expected that similar chemical and biochemical approaches will

be developed to eliminate the use of animal testing in pre-clinical drug evaluation and toxicological testing as well.

The concept of parametric release of end-product is being applied on the basis of complete knowledge and control of all phases of the process including such things as information on suppliers, process and product validation, operator training, and thorough process knowledge coupled with statistical process controls. The sum of these prospectively managed and controlled quality activities results in greater real-time control and, hence, a diminished need for end-product confirmatory testing.

In the operations area, newer types of dosage forms, such as liposomes and transdermal devices, are demanding innovative manufacturing and control procedures and practices. Nanotechnology also shows promise in the development of novel delivery modalities. Novel routes of administration such as pulmonary inhalation for the administration of insulin are also being explored. Automation and computerization continue to increase manufacturing yields and concomitant tighter tolerances. As a result, there is a renewed interest in functional testing of raw materials, to keep up with these manufacturing advances.

All of these advances will, no doubt, be refined with the passage of time and continuing diligent efforts on the part of industrial professionals and regulators. This will lead to ever-new issues affecting the industrial quality professional and, hence, the challenge and reward of such an exciting endeavor.

## FDA MODERNIZATION

The FDA Modernization Act (FDAMA) of 1997 was introduced with the intent of improving the review process and thereby making new drug products available to the public faster than in the past. This effort continues both in form and detail and, in general, has shortened the review and approval timeline. A recent decision by the FDA to merge many of the product categories regulated by the Center for Biologics (CBER) into the Center for Drugs (CDER) is intended to further expedite the review process. In addition, there have been a number of new initiatives by the FDA over the last 5 to 10 years to work more collaboratively with the pharmaceutical industry to encourage better definition and understanding of processes and products.

## GMP REGULATIONS

In March 1979, the FDA issued revised GMP regulations. These regulations, still in effect today, present the minimum requirements to be met by industry when manufacturing, packaging, and holding human and veterinary drugs. The Federal Food, Drug, and Cosmetic Act states that a drug is deemed to be adulterated unless the methods used in its manufacture, processing, packing, and holding, as well as the facilities in which it was produced and the controls used during its production, conform to the GMPs so that the drug will meet the safety requirements of the Act and that it has the correct identity and strength to meet the quality and purity characteristics that it is represented to possess. Through the intervening years, additional regulations and guidelines have been issued to supplement the original drug GMPs (see References/Bibliography for examples). The ICH, of which FDA is a part, has continued to work to provide global standards for manufacturing and testing of products, and the FDA has already adopted many of these. A number of other guidelines or concept papers have been prepared by various organizations within the industry itself, such as the Pharmaceutical Manufacturers Association (PhRMA), the Parenteral Drug Association (PDA), the International Society of Pharmaceutical Engineering (ISPE), and others. A partial listing is provided in the Bibliography. In addition, as of January 2011, the FDA has become a member of The Pharmaceutical Inspection Co-operation Scheme (PIC/S) whose mission is "to lead the international development, implementation and maintenance of harmonized Good Manufacturing Practice (GMP) standards

and quality systems of inspectorates in the field of medicinal products.”<sup>4</sup>

FDA Website at <http://www.fda.gov> has many current guidance documents available for review and/or downloading.

GMP Training Website at <http://gmpttraining.com> has training programs and materials for FDA compliance training.

PIC/S Website at <http://www.picscheme.org> has lists of several cGMP guidance documents.

International Conference on Harmonization Website at <http://www.ich.org> has lists of several quality guidance documents such as Q7A - Good Manufacturing Practice Guidance for Active Pharmaceutical Ingredients and QS (R2) – Pharmaceutical Development.

Other Websites providing useful references: ISPE (International Society for Pharmaceutical Engineering) at <http://www.ispe.org>; DIA (Drug Information Association) at <http://www.diahome.org>; RAPS (Regulatory Affairs Professionals Society) at <http://www.raps.org>; and PDA (Parenteral Drug Association) at <http://www.pda.org>.

The current GMP regulations and the additional guides and guidelines listed in the References/Bibliography should be read and understood thoroughly by those involved in or interested in pursuing QC and QA responsibilities. The scope of the present regulation is given in the following outline (Appendix A), along with a brief interpretation of each subpart.

## APPENDIX A 21 CFR FOOD AND DRUGS

### PART 211 CURRENT GOOD MANUFACTURING PRACTICE FOR FINISHED PHARMACEUTICALS

#### SUBPART A GENERAL PROVISIONS

- 211.1 The regulations in this part contain the minimum current good manufacturing practice for preparation of drug products for administration to humans or animals.
- 211.3 (Definitions) The scope of the regulations are explained for human prescription and OTC drug products including drugs used to produce medicated animal feed. Reference is made to Part 210.3 of the chapter that gives definitions for all significant terms used in the regulations.

#### SUBPART B ORGANIZATION AND PERSONNEL

- 211.22 (Responsibilities of Quality (QC) unit) The QC unit has total responsibility for ensuring that adequate systems and procedures exist and are followed to ensure product quality.
- 211.25 (Personnel qualifications) Personnel, either supervisory or operational, must be qualified by training and experience to perform their assigned tasks.
- 211.28 (Personnel responsibilities) The obligations of personnel engaged in the manufacture of drug products concerning their personal hygiene, clothing, and medical status are defined.
- 211.34 (Consultants) The qualifications (education, training, and experience, or any combination thereof) of consultants must be sufficient for the project to which they are assigned.

#### SUBPART C BUILDINGS AND FACILITIES

Buildings and facilities are considered acceptable only if they are suitable for their intended purpose and can be cleaned and otherwise maintained. Design and construction features for lighting, pest control, and maintenance are described below.

- 211.42 (Design and construction features)
- 211.44 (Lighting)
- 211.46 (Ventilation, air filtration, air heating and cooling)
- 211.48 (Plumbing)
- 211.50 (Sewage and refuse)
- 211.52 (Washing and toilet facilities)
- 211.56 (Sanitation)
- 211.58 (Maintenance)

#### SUBPART D EQUIPMENT

Equipment must be designed, constructed, of adequate size, suitably located, and able to be maintained and cleaned to be considered suitable for its intended use. Regarding the use of automatic equipment, data processors, and computers, there is a need for input/output verification and for proper calibration of recorders, counters, and other electrical or mechanical devices.

- 211.63 (Equipment design, size, and location)
- 211.65 (Equipment construction)
- 211.67 (Equipment cleaning and maintenance)
- 211.68 (Automatic, mechanical, and electronic equipment)
- 211.72 (Filters) Filters to be used liquid filtration shall not release fibers into products.

#### SUBPART E CONTROL OF COMPONENTS AND DRUG PRODUCT CONTAINERS AND CLOSURES

- 211.80 (General requirements) Written procedures must be available that describe the receipt, identification, storage, handling, sampling, testing, and approval or rejection of components (raw materials) and drug products.
- 211.82 (Receipt and storage of untested components, drug product containers, and closures)

- 211.84 (Testing and approval or rejection of components, drug product containers, and closures)
- 211.86 (Use of approved components, drug product containers, and closures) Materials shall be rotated so that the oldest approved stock is used first.
- 211.87 (Retesting of approved components, drug product containers, and closures) Materials shall be retested or reexamined as necessary after storage for long periods or after exposure to air, heat or other conditions that might adversely affect the component, drug product container, closure.
- 211.89 (Rejected components, drug product containers, and closures) These items shall be identified and controlled to prevent their use in manufacturing.
- 211.94 (Drug product containers and closures) Containers and closures (product contact materials) must protect the product and must be nonreactive with or additive to the product, suitable for their intended use, and controlled using written procedures.

#### SUBPART F PRODUCTION AND PROCESS CONTROLS

- 211.100 (Written procedures and deviations) Written standard operating procedures (SOPs) for each production process and control procedure are necessary. Any deviation from an SOP must be investigated, recorded, and approved prior to final product acceptance.
- 211.101 (Charge-in of components) The procedures used to formulate a batch shall be written and followed.
- 211.103 (Calculation of yield) Actual yields and theoretical yields shall be determined. All products are to be formulated to provide not less than 100% of the required amount of active ingredient. The identity and quantity of each component incorporated into a batch must be recorded.
- 211.105 (Equipment identification) Equipment shall be properly identified.
- 211.110 (Sampling and testing of in-process materials and drug products) Significant in-process steps are to be identified and appropriate sampling, testing, and approvals obtained before proceeding further in the production cycle. Rejected material must be controlled.
- 211.111 (Time limitations on production) If required, time limitations will be placed on in-process steps.
- 211.113 (Control of microbiological contamination) Appropriate procedures are to be prepared for the control and prevention of microbiological contamination. The sterilization process must be validated.
- 211.115 (Reprocessing) Reprocessing of product is allowed providing there are written procedures covering the methods and QC unit review to be used.

#### SUBPART G PACKAGING AND LABELING CONTROL

- 211.122 (Materials examination and usage criteria) Labeling and packaging materials are to be received, identified, stored, sampled, and tested following detailed written procedures.
- 211.125 (Labeling issuance) Strict control shall be exercised over labeling for use in drug product labeling operations.
- 211.130 (Packaging and labeling operations) There shall be written procedures designed to ensure that correct labels, labeling, and packaging materials are used for drug products. Special controls must be exercised over labeling to ensure that only the correct labels are issued to packaging for a specific product and that the quantities used are reconciled with the quantity issued.

- 211.132 (Tamper-resistant packaging requirements for over-the-counter (OTC) human drug products) Provides details of tamper-resistant packaging.
- 211.134 (Drug product inspection) Packaged and labeled products shall be inspected for correct labels.
- 211.137 (Expiration dating) As supported by appropriate stability studies, products on the market shall bear an expiration date.

#### **SUBPART H HOLDING AND DISTRIBUTION**

- 211.142 (Warehousing procedures) Describes the requirements for warehousing holding product under appropriate conditions of light, temperature, and humidity.
- 211.150 (Distribution procedures) Written procedures describing product distribution shall be prepared.

#### **SUBPART I LABORATORY CONTROLS**

- 211.160 (General requirements) The general requirements for laboratory control mechanisms are described.
- 211.165 (Testing and release for distribution) There shall be written procedures in the form of specifications, standards, sampling plans, and test procedures that are used in a laboratory for controlling components and finished drug products. Acceptance criteria for sampling and approval shall be adequate to support release of product for distribution.
- 211.166 (Stability testing) There shall be a written testing program designed to assess the stability characteristics of drug products. The results of this testing shall be used in assigning appropriate storage conditions and expiration dates.
- 211.167 (Special testing requirements) There are special testing requirements for sterile and/or pyrogen-free ophthalmic ointment and controlled-release dosage form products.
- 211.170 (Reserve samples) Reserve sample quantity and retention times are described.
- 211.173 (Laboratory animals) Animals used in any testing shall be maintained and controlled in a manner suitable for use.
- 211.176 (Penicillin contamination) Drug products cannot be marketed if, when tested by a prescribed procedure, found to contain any detectable levels of penicillin.

#### **SUBPART J RECORDS AND REPORTS**

- 211.180 (General requirements) Describes record retention time and availability for inspection.

- 211.182 (Equipment cleaning and use log) A written record of major equipment cleaning, maintenance, and use shall be included in major equipment logs.
- 211.184 (Component, drug product container, closure, and labeling records) Deals with the issues of the receipt, testing, and storage of components, drug product containers, and closures. Details the various records and documents that should be generated during the manufacture of drug products and that are to be available for review.
- 211.186 (Master production and control records) A master production record must be prepared for each drug product, describing all aspects of its manufacture, packaging, and control. Individual batch records are derived from this approved master.
- 211.188 (Batch production and control records) Batch production and control records with information about the production and control of each batch are prepared.
- 211.192 (Production record review) All drug product batch records shall be reviewed and approved by the QC unit (QA/QC) before the batch is released.
- 211.194 (Laboratory records) Complete records of any laboratory testing shall be maintained to include raw data, test procedures and results, initials or signatures of personnel performing the test or reviewing the results of tests, periodic equipment calibration, and stability test results.
- 211.196 (Distribution records) Distribution records include warehouse shipping logs, invoices, bills of lading, and all documents associated with distribution. These records should provide all the information necessary to trace lot distribution to facilitate product retrieval if necessary.
- 211.198 (Complaint files) Written records of complaints received from consumers and professionals are to be maintained along with the report of investigations and responses.

#### **SUBPART K RETURNED AND SALVAGED DRUG PRODUCTS**

- 211.204 (Returned drug products) Records are to be maintained of drug products returned from distribution channels and the reason for their return. These data can be used as part of the total lot accountability, should the need arise, to trace its distribution and/or for its recall.
- 211.208 (Drug product salvaging) Drug products that have been stored improperly are not to be salvaged.

# Chapter 4

## Stability of Pharmaceutical Products

Allan D. Bokser, PhD and Patrick B. O'Donnell, PhD

INTRODUCTION	37
REGULATORY REQUIREMENTS	38
PRODUCT STABILITY	39
PREDICTING SHELF LIFE	45

APPROXIMATIONS IN ASSESSING PRODUCT STABILITY	45
PHARMACEUTICAL CONTAINERS	47
CLOSURES	48

### INTRODUCTION

Stability of a pharmaceutical product may be defined as the capability of a particular formulation, in a specific container/closure system, to remain within its physical, chemical, microbiological, therapeutic, and toxicological specifications at a defined storage condition. Pharmaceutical products are expected to meet their specifications for identity, purity, quality, and strength throughout their defined storage period at specific storage conditions. Assurances that the packaged product will be stable for its anticipated shelf life must come from an accumulation of valid data on the drug in its commercial package. These stability data include selected parameters that, taken together, form the stability profile.

The stability of a pharmaceutical product is investigated throughout the various stages of the development process. The stability of a drug substance is first assessed in the preformulation stage. At this stage, pharmaceutical scientists determine the drug substance and its related salts stability/compatibility with various solvents, buffered solutions and excipients considered for formulation development. Suitable analytical methods must be employed in order to ensure the likelihood that this assessment will be successful. Optimization of a stable formulation of a pharmaceutical product is built (using statistical design) upon the information obtained from the preformulation stage and continues during the formulation development stages.

Typically, the first formulation development stage may be for preclinical studies or as late as the preparation of a “first in human” formulation which is often a non-elegant formulation optimized for short-term dose-ranging clinical studies. The second major formulation development stage occurs to support Phase II clinical studies (proof of concept phase). The pharmaceutical product developed at this stage is usually the prototype for the commercial product. Therefore, the pharmaceutical product will be formulated based in part on the stability information obtained from the previous formulations and must meet stability requirements for longer-term clinical studies. In the final formulation development state for Phase III clinical studies, the formulation must be truly representative of what the commercial pharmaceutical product will be in order to avoid delays in approval. In addition to building on the clinical requirements of the drug, the commercial pharmaceutical product must also incorporate the commercial or the final market image of the product, which includes the container closure system. The stability of this product must be demonstrated to the appropriate regulatory agencies in order to assign an expiration period and date for the product. This expiration period allows for the assignment of an expiration date based on the manufacture date of each lot of drug product.

Once a pharmaceutical product has gained regulatory approval and is marketed, the pharmacist must understand the proper storage and handling of the drug. In some cases, a pharmacist may need to prepare stable compounded preparations from this product.

Most drug products are not shipped directly from the manufacturer to a pharmacy. Typically, a drug product is shipped from a manufacturer to a distribution center. From the distribution center the drug product is then shipped to a wholesaler. From the wholesaler, the drug product may be shipped to the distribution center for a pharmacy chain or directly to the pharmacy. Finally, the drug product is dispensed by the pharmacy to the patient. Dispensing of the drug product may be at a hospital, a clinic, and a traditional “brick and mortar” pharmacy or from a mail-order pharmacy. Therefore, the stability typically must also assess the robustness of the drug product through its supply chain. It is not unusual for temperature excursions to occur during these transfers of control.

Inventory control, or holding, of each drug is important for a wholesaler or pharmacy. A drug must be within its expiration dating throughout its use by the patient. Solid oral dosages may be dispensed in the commercial packaging or in a pharmacy supplied container closure system. Most prescriptions are supplied to patients for up to 30 or 90 days by traditional and mail-order pharmacies, respectively. Inventory control of product by wholesalers and pharmacies must assess how much dating must remain on a product for it to be useful for its customer. This causes the actual holding of a product to be shorter than the expiration date. Under normal circumstances it is unusual for a pharmacy to accept any product with less than 6 month dating remaining on a product.

Much has been written about the development of a stable pharmaceutical product. Comprehensive treatments of all aspects of pharmaceutical product stability have been published by Connors *et al.*<sup>1</sup>, Carstensen<sup>2</sup> and more recently by Allen.<sup>3</sup> This chapter will outline the appropriate steps from preformulation to drug approval to assure that the pharmaceutical product developed is stable. Requirements for compounded products will also be discussed.

The United States Pharmacopeia (USP) General Chapter <1191><sup>4</sup> defines the stability of a pharmaceutical product as “extent to which a product retains, within specified limits, and throughout its period of storage and use (i.e., its shelf life), the same properties and characteristics that it possessed at the time of its manufacture.” There are five types of stability that must be considered for each drug (Table 4-1).

The use of kinetic and predictive studies for establishing credible expiration dating for pharmaceutical products is now accepted worldwide. Scientifically designed studies using reliable, meaningful, and specific stability-indicating assays, appropriate statistical concepts, and a computer to analyze the resulting data are used to determine an accurate and realistic shelf life. In this way the maximum amount of valid information is obtained to establish a reliable, defensible expiration date for each formulation. The assigned expiration date is a direct application and interpretation of the knowledge gained from the stability study.

Although there are exceptions, 90% of labeled potency generally is recognized as the minimum acceptable potency

**Table 4-1. Types of Stability**

Type of Stability	Conditions Maintained Throughout the Shelf Life of the Drug Product
Chemical	Each active ingredient retains its chemical integrity and labeled potency, within the specified limits.
Physical	The original physical properties, including appearance, palatability, uniformity, dissolution, and suspendability are retained.
Microbiological	Sterility or resistance to microbial growth is retained according to the specified requirements. Antimicrobial agents that are present retain effectiveness within the specified limits.
Therapeutic	The therapeutic effect remains unchanged.
Toxicological	No significant increase in toxicity occurs.

level over the shelf life of a drug product. Exceptions to this minimum potency include drugs with active pharmaceutical ingredients that have a narrow therapeutic thresholds and biologics.

The stability of a commercial pharmaceutical product is expressed as an expiration date (expiry). Expiration dating is defined, therefore, as the time in which a drug product in a specific packaging configuration will remain stable when stored under recommended conditions. This date is usually calculated by adding the established expiration period to the date of manufacture. The date of manufacture is many times defined as the date in which the active pharmaceutical ingredient is first combined with a drug product excipient.

An expiration date, which is expressed traditionally in terms of month and year, denotes the last day of the month. In the United States, the expiration date shall appear on the immediate container and the outer retail package. However, when single-dose containers are packaged in individual cartons, the expiration date may be placed on the individual carton instead of the immediate product container. If a dry product is to be reconstituted at the time of dispensing, expiration dates are assigned to both the dry mixture and the reconstituted product. Tamper-resistant packaging is to be used where applicable.

## REGULATORY REQUIREMENTS

Stability study requirements and expiration dating are covered in the Current Good Manufacturing Practices (cGMPs),<sup>5</sup> the USP,<sup>6</sup> and the FDA and ICH guidelines.

## GOOD MANUFACTURING PRACTICES

The GMPs<sup>5</sup> as stated in US 21 CFR part 211.166 requires that there shall be a written testing program designed to assess the stability characteristics of drug products. The results of such stability testing shall be used to determine appropriate storage conditions and expiration dating. The latter is to ensure that the pharmaceutical product meets applicable standards of identity, strength, quality, and purity at time of use. Regulatory agencies of other regions have similar requirements. For example Canadian regulations require that every distributor and importer shall monitor, by means of a continuing program, the stability of the drug in the package in which it is sold.<sup>7</sup> The European Union GMPs states “after marketing, the stability of the medicinal product should be monitored according to a continuous appropriate program that will permit the detection of any stability issue (e.g., changes in levels of impurities or dissolution profile) associated with the formulation in the marketed package.”<sup>8</sup> These regulations, which apply to both human and

veterinary drugs, are updated periodically in light of current knowledge and technology.

## COMPENDIA

The USP also contains extensive stability and expiration dating information. Included are a discussion of stability considerations in dispensing practices and the responsibilities of both the pharmaceutical manufacturer and the dispensing pharmacist. It now is required that product labeling of official articles provide recommended storage conditions and an expiration date assigned to the specific formulation and package. Official storage conditions as defined by the USP 34<sup>9</sup> are as follows:

- *Freezer* – a place where temperature is maintained thermostatically between  $-25^{\circ}\text{C}$  and  $-10^{\circ}\text{C}$ .
- *Cold* – any temperature not exceeding  $8^{\circ}\text{C}$  and *refrigerator* is a cold place where the temperature is maintained thermostatically between  $2$  and  $8^{\circ}\text{C}$ .
- *Controlled Cold Temperature* – temperature maintained thermostatically between  $2^{\circ}$  and  $8^{\circ}\text{C}$ .
- *Cool* is defined as any temperature between  $8$  and  $15^{\circ}\text{C}$ .
- *Room Temperature* – the temperature prevailing in a working area.
- *Controlled Room Temperature* – temperature maintained thermostatically between  $20$  and  $25^{\circ}\text{C}$ .
- *Warm* – any temperature between  $30$  and  $40^{\circ}\text{C}$ .
- *Excessive Heat* – any heat above  $40^{\circ}\text{C}$ .
- *Protect from Freezing* – where, in addition to the risk of breakage of the container, freezing subjects an article to loss of a product to a loss of strength, potency or to destructive alteration its characteristics, the container label should bear appropriate instructions to protect the product from freezing.
- *Dry Place* – denotes a place that does not exceed 40% average relative humidity (RH) at Controlled Room Temperature or the equivalent water vapor pressure at other temperatures.

Most drug products are stored at controlled room temperature and are labeled as such. As is noted above in USP 34, the definition of controlled room temperature was a “temperature maintained thermostatically between  $20$  and  $25^{\circ}\text{C}$  ( $68$  and  $77^{\circ}\text{F}$ ).” This definition was established to harmonize with international drug standards efforts. The usual or customary temperature range is identified as  $20$  to  $25^{\circ}\text{C}$ , with the possibility of encountering excursions in the  $15$  to  $30^{\circ}\text{C}$  range and with the introduction the mean kinetic temperature (MKT).

The mean kinetic temperature is calculated using the following equation:

$$T_k = \left[ \frac{\Delta H / R}{-\ln \left( \frac{e^{-\Delta H / RT_1} + e^{-\Delta H / RT_2} + \dots + e^{-\Delta H / RT_{n-1}} + e^{-\Delta H / RT_n}}{n} \right)} \right] \quad (1)$$

in which  $T_k$  is the mean kinetic temperature;  $\Delta H$  is the heat of activation,  $83.144 \text{ kJ} \cdot \text{mole}^{-1}$ ;  $R$  is the universal gas constant,  $8.3144 \times 10^{-3} \text{ kJ} \cdot \text{mole}^{-1} \cdot \text{degree}^{-1}$ ;  $T_1$  is the value for the temperature (in degrees Kelvin ( $^{\circ}\text{K}$ )) recorded during the first time period,  $T_2$  is the value for the temperature recorded during the second time period, e.g., second week;  $T_{n-1}$  is the value of the second to last time period, and  $T_n$  is the value for the temperature recorded during the  $n$ th time period. Typically, the time period is in days or weeks.

Mean kinetic temperature determine the thermal expose of a material. This allows an acceptable estimation to assess if a temperature excursion (or series of excursions) adversely affected a material.

**FDA and ICH Guidelines** provide recommendations for

1. the design of stability studies to establish appropriate expiry and product storage requirements

- the submission of stability information for investigational new drugs, biologics, new drug applications, and biological product license applications.

Thus, the guidelines represent a framework for the experimental design and data analysis as well as the type of documentation needed to meet regulatory requirements in the drug-development process.

The International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) is an ongoing project that brought together regulatory authorities and experts from the pharmaceutical industry from three regions of the world; Europe, Japan, and the US since its inception in 1990. The first conference (ICH1) took place in November 1991 in Brussels, and the second conference (ICH2) in Orlando, FL, in October 1993. These conferences continue to provide an open forum for discussion and resulted in the creation of an extensive set of guidelines dealing with the many aspects of safety, quality, and efficacy of medicinal products. The following ICH Harmonized Tripartite Guidelines related to stability are summarized below.

- Q1A (R2) provides the general requirements for *Stability Testing of New Drug Substances and Products*. The main thrust of the stability guideline centers on criteria for setting up stability protocols, shown in Table 4-2. ICH Q1A is considered the parent guideline for stability.<sup>10</sup>
- Q1B provides the general requirements for assessing the intrinsic photostability characteristics of new drug substances and drug products.<sup>11</sup>
- Q1C provides the reduced general requirements for stability testing of new drug products dosage forms that use active ingredients already approved in another dosage form.<sup>12</sup>
- Q1D provides approaches that allows for bracketing and matrixing designs for stability testing. This is especially important when a new drug product is to be commercialized with multiple strengths in multiple packaging configurations.<sup>13</sup>
- Q1E provides acceptable approaches for evaluating stability data to assess the shelf life of the product in a registration application.<sup>14</sup>
- Q1F was withdrawn. It provided definitions for testing conditions to register drugs marketed in Climatic Zones III and IV.<sup>15</sup> However, countries in Climatic Zone IV believed that a larger safety margin was required than presented in this guidance.

It should be noted that all ICH guidelines provide approaches that are now common in the industry for assessing stability of a drug substance or drug product. However, these guidelines also make it clear that alternative approaches can be used when there are scientifically justifiable reasons.

**Table 4-2a. Stability Protocols**

Conditions	Minimum Time Period at Submission
Long-term testing 25°C ± 2°C/60% RH ± 5%	12 month
Accelerated testing 40°C ± 2°C/75% RH ± 6%	6 month
Alternate testinga 30°C ± 2°C/65% RH ± 5%	12 month

Required if *significant change* occurs during 6-mo storage under conditions of accelerated testing.

**Table 4-2b. Example Stability Pull Schedule for a Solid Oral Dose for Zone I and II**

Storage Conditions	Durations (Months)								
	0	1	3	6	9	12	18	24	36
25 °C/60 % RH	R		X	X	X	X, Y	X	X	X
30 °C/65 % RH			O	O	O	O			
40 °C/75% RH		X	X	X, Y					

\*From Release testing if testing is within 30 days of stability set down  
 R= Release Tests; Appearance (visual); Identity; Assay (HPLC); Impurities (HPLC); Dissolution (USP <711>); Moisture Content (Karl Fischer); Uniformity of Dosage Unit  
 X = Tests at Every Stability Pull; Appearance (visual); Assay (HPLC); Impurities (HPLC); Dissolution USP <711>  
 O = Pull and test only after 40 °C/75% is out of specification; Appearance (visual); Assay (HPLC); Impurities (HPLC); Dissolution  
 Y = Additional tests periodically performed; Moisture Content (Karl Fischer)

The FDA and ICH guidelines are readily available on the internet. The pharmaceutical scientist can now access a complete listing of both FDA and ICH publications. To view the publications, go to: <http://www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/default.htm> for the FDA guidance webpage, and <http://www.ich.org/products/guidelines/quality/article/quality-guidelines.html> for the ICH guideline webpage.

## PRODUCT STABILITY

Many factors affect the stability of a pharmaceutical product including the intrinsic stability of the active ingredient(s), the potential interaction between active and inactive ingredients, the manufacturing process, the dosage form, the container-liner-closure system and the environmental conditions encountered during shipment, storage and handling and length of time between manufacture and usage.

Classically, pharmaceutical product stability evaluations have been separated into studies of chemical (including biochemical) and physical stability of formulations. Realistically, there is no absolute division between these two arbitrary divisions. Physical factors—such as heat, light, and moisture—may initiate or accelerate chemical reactions, whereas every time a measurement is made on a chemical compound, physical dimensions are included in the study.

One type of time-related chemical stability failure is a decrease in therapeutic activity of the preparation to below some arbitrary labeled content. A second type of chemical stability failure is the appearance of a toxic substance, formed as a degradation product upon storage of the formulation. The numbers of published cases reflecting this second type are few. However, it is possible, though remote, for both types of stability failures to occur simultaneously within the same pharmaceutical product. Thus, the use of stability studies with the resulting application of expiration dating to pharmaceuticals is an attempt to predict the approximate time at which the probability of occurrence of a stability failure may reach an intolerable level. This estimate is subject to the usual Type 1 or alpha error (setting the expiration too early so that the product will be destroyed or removed from the market appreciably earlier than actually is necessary) and the Type 2 or beta error (setting the date too late so that the failure occurs in an unacceptably large proportion of cases). Thus, it is obligatory that the manufacturer clearly and succinctly defines the method for determining the

degree of change in a formulation and the statistical approach to be used in making the shelf life prediction. An intrinsic part of the statistical methodology must be the statements of value for the two types of error. For the safety of the patient a Type 1 error can be accepted, but not a Type 2 error.

One type of time related physical stability failures may affect the availability or rate of drug release of a product. This type of physical stability failure may cause the active ingredient not to be released or a higher rate of drug release (dose dumping). Another type of time related physical stability failures are appearance related. These may just cause the drug product not to appear pharmaceutically elegant or may be an artifact of another physical or chemical stability failure.

In this treatment, physical and chemical stability are discussed along with those dosage form properties that can be measured and are useful in predicting shelf life. The effect of various physical and chemical phenomena of pharmaceuticals also is treated.

Knowledge of the physical stability of a formulation is very important for three primary reasons. First, a pharmaceutical product must appear fresh, elegant, and professional, for as long as it remains on the shelf. Any changes in physical appearance such as color fading or haziness can cause the patient or consumer to lose confidence in the product. Second, since some products are dispensed in multiple-dose containers, potency of the active ingredient over time must be ensured for each individual dose. A cloudy solution or a broken emulsion can lead to a non-uniform dosage pattern. Third, the active ingredient must be bioavailable to the patient throughout the expected shelf life of the preparation. A breakdown in the physical system can lead to non-availability or "dose dumping" of the medication to the patient. In the case of metered-dose inhaler pulmonary aerosols, particle aggregation may result in inadequate lung deposition of the medication.

The chemical causes of drug deterioration have been classified as incompatibility, oxidation, reduction, hydrolysis, racemization, and other mechanisms. In the latter category, decarboxylation, deterioration of hydrogen peroxide and hypochlorites and the formation of precipitates have been included.

## PHARMACEUTICAL DOSAGE FORMS

As the various pharmaceutical dosage forms present unique stability problems, they are discussed separately in the following section.

### Tablets

Stable tablets retain their original size, shape, weight, and color under normal handling and storage conditions throughout their shelf life. In addition, the *in vitro* availability of the active ingredients should not change appreciably with time.

Excessive powder or solid particles at the bottom of the container, cracks or chips on the face of a tablet, or appearance of crystals on the surface of tablets or on container walls are indications of physical instability of uncoated tablets. Hence, the effect of mild, uniform, and reproducible shaking and tumbling of tablets should be studied. The recommended test for such studies is the determination of tablet friability as described in the USP. Tablet Friability USP <1216> describes the recommended apparatus and the test procedure. After visual observation of the tablets for chips, cracks, and splits, the intact tablets are sorted and weighed to determine the amount of material worn away by abrasion. In general, a maximum weight loss of not more than 1% of the weight of the tablets being tested is considered acceptable for most products. The results of these tests are comparative rather than absolute and should be correlated with actual stress experience. Packaged tablets also should be subjected to cross-country shipping tests as well as to various *drop tests*.

Tablet hardness (or resistance to crushing or fracturing) can be assessed by commercially available hardness testers. As

results will vary with the specific make of the test apparatus used, direct comparison of results obtained on different instruments may not necessarily be made. Thus, the same instrument should be used consistently throughout a particular study.

Color stability of tablets can be followed by an appropriate colorimeter or reflectometer with heat, sunlight, and intense artificial light employed to accelerate the color deterioration. It is still not unusual for color assessment to be performed visually. Caution must be used in interpreting the elevated temperature data, as the mechanism for degradation at that temperature may differ from that at a lower temperature. It is not always proper to assume that the same changes will occur at elevated temperatures as will be evidenced later at room temperature. Cracks, mottling, or tackiness of the coating indicates evidence of instability of coated tablets.

Typically, dissolution is the *in vitro* test performed to estimate bioavailability for a tablet regardless of the solubility of the active ingredients. Disintegration has been relegated to an in-process test or used to help dissolution. Dissolution tests should be run in an appropriate medium at 37°C. Actual dissolution conditions, including medium, are developed during the clinical development phase of a product. The dissolution method developed has to demonstrate a correlation that is relevant to the bioavailability of the dosage form. Dissolution profiles are examined during development to provide sufficient information to define a single sample time point with a minimum concentration for immediate release product. Controlled release drug products require a dissolution profile with concentration ranges at set sampling points for product assessment. When no significant change (such as a change in the polymorphic form of the crystal) has occurred, an unaltered dissolution-rate profile of a tablet formulation usually indicates constant *in vivo* bioavailability.

Uniformity of weight, odor, texture, drug and moisture contents, and humidity effect may also be studied during a tablet stability test.

### Gelatin Capsules

Hard gelatin capsules are the type used by pharmaceutical manufacturers in the production of the majority of their capsule products. The pharmacist in the extemporaneous compounding of prescriptions may also use hard gelatin capsules. Soft gelatin capsules are prepared from shells of gelatin to which glycerin or a polyhydric alcohol such as sorbitol has been added to render the gelatin elastic or plastic-like. Gelatin is stable in air when dry but is subject to microbial decomposition when it becomes moist or when it is maintained in aqueous solution. Normally hard gelatin capsules contain between 13 and 16% moisture. If stored in a high humidity environment capsule shells may soften, stick together or become distorted and lose their shape. On the other hand, in an environment of extreme dryness, gelatin capsules may harden and crack under slight pressure. Gelatin capsules should be protected from sources of microbial contamination. Encapsulated products, like all other dosage forms, must be packaged properly.

Because moisture may be absorbed or released by gelatin capsules depending on the environmental conditions, capsules offer little physical protection to hygroscopic or deliquescent materials enclosed within a capsule when stored in an area of high humidity. It is not uncommon to find capsules packaged in containers along with a packet of desiccant material as a precautionary measure.

Dissolution development and requirements for capsules are similar to tablets. The capsule shell can affect dissolution test results but not be relevant to bioavailability. Both hard and soft gelatin capsules exposed to excessive heat and moisture may exhibit delayed or incomplete dissolution due to cross-linking of the gelatin in the capsule shell. The cross-linking of gelatin capsules is an irreversible chemical reaction. Cross-linking may also occur in capsules that are exposed to aldehydes and peroxides. Although cross-linked capsules may fail dissolution due to

pellicle formation, digestive enzymes will dissolve the capsules. For hard or soft gelatin capsules that do not conform to the dissolution specification, the dissolution test may be repeated with the addition of enzymes. Where water or a medium with a pH less than 6.8 is specified as the medium in the individual monograph, the same medium specified may be used with the addition of purified pepsin that results in an activity of 750,000 units or less per 1000 mL. For media with a pH of 6.8 or greater, pancreatin can be added to produce not more than 1750 USP units of protease activity per 1000 mL.

## Suspensions

A stable suspension can be redispersed homogeneously with moderate shaking and can be poured easily throughout its shelf life, with neither the particle size distribution, the crystal form, nor the physiological availability of the suspended active ingredient changing appreciably with time.

Most stable pharmaceutical suspensions are flocculated; that is, the suspended particles are bonded together physically to form a loose, semi rigid structure. The particles are said to uphold each other while exerting no significant force on the liquid. Sedimented particles of a flocculated suspension can be redispersed easily at any time with only moderate shaking.

In non-flocculated suspensions, the particles remain as individuals unaffected by neighboring particles and are affected only by the suspension vehicle. These particles, which are smaller and lighter, settle slowly. Once they have settled, they often form a hard, difficult-to-disperse sediment. Non-flocculated suspensions can be made acceptable by decreasing the particle size of the suspended material or by increasing the density and viscosity of the vehicle, thus reducing the possibility of settling.

When studying the stability of a suspension, a differential manometer is used to determine if the suspension is flocculated. If the suspension is flocculated, the liquid will travel the same distance in the two side arms. With non-flocculated suspensions, the hydrostatic pressures in the two arms are unequal; hence, the liquids will be at different levels.

The history of settling of the particles of a suspension may be followed by a Brookfield viscometer fitted with a Helipath attachment. This instrument consists of a rotating T-bar spindle that descends slowly into the suspension as it rotates. The dial reading on the viscometer is a measure of the resistance that the spindle encounters at various levels of the sedimented suspension. This test must be run only on fresh, undisturbed samples.

An electronic particle counter and sizer, such as a Coulter counter, or a microscope may be used to determine changes in particle size distribution. Crystal form alterations may be detected by microscopic, near-IR or Raman examination and, when suspected, must be confirmed by X-ray powder diffraction.

All suspensions should be subjected to cycling temperature conditions to determine the tendency for crystal growth to occur within the suspension. Shipping tests, namely transporting bottles across the country by rail or truck are also used to study the stability of suspensions.

## Solutions

A stable solution retains its original clarity, color, and odor throughout its shelf life. Retention of clarity of a solution is a main concern of a physical stability program. As visual observation alone under ordinary light is a poor test of clarity, a microscope light should be projected through a diaphragm into the solution. Undissolved particles will scatter the light, and the solution will appear hazy. Although the Coulter counter also can be used, light-scattering instruments are the most sensitive means of following solution clarity.

Solutions should remain clear over a relatively wide temperature range such as 4 to 47°C. At the lower range an ingredient may precipitate due to its lower solubility at that temperature, whereas at the higher temperature the flaking of particles from

the glass containers or rubber closures may destroy homogeneity. Thus, solutions should be subjected to cycling temperature conditions.

The stability program for solutions also should include a study of pH changes, especially when the active ingredients are soluble salts of insoluble acids or bases. Among other tests are observations for changes in odor, appearance, color, taste, light-stability, pourability, viscosity, isotonicity, gas evolution, microbial stability, specific gravity, surface tension, and pyrogen content, in the case of parenteral products.

When solutions are filtered, the filter medium may absorb some of the ingredients from the solution. Thus, the same type of filter should be used for preparing the stability samples as will be used to prepare the production-size batches.

For dry-packaged formulations reconstituted prior to use, the visual appearance should be observed on both the original dry material and on the reconstituted preparation. The color and odor of the cake, the color and odor of the solution, the moisture content of the cake, and the rate of reconstitution should be followed as a part of its stability profile.

## Emulsions

A stable emulsion can be redispersed homogeneously to its original state with moderate shaking and can be poured at any stage of its shelf life. Although most of the important pharmaceutical emulsions are of the oil in water (O/W) type, many stability test methods can be applied to either an O/W or water in oil (W/O) emulsion.

Two simple tests are used to screen emulsion formulations. First, heating to 50 to 70°C and observing its gross physical stability either visually or by turbidimetric measurements can determine the stability of an emulsion. Usually the emulsion that is the most stable to heat is the one most stable at room temperature. However, this may not be true always, because an emulsion at 60°C may not be the same as it is at room temperature. Second, the stability of the emulsion can be estimated by the *coalescence time* test. Although this is only a rough quantitative test, it is useful for detecting gross differences in emulsion stability at room temperature.

Emulsions also should be subjected to refrigeration temperatures. An emulsion stable at room temperature has been found to be unstable at 4°C. It was reasoned that an oil-soluble emulsifier precipitated at the lower temperature and disrupted the system. An emulsion chilled to the extent that the aqueous base crystallizes is damaged irreversibly.

The ultracentrifuge also is used to determine emulsion stability. When the amount of separated oil is plotted against the time of centrifugation, a plateau curve is obtained. A linear graph results when the oil flotation (creaming) rate is plotted versus the square of the number of centrifuge revolutions per minute. The flotation rate is represented by the slope of the line resulting when the log distance of emulsion-water boundary from the rotor center is plotted against time for each revolution per minute.

For stability studies, two batches of an emulsion should be made at one time on two different sizes of equipment. One should be a bench-size lot and the other a larger, preferably production-size, batch. Different types of homogenizers produce different results, and different sizes of the same kind of homogenizer can yield emulsions with different characteristics.

## Ointments

Ointments have been defined as high-viscosity suspensions of active ingredients in a non-reacting vehicle. A stable ointment is one that retains its homogeneity throughout its shelf life period. The main stability problems observed in ointments are *bleeding* and changes in consistency due to aging or changes in temperature. When fluid components such as mineral oil separate at the top of an ointment, the phenomenon is known as *bleeding* and can be observed visually. Unfortunately, as there is no known way to accelerate this event, the tendency to *bleed* cannot be predicted.

An ointment that is too soft is messy to use, whereas one that is very stiff is difficult to extrude and apply. Hence, it is important to be able to define quantitatively the consistency of an ointment. This may be done with a penetrometer, an apparatus that allows a pointed weight to penetrate into the sample under a measurable force. The depth of the penetration is a measure of the consistency of an ointment. Consistency also can be measured by the Helipath attachment to a high-viscosity viscometer or by a Burrell Severs rheometer. In the latter instrument the ointment is loaded into a cylinder and extruded with a measured force. The amount extruded is a measure of the consistency of the ointment.

Ointments have a considerable degree of structure that requires a minimum of 48 hours to develop after preparation. As rheological data on a freshly made ointment may be erroneous, such tests should be performed only after the ointment has achieved equilibrium. Slight changes in temperature (1 or 2°C) can affect the consistency of an ointment greatly; hence, rheological studies on ointments must be performed only at constant and controlled temperatures.

Among the other tests performed during the stability study of an ointment are a check of visual appearance, color, odor, viscosity, softening range, consistency, homogeneity, particle size distribution, and sterility. Undissolved components of an ointment may change in crystal form or in size with time. Microscopic examination or an X-ray diffraction measurement may be used to monitor these parameters.

In some instances it is necessary to use an ointment base that is less than ideal, to achieve the required stability. For example, drugs that hydrolyze rapidly are more stable in a hydrocarbon base than in a base containing water, even though they may be more effective in the latter.

### Transdermal Patches

A typical transdermal patch consists of a protective backing, a matrix containing active drug, an adhesive that allows the patch to adhere to the skin and a release liner to protect the skin adhering adhesive. Therefore, the transdermal patch must deliver drug as labeled, adhere properly to both the backing and to the patient's skin. In addition, the transdermal patch must be pharmaceutically elegant through the shelf life of the product. For a transdermal patch, this means that the release line peels easily with minimal transfer of adhesive onto the release liner and that the adhesive does not ooze from the sides of the patch. Therefore, the typical stability related tests for transdermal patches are appearance, assay, impurities, drug release per USP<724>, and backing peel force.

### Metered-Dose Aerosols Drug Products

A metered dose inhalation product comprises an aerosol can containing a propellant and drug, and a mouthpiece used to present an aerosolized drug to the patient. There are many drug contact components in a metered-dose inhalation product. Therefore, the drug may be in contact with materials that could allow plasticizer leach into the propellant. The typical stability related tests for metered-dose aerosols include appearance, assay, impurities, plume geometry, emitted dose, particle size distribution of the emitted dose, and number of doses per unit. In addition, stability studies on leachables may be required. Shelf life of metered-dose aerosols drug products may also be dependent on the orientation that the drug product is stored. Typically most canister type products are tested at least in the upright orientation.

### Dry-Powdered Inhalation Products

A dry-powdered inhalation product consists of drug with excipients delivered in a dry powdered form. The delivery system for a dry-powdered inhalation product may be a separate device or integrated with the active. A dry-powdered dosage must reproducibly deliver a specific amount of drug at a particle size that can be deposited into the lungs. Particles too large will get

trapped in the throats and particles too small will just be carried out of the lungs on the next expiration. The typical stability related tests for dry powder inhalation products include appearance, assay, impurities, emitted dose, particle size distribution of the emitted dose, and water content.

### Nasal Inhalation Products

A nasal inhalation product consists of drug with excipients delivered from a delivery system. The delivery system for a nasal inhalation product may be a separate device or integrated with the active. A nasal inhalation product must reproducibly deliver a specific amount of drug at a particle size and plume that can be deposited into the nasal membrane. Particles too large will not be absorbed into nasal membrane or run out of the nose; and poor spray pattern will deposit the drug ineffective in the nasal cavity. The typical stability related tests for nasal inhalation products include appearance, assay, impurities, spray content uniformity, particle (droplet) size distribution of the emitted dose, spray pattern or /and plume geometry, leachables, weight loss and preservative content. Sterility and microbial testing may be required periodically for stability testing.

### INCOMPATIBILITY

Typically, physicochemical stability is assessed at the preformulation stage of development. A drug substance candidate is treated with acid, base, heat, light, and oxidative conditions to assess its inherent chemical stability. Binary mixtures of the drug substance with individual excipients are also investigated at the preformulation stage. These tests are performed to determine the drug substance sensitivity to degrade or reactivity with common pharmaceutical excipients. The most common reactions observed for drug substances from these tests include: hydrolysis, epimerization (racemization), decarboxylation, dehydration, oxidation, polymerization, photochemical decomposition and addition. All drug substances have the potential to degrade by at least one of the reactions mentioned above. With an understanding of the stability/reactivity of a drug substance in the preformulation stage, it is possible to formulate the drug product to minimize drug decomposition. Numerous examples are described in other sections of this book, and the literature is replete with illustrations.

Although undesirable reactions between two or more drugs are said to result in a *physical, chemical, or therapeutic incompatibility*, physical incompatibility is somewhat of a misnomer. It has been defined as a physical or chemical interaction between two or more ingredients that leads to a visibly recognizable change. The latter may be in the form of a gross precipitate, haze, or color change.

On the other hand, a chemical incompatibility is classified as a reaction in which a visible change is not necessarily observed. Since there is no visible evidence of deterioration, this type of incompatibility requires trained, knowledgeable personnel to recognize it.

A therapeutic incompatibility has been defined as an undesirable pharmacological interaction between two or more ingredients that leads to:

1. Potentiation of the therapeutic effects of the ingredients.
2. Destruction of the effectiveness of one or more of the ingredients.
3. Occurrence of a toxic manifestation within the patient.

### CHEMICAL REACTIONS

The most frequently encountered chemical reactions, which may occur within a pharmaceutical product, are described below.

#### Oxidation-Reduction

Oxidation is a prime cause of product instability, and often, but not always, the addition of oxygen or the removal of hydrogen is involved. When molecular oxygen is involved, the reaction

is known as auto-oxidation because it occurs spontaneously, though slowly, at room temperature.

Oxidation, or the loss of electrons from an atom, frequently involves free radicals and subsequent chain reactions. Only a very small amount of oxygen is required to initiate a chain reaction. In practice, it is easy to remove most of the oxygen from a container, but very difficult to remove it all. Hence, nitrogen and carbon dioxide frequently are used to displace the head-space air in pharmaceutical containers to help minimize deterioration by oxidation.

As an oxidation reaction is complicated, it is difficult to perform a kinetic study on oxidative processes within a general stability program. The redox potential, which is constant and relatively easy to determine, can, however, provide valuable predictive information. In many oxidative reactions, the rate is proportional to the concentration of the oxidizing species but may be independent of the concentration of the oxygen present. The rate is influenced by temperature, radiation, and the presence of a catalyst. An increase in temperature leads to an acceleration in the rate of oxidation. If the storage temperature of a preparation can be reduced to between 0-5° C, usually it can be assumed that the rate of oxidation will be at least halved.

The molecular structures most likely to oxidize are those with a hydroxyl group directly bonded to an aromatic ring (e.g., phenol derivatives such as catecholamines and morphine), conjugated dienes (e.g., vitamin A and unsaturated free fatty acids), heterocyclic aromatic rings, nitroso and nitrite derivatives, and aldehydes (e.g., flavorings). Products of oxidation usually lack therapeutic activity. Visual identification of oxidation, for example, the change from colorless epinephrine to its amber colored products, may not be visible in some dilutions or to some eyes.

Oxidation is catalyzed by pH values that are higher than optimum, polyvalent heavy metal ions (e.g., copper and iron), and exposure to oxygen and UV illumination. The latter two causes of oxidation justify the use of antioxidant chemicals, nitrogen atmospheres during ampoule and vial filling, opaque external packaging, and transparent amber glass or plastic containers.

Trace amounts of heavy metals such as cupric, chromic, ferrous, or ferric ions may catalyze oxidation reactions. As little as 0.2 mg of copper ion per liter considerably reduces the stability of penicillin. Similar examples include the deterioration of epinephrine, phenylephrine, lincomycin, isoprenaline, and procaine hydrochloride. Adding chelating agents to water to sequester heavy metals and working in special manufacturing equipment (e.g., glass) are some means used to reduce the influence of heavy metals on a formulation. Parenteral formulations should not come in contact with heavy metal ions during their manufacture, packaging, or storage.

Hydronium and hydroxyl ions catalyze oxidative reactions. The rate of decomposition for epinephrine, for example, is more rapid in a neutral or alkaline solution with maximum stability (minimum oxidative decomposition) at pH 3.4. There is a pH range for maximum stability for any antibiotic and vitamin preparation, which usually can be achieved by adding an acid, alkali, or buffer.

Oxidation may be inhibited by the use of antioxidants, called negative catalysts. They are very effective in stabilizing pharmaceutical products undergoing a free-radical-mediated chain reaction. These substances, which are easily oxidizable, act by possessing lower oxidation potentials than the active ingredient. Thus, they undergo preferential degradation or act as chain inhibitors of free radicals by providing an electron and receiving the excess energy possessed by the activated molecule.

The ideal antioxidant should be stable and effective over a wide pH range, soluble in its oxidized form, colorless, nontoxic, nonvolatile, nonirritating, effective in low concentrations, thermostable, and compatible with the container-closure system and formulation ingredients.

The commonly used antioxidants for aqueous systems include sodium sulfite, sodium metabisulfite, sodium bisulfite,

sodium thiosulfate, and ascorbic acid. For oil systems, ascorbyl palmitate, hydroquinone, propyl gallate, nordihydroguaiaretic acid, butylated hydroxytoluene, butylated hydroxyanisole, and alpha-tocopherol are employed.

Synergists, which increase the activity of antioxidants, are generally organic compounds that complex small amounts of heavy metal ions. These include the ethylenediamine tetraacetic acid (EDTA) derivatives, dihydroethylglycine, and citric, tartaric, gluconic, and saccharic acids. EDTA has been used to stabilize ascorbic acid, oxytetracycline, penicillin, epinephrine, and prednisolone.

Reduction reactions are much less common than oxidative processes in pharmaceutical practice. Examples include the reduction of gold, silver, or mercury salts by light to form the corresponding free metal.

## Hydrolysis

Drugs containing esters (e.g., cocaine, physostigmine, aspirin, tetracaine, procaine, and methyl dopa), amides (e.g., dibucaine), imides (e.g., amobarbital), imines (e.g., diazepam), and lactams (e.g., penicillins, cephalosporins) functional groups are among those prone to hydrolysis.

Hydrolysis reactions are often pH dependent and are catalyzed by either hydronium ion or hydroxide ions (specific-acid or specific-base catalysis, respectively). Hydrolysis reactions can also be catalyzed by either a Brønsted acid or a Brønsted base (general-acid or general-base catalysis, respectively). Sources of Brønsted acid or base include buffers and some excipients. Sometimes, it is necessary to compromise between the optimum pH for stability and that for pharmacological activity. For example, several local anesthetics are most stable at a distinctly acid pH, whereas for maximum activity they should be neutral or slightly alkaline. Small amounts of acids, alkalines, or buffers are used to adjust the pH of a formulation. Buffers are used when small changes in pH are likely to cause major degradation of the active ingredient.

Obviously, the amount of water present can have a profound effect on the rate of a hydrolysis reaction. When the reaction takes place fairly rapidly in water, other solvents sometimes can be substituted. For example, barbiturates are much more stable at room temperature in propylene glycol-water than in water alone.

Modification of chemical structure may be used to retard hydrolysis. In general, as it is only the fraction of the drug in solution that hydrolyzes, a compound may be stabilized by reducing its solubility. This can be done by adding various substituents to the alkyl or acyl chain of aliphatic or aromatic esters or to the ring of an aromatic ester. In some cases less-soluble salts or esters of the parent compound have been found to aid product stability. Steric and polar complexation has also been employed to alter the rate of hydrolysis. Caffeine reduces the rate of hydrolysis and thus promotes stability by complexation with local anesthetics such as benzocaine, procaine, or tetracaine.

Esters and  $\beta$ -lactams are the chemical bonds that are most likely to hydrolyze in the presence of water. For example, the acetyl ester in aspirin is hydrolyzed to acetic acid and salicylic acid in the presence of moisture, but in a dry environment the hydrolysis of aspirin is negligible. The aspirin hydrolysis rate increases in direct proportion to the water vapor pressure in an environment.

The amide bond also hydrolyzes, though generally at a slower rate than comparable esters. For example, procaine (an ester) will hydrolyze upon autoclaving, but procainamide will not. The amide or peptide bond in peptides and proteins varies in the lability to hydrolysis. The lactam and azomethine (or imine) bonds in benzodiazepines are also labile to hydrolysis. The major chemical accelerators or catalysts of hydrolysis are adverse pH and specific chemicals (e.g., dextrose and copper in the case of ampicillin hydrolysis).

The rate of hydrolysis depends on the temperature and the pH of the solution. A much-quoted estimation is that for each

10°C rise in storage temperature, the rate of reaction doubles or triples. As this is an empiricism, it is not always applicable.

When hydrolysis occurs, the concentration of the active ingredient decreases while the concentration of the decomposition products increases. The effect of this change on the rate of the reaction depends on the order of the reaction. With zero-order reactions the rate of decomposition is independent of concentration of the ingredient. Although weak solutions decompose at the same absolute rate as stronger ones, the weaker the solution, the greater the proportion of active ingredient destroyed in a given time; i.e., the percentage of decomposition is greater in weaker solutions. Increasing the concentration of an active ingredient that is hydrolyzing by zero-order kinetics will slow the percentage decomposition.

With first-order reactions, which occur frequently in the hydrolysis of drugs, the rate of change is directly proportional to the concentration of the reactive substance. Thus, changes in the concentration of the active ingredient have no influence on the percentage decomposition.

The degradation of many drugs in solution accelerates or decelerates exponentially as the pH is decreased or increased over a specific range of pH values. Improper pH ranks with exposure to elevated temperature as a factor most likely to cause a clinically significant loss of drug, resulting from hydrolysis and oxidation reactions. A drug solution or suspension, for example, may be stable for days, weeks, or even years in its original formulation, but when mixed with another liquid that changes the pH, it may degrade in minutes or days. It is possible that a pH change of only one unit (e.g., from 4 to 3 or 8 to 9) could decrease drug stability by a factor of ten or greater.

A pH-buffer system, which is usually a weak acid or base and its salt, are common excipients used in liquid preparations to maintain the pH in a range that minimizes the drug degradation rate. The pH of drug solutions may also be either buffered or adjusted to achieve drug solubility. For example, pH in relation to pKa controls the fractions of the usually more soluble ionized and less soluble nonionized species of weak organic electrolytes.

### Interionic (Ion N+ - Ion N - ) Compatibility

The compatibility or solubility of oppositely charged ions depends mainly on the number of charges per ion and the molecular size of the ions. In general, polyvalent ions of opposite charge are more likely to be incompatible. Thus, an incompatibility is likely to occur upon the addition of a large ion with a charge opposite to that of the drug.

As many hydrolytic reactions are catalyzed by both hydronium and hydroxyl ions, pH is an important factor in determining the rate of a reaction. The pH range of minimum decomposition (or maximum stability) depends on the ion having the greatest effect on the reaction. If the minimum occurs at about pH 7, the two ions are of equal effect. A shift of the minimum toward the acid side indicates that the hydroxyl ion has the stronger catalytic effect and *vice versa* in the case of a shift toward the alkaline side. In general, hydroxyl ions have the stronger effect. Thus, the minimum is often found between pH 3 and 4.

The influence of pH on the physical stability of two-phase systems, especially emulsions, is also important. For example, intravenous fat emulsion is destabilized by acidic pH.

### Decarboxylation

Pyrolytic solid-state degradation through decarboxylation usually is not encountered in pharmacy, as relatively high heats of activation (25 to 30 kcal) are required for the reaction. However, solid *p*-aminosalicylic acid undergoes pyrolytic degradation to *m*-aminophenol and carbon dioxide. The reaction, which follows first-order kinetics, is highly pH-dependent and is catalyzed by hydronium ions. The decarboxylation of *p*-aminobenzoic acid occurs only at extremely low pH values and at high temperatures. Some dissolved carboxylic acids, such as *p*-aminosalicylic acid, lose carbon dioxide from the carboxyl

group when heated. The resulting product has reduced pharmacological potency.  $\beta$ -Keto decarboxylation can occur in some solid antibiotics that have a carbonyl group on the  $\beta$ -carbon of a carboxylic acid or a carboxylate anion. Such decarboxylations will occur in the following antibiotics: carbenicillin sodium, carbenicillin free acid, ticarcillin sodium, and ticarcillin free acid.

### Racemization

Racemization, or the action or process of changing from an optically active compound into a racemic compound or an optically inactive mixture of corresponding *R* (*rectus*) and *S* (*sinister*) forms, is a major consideration in pharmaceutical stability. Optical activity of a compound may be monitored by polarimetry and reported in terms of specific rotation. Chiral high performance liquid chromatography (HPLC) has been used in addition to polarimetry to confirm the enantiomeric purity of a sample.

### Epimerization

Members of the tetracycline family are most likely to incur epimerization. This reaction occurs rapidly when the dissolved drug is exposed to a pH of an intermediate range (higher than 3), and it results in the steric rearrangement of the dimethylamino group. The epimer of tetracycline, epitetracycline, has little or no antibacterial activity.

In general, racemization follows first-order kinetics and depends on temperature, solvent, catalyst, and the presence or absence of light. Racemization appears to depend on the functional group bound to the asymmetric carbon atom, with aromatic groups tending to accelerate the process.

### PHOTOCHEMICAL REACTIONS

Photolytic degradation can be an important limiting factor in the stability of pharmaceuticals. A drug can be affected chemically by radiation of a particular wavelength only if it absorbs radiation at that wavelength and the energy exceeds a threshold. Ultraviolet radiation, which has a high energy level, is the cause of many degradation reactions. Exposure to, primarily, Ultraviolet (UV) illumination may cause oxidation (photo-oxidation) and scission (photolysis) of covalent bonds. Nifedipine, nitroprusside, riboflavin, and phenothiazines are very labile to photo-oxidation. In susceptible compounds, photochemical energy creates free radical intermediates, which can perpetuate chain reactions.

If the absorbing molecule reacts, the reaction is said to be photochemical in nature. When the absorbing molecules do not participate directly in the reaction, but pass their energy to other reacting molecules, the absorbing substance is said to be a photosensitizer.

As many variables may be involved in a photochemical reaction, the kinetics can be quite complex. The intensity and wavelength of the light and the size, shape, composition, and color of the container may affect the velocity of the reaction.

The photodegradation of chlorpromazine through a semiquinone free-radical intermediate follows zero-order kinetics. On the other hand, alcoholic solutions of hydrocortisone, prednisolone, and methylprednisolone degrade by reactions following first-order kinetics.

Colored-glass containers most commonly are used to protect light-sensitive formulations. Yellow-green glass gives the best protection in the ultraviolet region, whereas amber confers considerable protection from ultraviolet radiation but little from infrared radiation. Riboflavin is best protected by a stabilizer that has a hydroxyl group attached to or near the aromatic ring. The photodegradation of sulfacetamide solutions may be inhibited by an antioxidant such as sodium thiosulfate or metabisulfite.

A systematic approach to photostability testing is recommended covering, as appropriate, studies such as tests on the drug substance, tests on the exposed drug product outside of the immediate pack; and if necessary, tests on the drug product in the immediate pack. The ICH Q1B guidance discusses

the minimum requirements for assessing photostability. Drug substance is first assessed by exposing sample powder having a depth of not more than 3 mm to an overall illumination of not less than 1.2 million lux hours and an integrated near ultraviolet energy of not less than 200 watt hours/square meter. If the drug substance shows sensitivity to photodegradation, then the drug product will need to be tested as well. The testing of drug product uses the same light exposure that was used to test drug substance. The drug product should be tested directly exposed to light and in its container closure system.

### ULTRASONIC ENERGY

Ultrasonic energy, which consists of vibrations and waves with frequencies greater than 20,000 Hz, promotes the formation of free radicals and alters drug molecules. Changes in prednisolone, prednisone acetate, or deoxycorticosterone acetate suspensions in an ultrasonic field have been observed spectrometrically in the side chain at C-17 and in the oxo group of the A ring. With sodium alginate, in an ultrasonic field, it has been reported that above a minimum power output, degradation increased linearly with increased power.

### IONIZING RADIATION

Ionizing radiation, particularly gamma rays, has been used for the sterilization of certain pharmaceutical products. At the usual sterilizing dose, 2.5 mRad, it seldom causes appreciable chemical degradation. In general, formulations that are in the solid or frozen state are more resistant to degradation from ionizing radiation than those in liquid form. For example, many of the vitamins are little affected by irradiation in the solid state but are decomposed appreciably in solution. On the other hand, both the liquid- and solid-state forms of atropine sulfate are affected seriously by radiation.

## PREDICTING SHELF LIFE

### ICH RECOMMENDED EVALUATION

The shelf life of a commercial drug product must be determined in the commercial container closure at the defined storage conditions. The FDA and ICH Q1A (R2) guidances require at least 12 months stability data at the time of submission. Most products require at least 24 months shelf life to be commercially viable. The ICH Q1E recommends how the 12 months data may be used to predict long-term stability. Figures 4-1 and 4-2 show trending graphs with double-sided and single-sided 95%

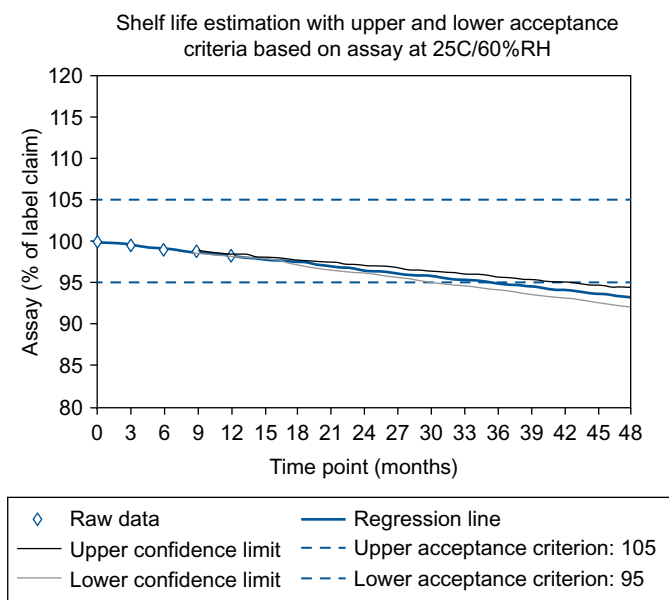

Figure 4-1. Typical Two-sided Shelf Life Estimation plot.

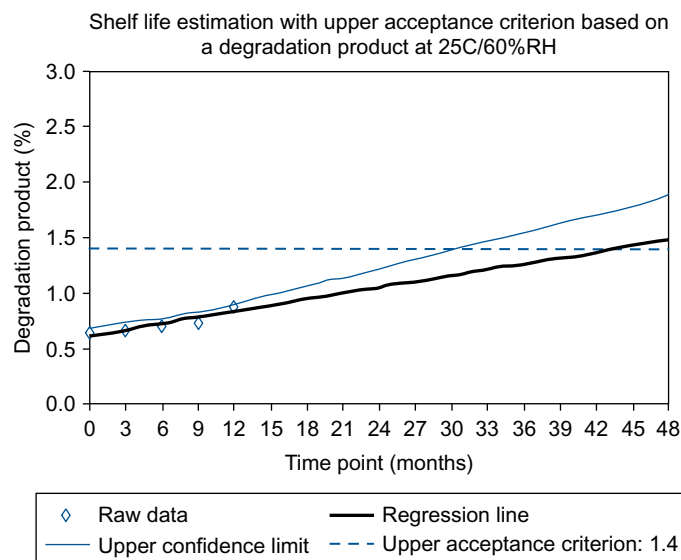

Figure 4-2. Typical One-sided Shelf Life Estimation plot.

confidence limits plots, respectively. The expiration of a product is the time where the confidence line intersects with the acceptance limit. Trend analysis of data need only be performed on test data that show a change related to time.

## APPROXIMATIONS IN ASSESSING PRODUCT STABILITY

### ESTIMATION OF TEMPERATURE EFFECT

In early development, a shelf life prediction of a clinical material, especially a Phase I material, may be based on a very limited amount of sample and a very limited amount of time to make the evaluation. One way to estimate long-term storage for a material is by extrapolating data from studies performed at elevated conditions. An understanding of potential activation energy is needed to make the long-term stability prediction. Many may have heard of the estimate that for every 10°C decrease in storage temperature the shelf life doubles. This is only true, however, if the activation energy of the reaction(s) that cause degradation is 15 kcal/moles. The activation energy,  $E_a$ , for many chemical processes related to the degradation of a drug substance/product is typically within the range of 10 to 25 kcal/moles. The equation below shows a way of calculating the  $Q_{\Delta T}$  value that may be used to estimate the affect of temperature on shelf life (Table 4-3).

$$Q_{\Delta T} = \exp \left[ \frac{E_a}{R} \left( \frac{\Delta T}{(T+\Delta T)(T)} \right) \right] \quad (2)$$

The technique of estimating the shelf life of a formulation from its accumulated stability data has evolved from examining the data and making an educated guess through plotting the time-temperature points on appropriate graph paper and crudely extrapolating a regression line to the application of rigorous

Table 4-3. An Approximation for Estimating the Temperature Effects

$E_a$ (kcal/mole)	Q5 (30 to 25 °C)	Q10 (35 to 25 °C)	Q15 (40 to 25 °C)
10	1.32	1.73	2.24
15	1.52	2.27	3.36
20	1.75	2.99	5.04
25	2.01	3.93	7.55

physical-chemical laws, statistical concepts, and computers to obtain meaningful, reliable estimates.

A simple means of estimating shelf life from a set of computer-prepared tables has been described by Lintner *et al.*<sup>6</sup> This system was developed to select the best prototype formulation on the basis of short-term stability data and predict both estimated and minimum shelf life values for the formulation. It is a middle-ground approach between the empirical methods and the modern, rigorous statistical concepts. All calculations can be made readily by hand, and the estimated values can be obtained easily from appropriate tables. The system assumes that:

1. Shelf life predictions can be made satisfactorily for lower temperatures using the classical Arrhenius model from data obtained at higher temperatures.
2. The energy of activation of the degradation reaction is between 10 and 20 kcal/mol (this is a safe assumption, as Kennon<sup>16</sup> has noted that rarely are drugs with energies of activation below 10 kcal/mol used in pharmacy, and for values as high as 20 kcal/mol, the error in the shelf life prediction will be on the conservative side).
3. The rate of decomposition will not increase beyond that already observed.
4. The standard deviation of the replicated assays is known or can be estimated from the analytical data.

This concept further assumes that the degradation reaction follows zero- or pseudo-zero-order kinetics. For data corresponding to a zero-, first-, or second-order degradation pattern, it is impossible to distinguish one order from another with usual analytical procedures, when the total degraded material is not large. In addition, shelf life calculations assuming zero-order kinetics are more conservative than those for higher orders.

This middle-ground system is useful in creating the experimental design for the stability study. The formulator has the opportunity to study various combinations of parameters to try to optimize the physical-statistical model. The effect of improving the assay standard deviation, running additional replicates, using different time points, and assuming various degradation rates and energies of activation on the stability of the test formulation can be checked.

McMinn and Lintner later developed and reported on an information-processing system for handling product stability data.<sup>17</sup> This system saves the time of formulators in analyzing and interpreting their product stability data, in addition to minimizing the amount of clerical help needed to handle an ever-increasing assay load. For products such as those of vitamins, for example, where large overages are required, the statistical portions of this advanced technique aid the manufacturer to tailor the formula composition to obtain the desired and most economical expiration dating.

This system stores both physical and chemical data and retrieves the information in three different formats (one of which was designed specifically for submitting to regulatory agencies). It analyzes single-temperature data statistically by analysis of covariance and regression or multiple-temperature data by weighted or unweighted analysis using the Arrhenius relationship; provides estimates of the shelf life of the preparation with the appropriate confidence intervals; preprints the assay request cards that are used to record the results of the respective assay procedures and to enter the data into the system; and produces a 5-year master-stability schedule as well as periodic 14-day schedules of upcoming assays.

As mentioned above, a portion of the advanced system analyzes the stability data obtained at a single temperature by analysis of covariance and regression. This analysis is based on the linear (zero-order) model

$$Y_{ij} = \beta_i X_{ij} + \alpha_i + \varepsilon_{ij} \quad (3)$$

where  $Y_{ij}$  is the percentage of label of the  $j$ th stability assay of the  $i$ th lot,  $X_{ij}$  is the time in months at which  $Y_{ij}$  was observed,

$\beta_i$  and  $\alpha_i$  are the slope and intercept, respectively, of the regression line of the  $i$ th lot, and  $\varepsilon_{ij}$  is a random error associated with  $Y_{ij}$ . The random errors are assumed to be identically and independently distributed normal variables with a zero mean and a common variance,  $\sigma^2$ .

A summary of the regression analysis for each individual lot and for the combination of these lots, plus a summary of the analyses of covariance and deviation from regression is prepared by the computer.

Because the computer combines, or pools, the stability data from the individual lots, irrespective of the statistical integrity of this step, the pooled data are examined for validity by the *F* test. The mean square of the regression coefficient (slope) is divided by the mean square of the deviation within lots, and similarly, the adjusted mean ( $y$  intercept) is divided by the common mean square to give the respective *F* ratios. The latter values then are compared with the critical 5% *F* values. When the calculated *F* values are smaller than the critical *F* values, the data may be combined, and the pooled data analyzed.

A printout for the combined lots as well as for each individual lot provides the estimated rate of degradation and its standard error in percentage per month for each ingredient. The *Student's t test* value is calculated from these estimates and tested for significance from zero. When the *t* value is significant, the printout contains an estimate of the shelf life with the appropriate confidence interval. When the *t* value is not significantly different from zero, estimates of the minimum and projected shelf life values are made. In addition, coordinates of the calculated least-squares regression line with appropriate confidence limits for the mean and individual predicted assays are printed.

Plots of the resulting least-squares line containing the individual data points also are printed by the computer. For the calculation of  $X_0$ ,  $\hat{Y}$  equals  $\langle \text{obar} \rangle Y + \langle \text{caret} \rangle \beta (X_0 - \langle \text{obar} \rangle X_{..})$ , where  $\langle \text{caret} \rangle \beta$  is the least-squares estimate of the slope, and  $\langle \text{obar} \rangle X_{..}$  is the mean time of assay.

The sample variance for this estimate,  $S^2(\hat{Y})$ , is equal to

$$S_{y..x}^2 \left[ \frac{1}{N} + \frac{\left( X_0 - \overline{X_{..}} \right)^2}{\sum \left( X_{ij} - \overline{X_{..}} \right)^2} \right] \quad (4)$$

where  $N$  is the number of assays. The 95% confidence interval is equal to  $Y \pm t_{0.05S(y)}$ .

For cases in which the slope of the best fitting line is positive and significantly different from zero (resulting, e.g., from solvent evaporation), the statement "no degradation has been detected and hence no shelf life estimate is made" is printed. When the computed line has a positive slope but not significantly different from zero, only the minimum shelf life value is calculated.

Traditionally, extensive stability data are collected at the recommended storage temperatures (usually refrigerator and/or room temperature) to be placed on the label of the package. However, elevated-temperature data are very valuable in determining the shelf life of a product. In practice, multiple levels of thermal stress are applied to the formulation so that appropriate shelf life estimates can be made for normally expected marketing conditions. In cases in which data from accelerated studies are used to project a tentative expiration date that is beyond the date supported by actual shelf life studies, testing must continue until the tentative expiration date is verified.

The effect of temperature variation on the rate of a reaction could be expressed by an integrated form of the Arrhenius equation

$$k = se^{-E_A / RT} \quad (5)$$

$$\log \frac{k_2}{k_1} = \frac{E_a}{2.303R} \left( \frac{T_2 - T_1}{T_2 * T_1} \right) \quad (6)$$

A weighted modification of this model has been incorporated into the previously described computerized system. Each

printout contains a statement concerning the acceptability of the Arrhenius assumption with its appropriate probability level, the slope and intercept for the Arrhenius line, the estimated apparent energy of activation with its 95% confidence limits, plus the estimated shelf life values at selected temperatures.

The analysis of first-order stability data is based on the linear model

$$Y_{ij} = \alpha_i + \beta_i X_{ij} + \varepsilon_{ij} \quad (7)$$

where  $Y_{ij}$  is the natural logarithm of the assay value for the  $j$ th observation of the  $i$ th temperature,  $X_{ij}$  is the elapsed time in months for the assay sample for the  $i$ th temperature,  $\beta_i$  and  $\alpha_i$  are the slope and intercept, respectively, and  $\varepsilon_{ij}$  is a random error associated with  $Y_{ij}$ . The errors are assumed to be distributed identically and independently, normally with a zero mean and variance  $\sigma^2$ .

For orders other than first,  $Y_{ij}$  represents the concentration raised to the power of 1 minus the order.

The estimated rate constant (i.e., the negative slope) is

$$-b_i = -\frac{\sum_j (Y_{ij} - Y_i)(X_{ij} - X_i)}{\sum_j (X_{ij} - X_i)^2} \quad (8)$$

The standard error of the estimated rate constant is

$$S_{-b_i} = \frac{S(X/Y)}{\left[ \sum_j (x_{ij} - X_i)^2 \right]^{1/2}} \quad (9)$$

where  $S(Y/X)$ , the residual standard error, is equal to

$$S(X/Y) = \left\{ \frac{1}{N-2} \left[ \sum_{j=1}^{12} (Y_{ij} - Y_i)^2 - \frac{\left[ \sum_j (X_{ij} - X_i)(Y_{ij} - Y_i) \right]^2}{\sum_j (X_{ij} - X_i)^2} \right] \right\}^{1/2} \quad (10)$$

According to the Arrhenius relationship, faster degradation occurs at the higher temperatures; hence, assays for the high-temperature data usually are run more often but for a shorter period of time. The effect of simple least-squares analysis of this type of data is to force the Arrhenius equation through the low temperature data and essentially ignore the high-temperature information. Thus, much more credence is placed in the point estimates of the low temperature than is warranted. In addition, the usual confidence limits on extrapolated degradation rates at refrigerator or room temperature cannot be made validly. For these reasons, Bentley<sup>18</sup> presented a method based on a weighted least-squares analysis to replace the un-weighted approximation. He also developed a statistical test for the validity of the Arrhenius assumption, which is computed easily from the results of the unweighted method.

To make shelf life estimates from elevated temperature data, two storage temperatures are obviously the minimum. As the accuracy of the extrapolation is enhanced by using additional temperatures, a minimum of four different temperatures is recommended for most product stability studies. With the current use of computers to do the bulk of stability calculations, including weighted least-squares analysis, the temperatures, and storage conditions need not be selected for arithmetic convenience.

It is not necessary to determine the mechanism of the degradation reaction. In most cases, it is necessary only to follow some property of degradation and to linearize this function. Either the amount of intact drug or the amount of a formed degradation product may be followed. It usually is impractical to determine the exact order of the reaction. With assay errors in the range of 2 to 5%, at least 50% decomposition must occur before the reaction order can be determined. As the loss with pharmaceuticals generally is less, zero-order kinetics should be assumed, unless the reaction order is known from previous work. In any case, replication of stability assays is advisable.

The batches of drugs used for a stability study should be representative of production run material or at least material of a known degree of purity. The quality of the excipients also should be known, as their impurities or even their moisture

content can affect product stability deleteriously. Likewise, the samples of the formulation taken for the stability study must be representative of the lot.

Specific, stability-indicating assay methods must be used, to make meaningful shelf life estimates. The reliability and specificity of the test method on the intact molecule and on the degradation products must be demonstrated.

## PHARMACEUTICAL CONTAINERS

The official standards for containers apply to articles packaged by either the pharmaceutical manufacturer or the dispensing pharmacist unless otherwise indicated in a compendial monograph. In general, repackaging of pharmaceuticals is inadvisable. However, if repackaging is necessary, the manufacturer of the product should be consulted for potential stability problems.

A pharmaceutical container has been defined as a device that holds the drug and is, or may be, in direct contact with the preparation. The immediate container is described as that which is in direct contact with the drug at all times. The liner and closure traditionally have been considered to be part of the container system. The container should not interact physically or chemically with the formulation so as to alter the strength, quality, or purity of its contents beyond permissible limits.

The choice of containers and closures can have a profound effect on the stability of many pharmaceuticals. Now that a large variety of glass, plastics, rubber closures, tubes, tube liners, etc are available, the possibilities for interaction between the packaging components and the formulation ingredients are immense. Some of the packaging elements themselves are subject to physical and chemical changes that may be time-temperature dependent.

Frequently, it is necessary to use a well-closed or a tight container to protect a pharmaceutical product. A *well-closed container* is used to protect the contents from extraneous solids or a loss in potency of the active ingredient under normal commercial conditions. A *tight container* protects the contents from contamination by extraneous materials, loss of contents, efflorescence, deliquescence, or evaporation and is capable of tight re-closure. When the packaging and storage of an official article in a well-closed or tight container is specified, water-permeation tests should be performed on the selected container.

In a stability program, the appearance of the container, with special emphasis on the inner walls, the migration of ingredients onto/into the plastic or into the rubber closure, the migration of plasticizer or components from the rubber closure into the formulation, the possibility of two-way moisture penetration through the container walls, the integrity of the tac-seal, and the back-off torque of the cap, must be studied.

## GLASS

Traditionally, glass has been the most widely used container for pharmaceutical products to ensure inertness, visibility, strength, rigidity, moisture protection, ease of re-closure, and economy of packaging. Although glass has some disadvantages, such as the leaching of alkali and insoluble flakes into the formulation, these can be offset by the choice of an appropriate glass. As the composition of glass may be varied by the amounts and types of sand and silica added and the heat treatment conditions used, the proper container for any formulation can be selected.

According to USP 34, glass containers suitable for packaging pharmacopeial preparations may be classified as either Type I, Type II, Type III, or type NP. Containers of Type I borosilicate glass are generally used for preparations that are intended for parenteral administration, although Type II treated soda-lime glass may be used where stability data demonstrates its suitability. Containers of Type III and Type NP are intended for packaging articles intended for oral or topical use.

New, unused glass containers are tested for resistance to attack by high-purity water by use of a sulfuric acid titration to

determine the amount of released alkali. Both glass and plastic containers are used to protect light-sensitive formulations from degradation. The amount of transmitted light is measured using a spectrometer of suitable sensitivity and accuracy.

Glass is generally available in flint, amber, blue, emerald green, and certain light-resistant green and opal colors. The blue-, green-, and flint-colored glasses, which transmit ultraviolet and violet light rays, do not meet the official specifications for light-resistant containers.

Colored glass usually is not used for injectable preparations, since it is difficult to detect the presence of discoloration and particulate matter in the formulations. Light-sensitive drugs for parenteral use usually are sealed in flint ampoules and placed in a box. Multiple-dose vials should be stored in a dark place.

Manufacturers of prescription drug products should include sufficient information on their product labels to inform the pharmacist of the type of dispensing container needed to maintain the identity, strength, quality, and purity of the product. This brief description of the proper container, such as light-resistant, well-closed, or tight, may be omitted for those products dispensed in the manufacturer's original container.

## PLASTICS

Plastic containers have become very popular for storing pharmaceutical products. Polyethylene, polystyrene, polyvinyl chloride, and polypropylene are used to prepare plastic containers of various densities to fit specific formulation needs.

Factors such as plastic composition, processing and cleaning procedures, contacting media, inks, adhesives, absorption, adsorption, and permeability of preservatives also affect the suitability of a plastic for pharmaceutical use. Hence, biological test procedures are used to determine the suitability of a plastic for packaging products intended for parenteral use and for polymers intended for use in implants and medical devices. Systemic injection and intracutaneous and implantation tests are employed. In addition, tests for nonvolatile residue, residue on ignition, heavy metals, and buffering capacity were designed to determine the physical and chemical properties of plastics and their extracts.

The high-density polyethylene (HDPE) containers, which are used for packaging capsules and tablets, possess characteristic thermal properties, a distinctive infrared absorption spectrum, and a density between 0.941 and 0.965 g/cm<sup>3</sup>. In addition, these containers are tested for light transmission, water-vapor permeation, extractable substances, nonvolatile residue, and heavy metals. When a stability study has been performed to establish the expiration date for a dosage form in an acceptable high-density polyethylene container, any other high-density polyethylene container may be substituted provided that it, too, meets compendial standards and that the stability program is expanded to include the alternative container.

Materials from the plastic itself can leach into the formulation, and materials from the latter can be absorbed onto, into, or through the container wall. The barrels of some plastic syringes bind various pharmaceutical preservatives. However, changing the composition of the syringe barrel from nylon to polyethylene or polystyrene has eliminated the binding in some cases.

A major disadvantage of plastic containers is the two-way permeation or *breathing* through the container walls. Volatile oils and flavoring and perfume agents are permeable through plastics to varying degrees. Components of emulsions and creams have been reported to migrate through the walls of some plastics, causing either a deleterious change in the formulation or collapse of the container. Loss of moisture from a formulation is common. Gases, such as oxygen or carbon dioxide in the air, have been known to migrate through container walls and affect a preparation.

Solid dosage forms, such as penicillin tablets, when stored in some plastics, are affected deleteriously by moisture penetration from the atmosphere into the container.

Single unit dosage packaging in the form of blister packages are often used to package capsule and tablet dosage forms. A typical blister package is comprised of a polymeric film that is molded to have a cavity into which the dosage form is placed. The polymer film is then heat bonded to a paper backed foil liner.

As with plastic bottles, the blister package will allow a certain amount of moisture vapor permeation to occur, and this must be a consideration when selecting the type of film used for the package. The choice of packaging materials used depends on the degree to which the product needs to be protected from light, heat, and moisture. Each material has different resistance to each of these elements and will affect the shelf life and storage conditions of the packaged pharmaceutical.

Polyvinylchloride (PVC) offers the least resistance to moisture vapor permeation. Polyvinylidenechloride (PVdC) has characteristics similar to PVC but offers superior resistance to moisture vapor permeation. Aclar, which is a polychlorotrifluoroethylene (PVC-CTFE) film has the lowest water vapor permeability and thus offers the best protection from moisture.

## METALS

The pharmaceutical industry was, and to a degree still is, a tin stronghold. However, as the price of tin constantly varies, more-collapsible aluminum tubes are being used.

A variety of internal linings and closure fold seals are available for both tin and aluminum tubes. Tin tubes can be coated with wax or with vinyl linings. Aluminum tubes are available with lining of epoxy or phenolic resin, wax, vinyl, or a combination of epoxy or phenolic resin with wax. As aluminum is able to withstand the high temperatures required to cure epoxy and phenolic resins adequately, tubes made from this metal presently offer the widest range of lining possibilities.

Closure fold seals may consist of unmodified vinyl resin or plasticized cellulose and resin, with or without added color.

Collapsible tubes are available in many combinations of diameters, lengths, openings, and caps. Custom-use tips for ophthalmic, nasal, mastitis, and rectal applications also are available. Only a limited number of internal liners and closure seals are available for tubes fitted with these special-use tips.

Lined tubes from different manufacturers are not necessarily interchangeable. Although some converted resin liners may be composed of the same base resin, the actual liner may have been modified to achieve better adhesion, flow properties, drying qualities, or flexibility. These modifications may have been necessitated by the method of applying the liner, the curing procedure, or, finally, the nature of the liner itself.

## CLOSURES

The closures for the formulations also must be studied as a portion of the overall stability program. Although the closure must form an effective seal for the container, the closure must not react chemically or physically with the product. It must not absorb materials from the formulation or leach its ingredients into the contents.

The integrity of the seal between the closure and container depends on the geometry of the two, the materials used in their construction, the composition of the cap liner, and the tightness with which the cap has been applied. Torque is a measure of the circular force, measured in inch-pounds, which must be applied to open or close a container. When pharmaceutical products are set up on a stability study, the formulation must be in the proposed market package. Thus, they should be capped with essentially the same torque to be used in the manufacturing step.

Rubber is a common component of stoppers, cap liners, and parts of dropper assemblies. Sorption of the active ingredient, preservative, or other formulation ingredients into the rubber and the extraction of one or more components of the rubber into the formulation are common problems.

The application of an epoxy and polytetrafluoroethylene lining to the rubber closure reduces the amount of leached

extractives but essentially has no effect on the sorption of the preservative from the solution. Polytetrafluoroethylene-coated rubber stoppers may prevent most of the sorption and leaching.

### INTRODUCTION

Understanding the concepts of bioavailability and bioequivalence testing is essential in the drug development process because they create the foundation for regulatory decision making when evaluating formulation changes and lot-to-lot consistency in innovator products. They also serve as the primary components to demonstrate therapeutic equivalence between generic products and the reference innovator product.

Changes in bioavailability can be thought of in terms of changes in exposure to the drug. If these changes are substantial, then they can alter the safety and efficacy profile of the compound in question. The bioavailability of orally administered drugs can be affected by numerous factors. These include food or fed state, differences in drug metabolism, drug–drug interactions, gastrointestinal transit time, and changes in dosage form release characteristics (especially for modified release products).

Bioequivalence is an important consideration in ensuring lot-to-lot consistency, including whenever evaluating changes in a marketed product's formulation, manufacturing process, and dosage strength. Bioequivalence is also critical in regulatory authority decision making when determining whether a generic product is therapeutically equivalent to the original innovator product.

In addition, chemical equivalence, lot-to-lot uniformity of physicochemical characteristics, and stability equivalence are other factors that are important, as they too can affect product quality. In this chapter, bioavailability and bioequivalence topics are emphasized for solid oral dosage forms. However, many of the general concepts can also be applied to other dosage forms, including biologics.

### GENERAL CONCEPTS

The terms used in this chapter require careful definition, since, as in any area, some terms have been used in different contexts by different authors.

*Bioavailability* is a term that indicates measurement of both the rate of drug absorption and the total amount (extent) of drug that reaches the systemic circulation from an administered dosage form. It is specific to the parent or active drug substance as contrasted to metabolites.

*Equivalence* is more a general and relative term that indicates a comparison of one drug product with another. Equivalence may be defined in several ways:

- *Bioequivalence* indicates that a drug in two or more similar dosage forms reaches the systemic circulation at the same relative rate and extent (i.e., the plasma level

profiles of the drug obtained using the two dosage forms are the same).

- *Chemical equivalence* considers that two or more dosage forms contain the same labeled quantities (within specified limits) of the drug.
- *Clinical equivalence* occurs when the same drug from two or more dosage forms gives identical *in vivo* effects as measured by a pharmacological response or by control of a symptom or disease.
- *Pharmaceutical equivalence* refers to two drug products with the same dosage form and same strength.
- *Therapeutic equivalence* implies that two brands of a drug product are expected to yield the same clinical result. The FDA specifically uses the term “therapeutic equivalence” in the evaluation of multi-source prescription drug products (generic drugs).

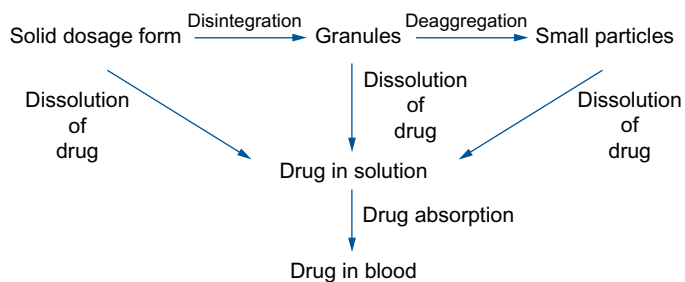

*Area under the Concentration–Time Curve (AUC)* is the integral of the concentration–time curve after administration of a single dose of drug or after achieving a steady state. The calculated area under the serum, blood, or plasma concentration–time curve is reported in amount/volume multiplied by time (e.g.,  $\mu\text{g}/\text{mL} \times \text{h}$  or  $\text{g}/100 \text{ mL} \times \text{h}$ ) and can be considered representative of the amount of drug absorbed. Several variants of AUC exist, including  $\text{AUC}_{0-t}$ ,  $\text{AUC}_{0-\infty}$ , and  $\text{AUC}_{\tau, \text{SS}}$ , corresponding to the calculated area from time zero to a truncated time point (e.g.,  $\text{AUC}_{0-4\text{h}}$ ), the total area under the curve, and the area when steady state has been achieved.

*Peak-height Concentration ( $C_{\text{max}}$ )* is the peak of the blood level–time curve and represents the highest drug concentration achieved after drug administration.

*Time of Peak Concentration ( $T_{\text{max}}$ )* is the measured length of time necessary to achieve the maximum concentration ( $C_{\text{max}}$ ) after drug administration.

### DISSOLUTION

For a drug to be absorbed, it must first go into solution. In Figure 5-1 the steps in the dissolution and subsequent absorption process of a tablet or capsule dosage form are outlined. Similar profiles could be obtained for any solid or semisolid dosage form, including oral suspensions, parenteral suspensions, and suppositories. The theory and mechanics of drug dissolution rate are described in detail in Chapter 6. The physical characteristics of the drug and the composition of the tablet (dosage form) can have an effect on the rates of disintegration, deaggregation, and dissolution of the drug. As such, these can affect the rate of absorption and resultant blood levels of the drug.

**Figure 5-1.** Sequence of events involved in the dissolution and absorption of a drug from a solid oral dosage form.

An important aspect of product quality for marketed oral solid dosage forms relates to dissolution testing. The dosage forms actually used by patients will be from lots that have not directly undergone human bioavailability testing. Once adequate product quality has been established by bioavailability testing, subsequent batches manufactured using the same formulation, equipment, and process are likely to be bioequivalent to the original batch tested in humans. This is an important concept in the regulatory control of product quality and is where *in vitro* testing such as assay, content uniformity, tablet hardness, and dissolution are important. Among these several *in vitro* tests, dissolution testing is probably the most important, related to bioavailability. As part of the drug approval process, a dissolution test procedure is established for all oral solid dosage forms. These dissolution tests are incorporated into the United States Pharmacopeia (USP) and apply both to innovator and generic drug products. All marketed batches of these drug products must meet the Abbreviated New Drug Application (ANDA)/New Drug Application (NDA)/USP dissolution tests throughout the shelf-life of the product. Products failing their approved dissolution test and/or a USP dissolution test must be removed from the market.

### PROPERTIES OF THE DRUG

The physical characteristics of the drug that can alter bioavailability are discussed in Chapter 39 and consist of the polymorphic crystal form, choice of the salt form, particle size, hydrated or anhydrous form, wettability, and solubility of the drug. These factors should be investigated during product development and should not, therefore, affect the bioavailability of the drug product.

### PROPERTIES OF THE DOSAGE FORM

The various components of the solid or semisolid dosage form, other than the active ingredient, are discussed in Chapter 30. Only an overview, for tablet dosage forms, is given here. In addition to the active ingredient, a tablet product usually will contain the following types of inactive ingredients:

- *Glidants* are used to provide a free-flowing powder from the mix of tablet ingredients so that the material will flow when used on a tablet machine.
- *Binders* provide cohesiveness to the tablet. Too little binder will produce tablets that do not maintain their integrity; too much may affect adversely the release (dissolution rate) of the drug from the tablet.
- *Fillers* are used to give the powder bulk so that an acceptably sized tablet is produced. Most commercial tablets weigh from 100 mg to 500 mg, so it is obvious that for many potent drugs the filler constitutes a large portion of the tablet. Binding of drug to the fillers may occur and affect bioavailability.
- *Disintegrants* are used to cause the tablets to disintegrate when exposed to an aqueous environment. Too much will produce tablets that may disintegrate in the bottle because of atmospheric moisture, and too little may be insufficient for disintegration to occur and may therefore

alter the rate and extent of release of the drug from the dosage form.

- *Lubricants* are used to enhance the flow of the powder through the tablet machine and to prevent sticking of the tablet in the die of the tablet machine after the tablet is compressed. Lubricants are usually hydrophobic materials such as stearic acid, magnesium, or calcium stearate. Too little lubricant will not permit satisfactory tablets to be made; too much may produce a tablet with a water-impervious hydrophobic coat, which can inhibit the disintegration of the tablet and dissolution of the drug.

## ABSORPTION FACTORS

A significant factor related to drug bioavailability is the fact that many drugs are administered, not as a solution, but as a solid dosage form. Optimal bioavailability might be expected from a solution, since a solid drug must first dissolve to be absorbed, but considerations such as drug stability, unpalatable taste, and the desired duration of action (for controlled-release drug products) may prevent the development of solution-based dosage form.

In the dose titration of any patient the objective is, in conceptual terms, to attain and maintain a blood level that exceeds the minimum effective level required for response but does not exceed the minimum toxic (side-effect) level. This is shown graphically in Figure 5-2. There are several absorption factors that can affect the general shape of this blood-level curve and thus drug response.

### DOSE ADMINISTERED

The blood levels will rise and fall in proportion to the dose administered.

### AMOUNT OF DRUG ABSORBED

Blood levels achieved are also dependent on the amount of drug absorbed. For example, the effect of having only one-half of the drug absorbed from a dosage form is equivalent to lowering the dose (Figure 5-3).

### RATE OF ABSORPTION

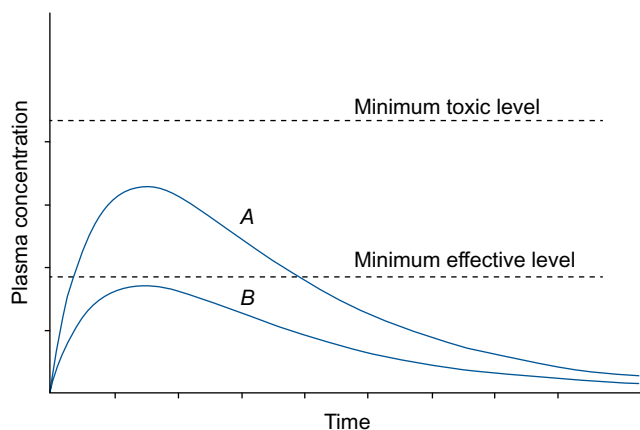

If absorption from the dosage form is more rapid than the rate of absorption that gave profile C in Figure 5-4, minimum toxic (side-effect) levels may be exceeded. If absorption from the dosage form is sufficiently slow, minimum effective levels may never be attained, as in profile B in Figure 5-4.

In either instance, the time course and extent of clinical response to the drug may be altered because of changes in dose or rate and extent of absorption.

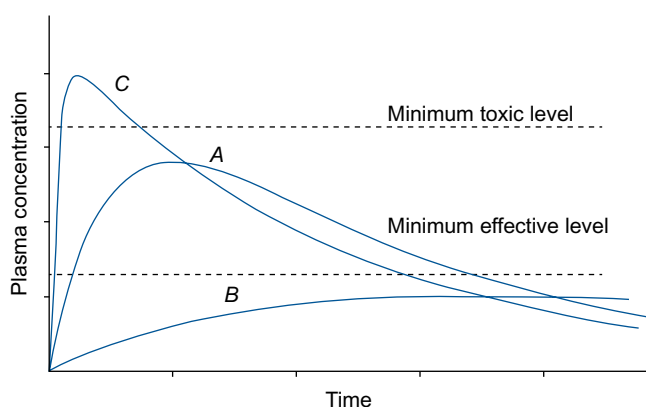

Both factors, rate and extent of drug absorption, can be affected by the dosage form in which the drug is contained. The

**Figure 5-2.** Typical plasma-level curve of a drug with effective and toxic (side-effect) profile levels defined.

**Figure 5-3.** Effect of the extent of drug absorption from a dosage form on drug-plasma levels and efficacy. The extent of absorption from dosage form B is 50% of that from dosage form A.

**Figure 5-4.** Effect of the rate of drug absorption from a dosage form on the plasma-level profile and efficacy. The rates of absorption from dosage forms B and C are 1/10 and 10 times those from dosage form A.

effect of rate of absorption may be intentional, as in controlled-release products, or unintentional, for example, as brought about by a change in the composition and/or method of manufacture of the dosage form.

The choice of the inactive ingredients (excipients) used to prepare a dosage form is up to the individual manufacturer. It is through these changes in composition and manufacturing technique that unintended changes in bioavailability and bioequivalence may occur. Revalidation of bioequivalence may be needed for major changes in the manufacturing process, whereas small changes may not raise significant bioavailability concerns. In situations involving minor changes in the manufacturing process, comparative dissolution testing of the original and reformulated product provides adequate documentation of continued product quality, if the resulting dissolution profiles are similar. These considerations apply to all drug manufacturers, both innovator and generic companies.

## BIOEQUIVALENCE TESTING

The awareness of the potential for clinical differences between otherwise chemically equivalent drug products has been brought about by a multiplicity of factors that include, among others:

- better methods for clinical efficacy evaluation
- development of techniques to measure microgram or nanogram quantities of drugs in biological fluids

- improvements in the technology of dosage form formulation and physical testing
- awareness of reported clinical differences from the literature in otherwise similar products
- increased cost of classical clinical evaluation
- objective and quantitative nature of bioavailability tests
- an increase in the number of chemically equivalent products on the market because of patent expirations and the Drug Price Competition and Patent Term Restoration Act of 1984 (Hatch-Waxman Act), which established the generic drug approval procedures that are in place today.

The increase in the number of drugs that are available from multiple sources frequently has placed people involved in the delivery of healthcare in the position of having to select one from among several marketed products. As with any decision, the more data available, the more comfortable one is in arriving at the final decision. The need to make these choices, in light of the potential failure to demonstrate *in vivo* equivalence between products or different batches of the same product, has increased the demand for quantitative data. Bioequivalence testing represents a bridging alternative to clinical testing for efficacy and safety in such cases and is the means by which generic drugs are approved for marketing. In addition, this is also the means by which the quality of all drug products is maintained in situations involving major changes in formulation or manufacturing process.

Requirements for bioequivalence data on drug products should be applied reasonably. The reason for bioequivalence testing should not be overlooked (i.e., it is used as a surrogate, in certain situations, for the clinical evaluation of drug products). In some instances, bioequivalence data cannot reliably be obtained if the bioanalytical methodology is not available. However, in such cases pharmacodynamic data may provide a more sensitive, objective evaluation of a product's therapeutic equivalence and may be explored as an alternative evaluation method in the absence of relevant bioanalytical methodology.

Basic pharmacokinetic evaluation of bioavailability data is not necessary to show bioequivalence of two drug products. Pharmacokinetics has its major utility in the prediction or projection of dosage regimens and/or in providing a better understanding of observed drug reactions or interactions that result from the accumulation of drug in some specific site, tissue, or compartment of the body. The basis for the conclusion that two drug products are bioequivalent must be that the drug concentrations measured in a biological matrix, or alternatively the pharmacological response, for one drug product are essentially the same for the second drug product. The more straightforward decisions in the evaluation of bioequivalence between two drug products are those in which the two products are exactly superimposable (definitely bioequivalent). Those in which the two products differ in their bioequivalence parameters by a large amount, such as 50% or more, are most definitely not bioequivalent. Statistical evaluation of the data is necessary for all situations, particularly for data that exist between these two extremes.

## METHODS FOR DETERMINING BIOEQUIVALENCE

Bioequivalence usually involves human testing but sometimes may be demonstrated using an *in vitro* bioequivalence standard, especially when such an *in vitro* test has been correlated with human *in vivo* bioavailability data. In other situations, bioequivalence may be demonstrated through comparative clinical trials or pharmacodynamic studies.

The FDA has categorized (21CFR320.24) various *in vivo* and *in vitro* approaches that may be utilized to establish bioequivalence. These are, in descending order of accuracy, sensitivity and reproducibility,

1. An *in vivo* test in humans in which the active drug substance, as well as active metabolites when appropriate, is measured in plasma.
2. An *in vitro* test that has been correlated with human *in vivo* bioavailability data. This approach is most likely for oral modified release products and is described in detail in FDA Guidance.
3. An *in vivo* test in animals that has been correlated with human bioavailability data.
4. An *in vivo* test in humans, where urinary excretion of the active drug substance, as well as active metabolites when appropriate, is measured.
5. An *in vivo* test in humans in which an appropriate acute pharmacological effect is measured.
6. Well-controlled clinical trials in humans that establish the safety and efficacy of the drug product, for establishing bioavailability. For bioequivalence, comparative clinical trials may be considered. This approach is the least accurate, sensitive, and reproducible approach and should be considered only if other approaches are not feasible.
7. A currently available *in vitro* test, acceptable to FDA, that ensures bioavailability. This approach is intended only when *in vitro* testing is deemed adequate, but no *in vitro*–*in vivo* correlation (IVIVC) has been established. It also can relate to considerations involving the Biopharmaceutics Classification System (BCS).

Most bioequivalence studies involve the direct measurement of the parent drug, as described in item 1 above. Bioequivalence testing in animals is not a recommended approach due to possible differences in metabolism, gastrointestinal physiology, weight, and diet.

### MINIMIZING THE NEED FOR BIOEQUIVALENCE STUDIES

If a drug product has been adequately tested and approved for marketing, and if no changes in the manufacturing of the product are made, it is reasonable to assume that all subsequent batches of the product would be expected to be bioequivalent to the original product. If subsequently manufactured batches meet all tests of quality, including the dissolution test, no further human bioequivalence testing is needed.

Depending on the degree of change, bioequivalence may sometimes need to be reconfirmed. Although it is somewhat difficult to categorize such major changes, this issue has been described in a series of FDA guidance documents related to Scale-Up and Post-Approval Changes (SUPAC).

Drug characteristics related to solubility and permeability may allow a reasonable expectation that the drug is unlikely to be subject to significant bioavailability problems. For such drugs, *in vitro* dissolution testing may be adequate, in lieu of *in vivo* testing. These concepts are described in the Biopharmaceutics Classification System (BCS). This classification system provides a scientific framework for classifying drugs based on aqueous solubility and intestinal permeability. In addition, criteria for rapid dissolution are described (not less than 85% dissolved in 30 minutes, using mild agitation and physiological media). The BCS permits waivers of *in vivo* bioequivalence testing for high solubility, high permeability drugs (Class I), which are formulated into immediate release dosage forms having rapid dissolution. The basic tenet behind the BCS is that solutions of drugs are thought to have few bioavailability or bioequivalence issues. Dosage forms containing drugs that are of high solubility and exhibit rapid dissolution behave similarly to a solution. Particularly for such drugs that are, in addition, highly permeable (well absorbed), the likelihood of bioavailability problems is quite small, and consequently, bioequivalence testing for such drugs is thought to be unnecessary. Similarly for oral solutions, bioequivalence testing is not necessary.

### EVALUATION OF BIOEQUIVALENCE DATA

The following sections highlight some considerations when evaluating data from bioequivalence studies. The topics discussed are directed specifically toward plasma level evaluations. With minor modifications, the approaches outlined can be used for urinary excretion measurements or for suitable, quantitative, pharmacological response measurements.

Bioequivalence studies are usually conducted in healthy adults under standardized conditions. Most often, single doses of the test and reference product will be evaluated. However, in selected cases, multiple-dose regimens may be used (e.g., when patients are used and they cannot be discontinued from a medication). The goal of the study is to evaluate the *in vivo* performance, as measured by rate and extent of absorption, of the dosage forms under standardized conditions to minimize patient-related and other variability.

The protocol should define the acceptable age and weight range for the subjects to be included in the study, as well as the clinical parameters that will be used to characterize a healthy adult (e.g., physical examination observations, clinical chemistry, and hematological evaluations). The subjects should have been drug-free for at least two weeks prior to testing to eliminate possible drug-induced influences on liver enzyme systems. Normally, the subjects will fast overnight for at least ten hours prior to dosing and will not eat until a standard meal is provided four hours post-dosing. The dosage forms should be given to subjects in a randomized manner, using a suitable crossover design, so that possible daily variations are distributed equally between the dosage forms tested. The protocol should define sample collection times and techniques to collect the biological fluid. The method of sample storage should also be defined.

### BIOEQUIVALENCE ASSESSMENT AND DATA EVALUATION

Several parameters are used to provide a general evaluation of the overall rate and extent of absorption of a drug. An analysis of all characteristics is required before one can determine bioequivalence or lack of bioequivalence. It is implicit that the analytical methodology used for analysis of drug in the samples is specific, sensitive, and precise.

In assessing the bioequivalence of drug products, one must quantitate the rate and extent of absorption, which can be determined by evaluating parameters derived from the blood-level concentration–time profile. Three parameters describing a blood-level curve are considered important in evaluating the bioequivalence of two or more formulations of the same drug. These are the peak-height concentration ( $C_{max}$ ), the time of the peak concentration ( $T_{max}$ ), and the area under the blood (serum or plasma) concentration–time curve (AUC).

#### PEAK-HEIGHT CONCENTRATION ( $C_{max}$ )

The peak of the blood-level–time curve represents the highest drug concentration achieved after oral administration. It is reported as an amount per volume measurement (e.g., microgram/milliliter ( $\mu\text{g/mL}$ ), unit/mL, or gram/100 mL). The importance of this parameter is illustrated in Figure 5-5, where the blood concentration–time curves of two different formulations of a drug are represented. A line has been drawn across the curve at  $4 \mu\text{g/mL}$ . Suppose that the drug is an analgesic, and  $4 \mu\text{g/mL}$  is the minimum effective concentration (MEC) of the drug in blood. If the blood concentration curves in Figure 5-5 represent the blood levels obtained after administration of equal doses of two formulations of the drug and it is known that analgesia would not be produced unless the MEC was achieved or exceeded, it becomes clear that formulation A would be expected to provide pain relief, while formulation B, even though it is well absorbed regarding extent of absorption, might be ineffective in producing analgesia.

**Figure 5-5.** Blood concentration–time curves obtained for two different formulations of the same drug, demonstrating relationship of the profiles to the minimum effective concentration (MEC).

**Figure 5-6.** Blood concentration–time curves obtained for two different formulations of the same drug, demonstrating relationship of the profiles to the minimum toxic concentration (MTC) and the minimum effective concentration (MEC).

On the other hand, if the two curves represent blood concentrations following equal doses of two different formulations of the same cardiac glycoside, and 4  $\mu\text{g}/\text{mL}$  now represents the minimum toxic concentration (MTC) and 2  $\mu\text{g}/\text{mL}$  represents the MEC (Figure 5-6), formulation A, although effective, may also present safety concerns, while formulation B produces concentrations well above the MEC but never reaches toxic levels.

### Time of Peak Concentration ( $T_{\max}$ )

The second parameter of importance is the measurement of the length of time necessary to achieve the maximum concentration

after drug administration. This parameter is called the time of peak blood concentration ( $T_{\max}$ ). In Figure 5-5, for formulation A the time necessary to achieve peak blood concentration is 1 h. For formulation B,  $T_{\max}$  is 4 h. This parameter is related closely to the rate of absorption of the drug from a formulation and may be used as a simple measure of rate of absorption but is normally not evaluated statistically.

To illustrate the importance of  $T_{\max}$ , suppose that the two curves in Figure 5-6 now represent two formulations of an analgesic and that in this case the MEC is 2.0  $\text{g}/\text{mL}$ . Formulation A will achieve the MEC in 30 minutes; formulation B does not achieve that concentration until 2 h. Formulation A would produce analgesia much more rapidly than formulation B and would probably be preferable as an analgesic agent. On the other hand, if one were more interested in the duration of the analgesic effect than on the time of onset, formulation B would present more prolonged activity, maintaining serum concentrations above the MEC for a longer time (8 h) than formulation A (5.5 h).

### AREA UNDER THE CONCENTRATION-TIME CURVE (AUC)

The third, and sometimes the most important parameter for evaluation, is the area under the serum, blood, or plasma concentration–time curve (AUC). This area is reported in amount/volume multiplied by time (e.g.,  $\mu\text{g}/\text{mL} \times \text{h}$  or  $\text{g}/100 \text{ mL} \times \text{h}$ ) and can be considered representative of the amount of drug absorbed following administration of a single dose of the drug.

Although several methods exist for calculating the AUC, the trapezoidal rule method is most often used. This method assumes a linear function,  $y = bt + a$ , and its accuracy increases as the number of appropriate sampling intervals are increased. Table 5-1 and Figure 5-7 describe the process for calculating the AUC using the trapezoidal rule.

Returning to Figure 5-6, the curves, although much different in shape, have approximately the same areas ( $A = 34.4 \mu\text{g}/\text{mL} \times \text{h}$ ;  $B = 34.2 \mu\text{g}/\text{mL} \times \text{h}$ ), and both formulations can be considered to deliver the same amount of drug to the systemic circulation. Thus, one can see that AUC should not represent the only criterion on which bioequivalence is judged. All the results, as a composite, must be considered in reaching a decision about bioequivalence since no single parameter is adequate to serve this purpose.

The plasma concentration–time curve is the focal point of bioequivalence assessment and is obtained when serial blood samples are analyzed for drug concentration. The concentrations are plotted on the ordinate ( $y$ -axis), and the times after drug administration that the samples were obtained are plotted on the abscissa ( $x$ -axis).

A drug product is administered orally at time zero, and the plasma drug concentration at this time clearly should be zero. As a product passes through the gastrointestinal (GI) tract, it must undergo a sequence of events depicted in Figure 5-1. As

**Table 5-1. Using the Trapezoidal Rule to Calculate Area Under the Concentration-Time Curve.**

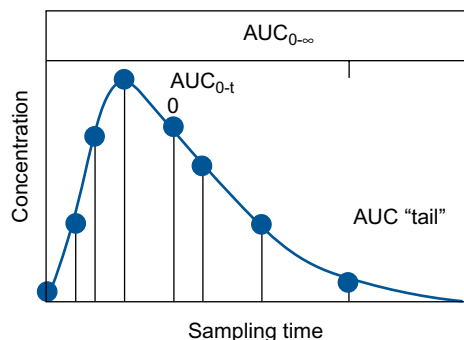

$AUC_{(0-E)}$  is used for bioequivalence analyses when the  $AUC_{(0-t)}$  makes up  $\geq 80\%$  of the  $AUC_{(0-E)}$ .  $AUC_{(0-t)}$  is used when the  $AUC_{(0-t)}$  makes up  $< 80\%$  of the  $AUC_{(0-E)}$ . When drugs with long half-lives are evaluated,  $AUC_{(0-t)}$  may sometimes be used with a truncated time point.

#### Area under the concentration-time curve from time zero to time $t$ ( $AUC_{0-t}$ )

1. Plot the concentration-time data for each subject
2. Divide the curve into trapezoids by drawing vertical lines from each datum point to the  $x$ -axis. Calculate the area of the trapezoids using the following formula:
3.  $AUC_{(t_2-t_1)} = [(C_2 + C_1)(t_2 - t_1)] / 2$   
 $AUC_{(0-t)}$  is then calculated by summing the individual areas to the time of the last concentration:
4.  $AUC_{(0-t)} = AUC_{(t_2-t_1)} + AUC_{(t_3-t_2)} + \dots + AUC_{(t_n-(t_{n-1}))}$

#### Area under the concentration-time curve from time zero to infinity ( $AUC_{0-E}$ )

5. To calculate  $AUC_{(0-E)}$ , the tail region of the curve must be added to  $AUC_{(0-t)}$ :  $AUC_{(0-E)} = AUC_{(0-t)} + AUC$  "tail"
6.  $AUC$  "tail" =  $C_t/\lambda_z$ , where:  $C_t$  is the last detectable concentration, and  $\lambda_z$  is the terminal elimination rate constant (see Figure 5-9).

**Figure 5-7.** Graphical depiction of use of the trapezoidal rule for calculating the area under the concentration–time curve.

the drug is absorbed, increasing concentrations of the drug are observed in successive samples until the maximum concentration is achieved. This point of maximum concentration ( $C_{max}$ ) is the peak of the concentration–time curve. If a simple model describes the pharmacokinetics of the drug tested, the peak concentration represents approximately the point in time when absorption and elimination of the drug have equalized.

The section of the curve to the left of the peak represents the absorption phase (or absorption and distribution), during which absorption predominates over elimination. The section of the curve to the right of the peak is called the elimination phase, during which elimination predominates over absorption. It should be understood that elimination begins as soon as the drug appears in the bloodstream and continues until the drug has been completely eliminated. Elimination is classically the log-linear portion of the curve. Absorption continues for some period of time into the elimination phase for as long as there is drug (in gradually decreasing amounts) available for absorption in the GI tract.

One must recognize that elimination of the drug includes all processes of elimination of the drug, involving urinary excretion, as well as metabolism by various tissues and organs. The efficiency of metabolism and urinary excretion will determine the shape of the elimination phase of the curve.

Bioequivalence studies normally are performed in healthy, adult volunteers under rigid conditions of fasting and activity because the objective is to obtain quantitative information on the influence of pharmaceutical formulation variables on the drug product's absorption. Drug blood-level profiles, therefore, allow quantification of the rate and extent of drug absorption and are critical in establishing the comparative efficiency of two drug products in delivering the drug to the systemic circulation.

Suggestions that bioequivalence studies should be conducted in a disease-state population are not tenable if the object of the study is to assess drug formulations, unless safety considerations prohibit administration of the drug to healthy volunteers. If, on the other hand, the purpose is to determine the effect of disease on the efficiency of absorption of the drug product, then one must use the disease-state population. The reasoning is obvious. To ensure that any differences observed in the drug blood-level profiles are attributable to formulation factors, as much as possible, one must hold all other variables constant (i.e., food, activity, and state of disease).

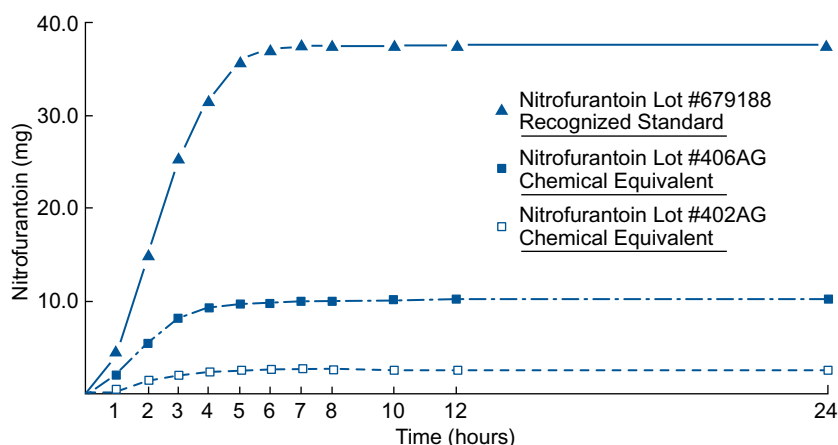

One need not be limited to drug blood-level profiles, but in a similar manner, may obtain cumulative urinary drug amount–time profiles. Drug concentration is determined in the urine at specified time intervals, and the amount excreted per interval is calculated by multiplying the concentration by the volume of urine obtained in that interval. The amounts per interval then are combined, and ultimately the total amount excreted in the urine is obtained. This value is analogous to the area under the blood concentration–time curve. However, one limitation to this method is that rate cannot be readily determined. A typical cumulative urinary drug amount–time profile for several nitrofurantoin products is presented in Figure 5-8.

## CRITERIA FOR BIOEQUIVALENCE

Under the Drug Price Competition and Patent Term Restoration Act of 1984 (Hatch-Waxman), manufacturers seeking approval to market a generic drug must submit data demonstrating that the drug product is bioequivalent to the pioneer (innovator) drug product. A major premise underlying the 1984 law is that bioequivalent drug products are therapeutically equivalent and, therefore, interchangeable.

The standard bioequivalence study is conducted in a cross-over fashion in a small number of volunteers, usually with 24 to 36 healthy adults. The number of subjects appropriate for a bioequivalence study can be determined on the basis of previous knowledge of the drug's variability. In general, the number of subjects should be sufficient to detect 20% differences in the measured parameters with 80% certainty. Single doses of the test and reference drugs are administered, and blood or plasma levels of the drug are measured over time. Characteristics of these concentration–time curves, such as the area under the curve (AUC) and the peak blood or plasma concentration ( $C_{max}$ ), are examined by statistical procedures.

Bioequivalence of different formulations of the same drug substance involves equivalence with respect to the rate and extent of drug absorption. Two formulations whose rate and extent of absorption differ by  $\pm 20\%$  or less are generally considered bioequivalent. The use of the  $\pm 20\%$  criterion is based on a

**Figure 5-8.** Average cumulative amounts of nitrofurantoin excreted from three lots of two commercially available products after a single oral dose of 100 mg of nitrofurantoin.

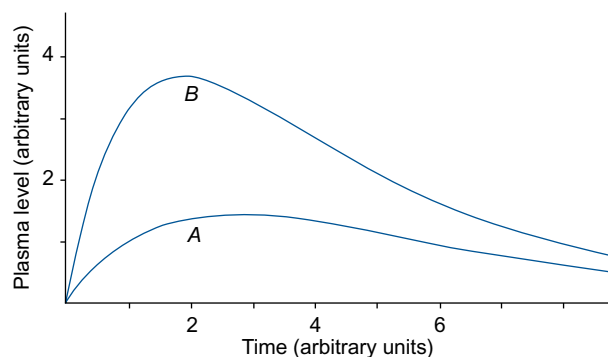

medical decision that for most drugs, a  $\pm 20\%$  difference in the concentration of the active ingredient in blood will not be clinically significant (Figure 5-9).

To verify, for a particular pharmacokinetic parameter, that the  $\pm 20\%$  criterion is satisfied, two one-sided statistical tests are carried out using the log-transformed data from the bioequivalence study. In order to interpret the statistical results, the log-transformed data must first be back-transformed. When the log-transformed data are back-transformed, the  $\pm 20\%$  now becomes  $-20\%/+25\%$ . One test is used to verify that the lower bound of the 90% confidence interval of the average response for the generic product is no more than 20% below that of the innovator product. The other test is used to verify that the upper bound of the 90% confidence interval of the average response for the generic product is no more than 25% above that for the innovator product. The current practice is to carry out each of the two one-sided tests at the 0.05 level of significance.

Computationally, the two one-sided tests are carried out by computing a 90% confidence interval. For approval of Abbreviated New Drug Applications (ANDA), in most cases, the generic manufacturer must show that a 90% confidence interval for the ratio of the mean response (usually AUC and  $C_{max}$ ) of its product to that of the innovator is within the limits of 0.80 and 1.25 after the log-transformed data have been back-transformed. If the true average response of the generic product in the population is near 20% below or 25% above the innovator average, one or both of the confidence limits is likely to fall outside the acceptable range, and the product will fail the bioequivalence test. Thus, an approved product is likely to differ from the innovator by far less than this quantity. These same criteria are applied to other bioequivalence situations, such as post-approval changes in innovator or generic products.

The current practice of carrying out two one-sided tests at the 0.05 level of significance ensures that if the two products truly differ by as much as or more than is allowed by the equivalence criteria, there is no more than a 5% chance that they will be approved as equivalent. This reflects the fact that the primary concern from the regulatory point of view is the protection of the patient against a conclusion of bioequivalence if this does not hold true. The results of a bioequivalence study usually must be acceptable for more than one pharmacokinetic parameter. As such, a generic product that truly differs by  $\pm 20\%$  or more from the innovator product with respect to one or more pharmacokinetic parameters would have less than a 5% chance of being approved. Different statistical criteria may be used when bioequivalence is demonstrated through comparative clinical trials, pharmacodynamic studies, or comparative *in vitro* methodology.

Using the two one-sided test procedures, when two drug products differ by more than 12–13% in means, they are unlikely to

**Figure 5-9.** Computer simulation of the plasma-level curves for two dosage forms of the same drug, assuming that the rate and extent of drug absorption for dosage form A were 50% and 50%, respectively, of those for dosage form B.

pass the bioequivalence confidence interval criteria of 80–125%. A study of more than 200 approved generic drugs indicated that a mean bioavailability difference of only 3.5% existed. Although somewhat larger differences might meet the bioequivalence criteria, the reality is that, for generic drug products approved by FDA, observed differences have been quite small.

## FED BIOEQUIVALENCE STUDIES

Food has been shown to alter the bioavailability of some drugs, and this alteration can have a negative impact on the interpretation of bioequivalence results between test and reference products. As a result, bioequivalence studies are usually conducted under fasting conditions. However, in some instances a fasting study may not be reasonable for a particular drug due to safety considerations or perhaps because of the drug's intended clinical indication. In these situations a fed bioequivalence study is sometimes acceptable. A fed bioequivalence study is similar to the standard bioequivalence study except that, following an overnight fast, the test or reference products are administered 30 minutes after the start of a standardized meal. The FDA currently recommends a high-fat, high-calorie meal as described in an FDA Guidance. The composition of this meal is described in Table 5-2. The same statistical criteria as used for the standard bioequivalence study are observed for the resultant fed bioequivalence study data.

## AVERAGE BIOEQUIVALENCE

The standard *in vivo* bioequivalence study design is based on administration of the test and reference products on separate occasions to healthy subjects, either in single or multiple doses, with random assignment to the two possible sequences of drug product administration. Samples of plasma or blood are analyzed for drug and/or metabolite(s) concentrations, and pharmacokinetic parameters are obtained from the resulting concentration–time curves. Parameters are analyzed statistically to determine if the test and reference products yield comparable values. Statistical analysis for pharmacokinetic parameters, such as area under the curve (AUC) and peak concentration ( $C_{max}$ ), is based on the two one-sided tests procedure, which determines whether the average values for pharmacokinetic parameters measured after administration of the test and reference products are comparable (i.e., average bioequivalence). This procedure involves the calculation of a 90% confidence interval for the ratio of the averages of the test and reference products. To establish bioequivalence, the calculated confidence interval must fall within a bioequivalence limit, usually 80–125% for the ratio of the product averages. In addition to this general approach for determining bioequivalence, a FDA Guidance provides specific recommendations for (1) logarithmic transformation of pharmacokinetic data, (2) methods to evaluate sequence effects, and (3) methods to evaluate outlier data.

**Table 5-2.** The FDA Standardized High-Fat Test Meal Composition.

Meal Composition	Energy (kcal)
Protein	150
Carbohydrate	250
Fat	500–600

The example test meal would be two eggs fried in butter, two strips of bacon, two slices of toast with butter, four ounces of hash brown potatoes, and eight ounces of whole milk. Substitutions in this test meal can be made as long as the meal provides a similar amount of calories from protein, carbohydrate, and fat and has a comparable meal volume and viscosity.

## POPULATION AND INDIVIDUAL BIOEQUIVALENCE

Statistically, the average bioequivalence approach focuses on the comparison of population averages of a bioavailability metric of interest and not on the variability of the metric for the test and reference products. In addition, average bioequivalence cannot describe a subject-by-formulation interaction, that is, the variation that may be present among individuals in the average test and reference difference. In contrast, population and individual bioequivalence approaches include comparisons of both averages and variability of the study metric. The population bioequivalence approach assesses the total variability of the metric in the population. The individual bioequivalence approach assesses the within-subject variability as well as the subject-by-formulation interaction. However, due to statistical and study design issues with population and individual bioequivalence, respectively, the FDA has deferred recommending these analysis methods.

## STUDY DESIGN

### AVERAGE OR POPULATION BIOEQUIVALENCE

A conventional, non-replicated crossover design, such as the standard two-formulation, two-period, two-sequence crossover design, may be used to generate data for assessment of population bioequivalence. Replicated-crossover designs or parallel designs also may be used.

### INDIVIDUAL BIOEQUIVALENCE

Three important parameters, the within-subject variability for the test metric, within-subject variability for the reference metric and subject-by-formulation interaction are integral components of the individual bioequivalence criterion. A replicated-crossover design of the bioequivalence study should be used to estimate these parameters.

Further information related to current FDA recommendations regarding the design and analysis of bioequivalence studies is available on the internet at <http://www.fda.gov/cder/>, under Regulatory Guidance Documents.

### PITFALLS ASSOCIATED WITH CROSS-STUDY COMPARISONS

This is a situation in which the blood concentration–time curve of a drug product in one study is compared with the blood concentration–time curve of that drug product in another study. There are several reasons why such cross-study comparisons are not recommended and may lead to false conclusions. However, if no other data are available, and if important comparisons must be made, cross-study comparison may be informative if one keeps in mind the possible limitations. The following examples, used to illustrate these three points, are taken from actual bioavailability data.

#### Subject Population

In Figure 5-10, a research lot of potassium phenoxymethyl penicillin was compared with the appropriate reference standard for that product. The research lot drug was found to be bioequivalent, with average peak-serum concentrations differing by 8% and the area differing by only 9%. In another study conducted with a full-manufacture lot of the test product, the same lot of the reference standard potassium phenoxymethyl penicillin was used.

The results of this study are shown in Figure 5-11. Again, the two products were found to be bioequivalent, as the peak and area parameters differed by less than 5%. In these two studies, identical test conditions were used, and the same analytical procedure and laboratory was employed. However, if one compares the plasma levels for the reference standard lot found in Figure 5-10 with the levels for the same lot of tablets in the study in Figure 5-11, sizable differences in blood levels are found, as shown in Figure 5-12.

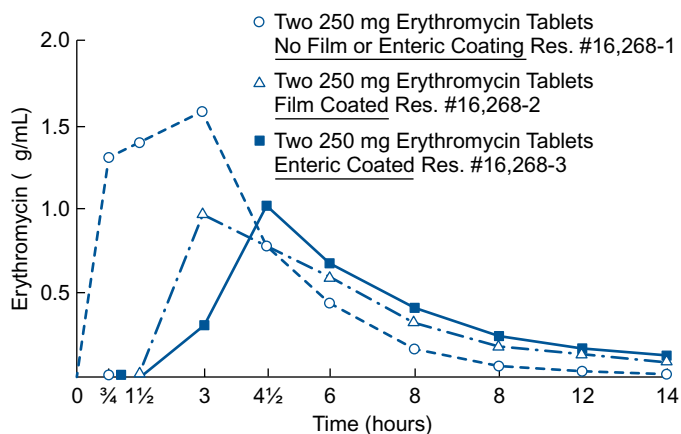

**Figure 5-10.** Average serum concentration of phenoxymethyl penicillin, following oral administration of 500 mg given as one tablet of recognized standard ( $\Delta$ ) or of test product, research lot ( $\square$ ).

**Figure 5-11.** Average serum concentration of phenoxymethyl penicillin following oral administration of 500 mg given as one tablet of recognized standard ( $\Delta$ ) or of test product full mfg lot ( $\blacksquare$ ).

**Figure 5-12.** Average serum concentration of phenoxymethyl penicillin following a single oral 500 mg dose of recognized standard, in two different subject populations.

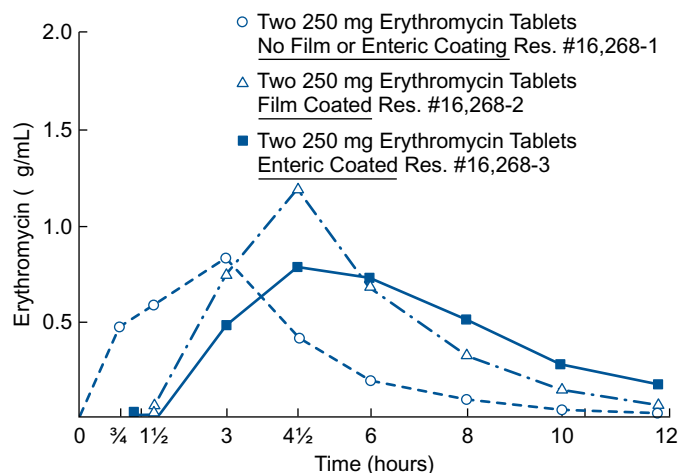

**Figure 5-13.** Average serum erythromycin concentration following administration in 500 mg doses as three different tablet dosage forms. The results were obtained from 21 healthy adult subjects following an overnight fast of 12 hours before, and 2 hours after, drug administration.

The average peak serum levels for this lot of tablets were found to be 8.5 and 12.5 units/mL in the two respective studies, a difference of approximately 31%. Likewise, the average AUC was found to differ by approximately 21%. Such apparent differences are solely the result of cross-study comparisons and are not due to differences in actual bioavailability.

The same lot of reference standard tablets was used in both studies. Hence, the difference must be due to the experimental variables that occur normally from study to study. The major difference between the two studies was the subject population involved. In the first study, healthy adult male prison volunteers were used, whereas in the second study there were 17 females and 7 males in a hospital clinic, also described as normal, healthy volunteers. An appreciable difference in sex distribution was obvious when comparing these studies. Adjustments for body weight and surface area alone did not correct for the apparent discrepancies in peak concentration or blood-level AUC. It is difficult to determine the exact factors that caused the observed differences. This example should serve as a note of caution in comparing bioavailability values of peak concentration and area under the curve from different studies.

### Study Conditions

Parameters such as the food or fluid intake of the subject before, during, and after drug administration can have dramatic effects on the absorption of certain drugs. Figure 5-13 shows the results of a three-way crossover test in which the subjects were fasted 12 hours overnight and 2 hours after drug administration

**Figure 5-14.** Average serum erythromycin concentration following administration in 500 mg doses as three different tablet dosage forms. The results were obtained from 12 healthy adult subjects with only a 2 hour fast before drug administration.

of an uncoated tablet, a film-coated tablet, or an enteric-coated tablet of erythromycin.

The results of this study suggest that the uncoated tablet is superior to both the film-coated and enteric-coated tablets in terms of blood level performance. These results also suggest that neither film coating nor enteric coating is necessary for optimal blood-level performance. Figure 5-14 shows results with the same tablets when the study conditions were changed to only a 2-hour pre-administration fast with a 2-hour post-administration fast. In this case, the blood levels of the uncoated tablet were depressed markedly, while the film-coated and enteric-coated tablets showed relatively little difference in blood levels.

From this second study, it might be concluded that film coating appears to impart the same degree of acid stability as an enteric coating. This might be acceptable if only one dose of the antibiotics was required. However, Figure 5-15 shows the results of a multiple-dose study in which the enteric-coated tablet and the film-coated tablet were administered four times a day, immediately after meals. The results show that the film coating does not impart the degree of acid stability that the enteric coating does when the tablets are administered immediately after food in a typical clinical situation.

### Assay Methodology

Depending on the drug under study, there may be more than one assay method available. For example, some steroids can be assayed by a radioimmunoassay, competitive protein-binding,

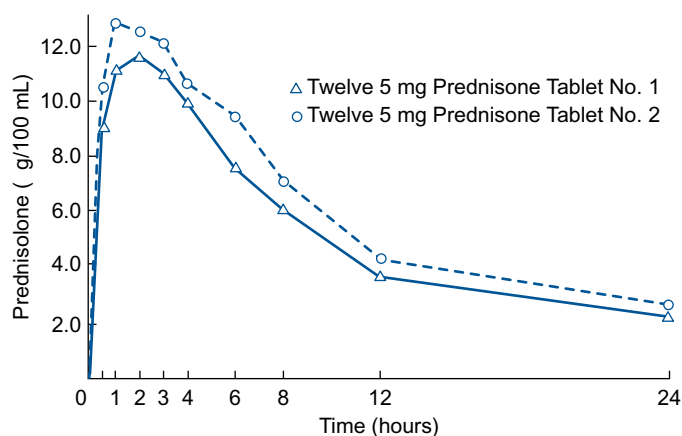

**Figure 5-15.** Average serum erythromycin concentration-time profiles from drug administered in two different tablet dosage forms. The results were obtained from 24 healthy adult subjects, following administration of 250 mg, four times a day, with meals and at bedtime.

gas-liquid chromatography, or indirectly by a 17-hydroxycorticosteroid assay.

Figures 5-16 and 5-17 show the results of a comparison of prednisone tablets using a competitive protein-binding method and a radioimmunoassay, respectively. The serum concentration–time curves resulting from each method lead to the same conclusion, that the products are bioequivalent. However, Figure 5-18 shows a comparison of the absolute values obtained by the two assay methods with the same product.

Obviously, the wrong conclusion would have been reached if one product had been assayed by one method and the other product by the other method and the results had been compared. Even in cases in which only one assay method is employed, there are numerous modifications with respect to technique among laboratories that make direct comparisons difficult.

The backbone of any bioavailability study involving plasma (or urine) levels of drug, in addition to good study design and subject controls, is the analytical methodology used to determine the levels of a drug. The precision and reliability of the method employed in a given study have been established to a sufficient degree to make the results of the study internally consistent. As demonstrated, major problems arise when, without careful evaluation of the analytical methodology employed, one attempts to compare the data of studies from different laboratories. Even with similar analytical methodology performed by the same laboratory, it would be unreasonable to expect

**Figure 5-16.** Average plasma prednisolone levels following 60 mg of prednisone administered to 24 normal adults as a single oral dose of twelve 5 mg prednisone tablets from two different manufacturers. Plasma levels were determined by a competitive protein-binding assay.

**Figure 5-17.** Average plasma prednisolone levels, following 60 mg of prednisone administered to 24 normal adults as a single oral dose of twelve 5 mg prednisone tablets from two different manufacturers. Plasma levels were determined by a radioimmunoassay procedure.

**Figure 5-18.** Average plasma prednisolone profiles from drug administered as a single 60-mg dose to 24 normal adults. Plasma levels were determined by both a competitive protein-binding assay and a radioimmunoassay.

agreement, using the same dosage form, closer than 20% to 25% for plasma levels from one study to the next.

Under the best conditions, cross-study comparisons are relatively insensitive, and at worst they can be misleading. Cross-study comparisons certainly cannot be used to make decisions or estimate differences in drug products with the generally acceptable sensitivity of difference detection of 20% or less.

## THERAPEUTIC EQUIVALENCE EVALUATIONS

The FDA publication *Approved Drug Products with Therapeutic Equivalence Evaluations* identifies drug products approved on the basis of safety and effectiveness. In addition, this list contains therapeutic equivalence evaluations for approved multi-source prescription drug products. These evaluations have been prepared to serve as public information and advice to state health agencies, physicians, and pharmacists to promote public education in the area of drug product selection and to foster containment of healthcare costs.

To help contain drug costs, virtually every state has adopted laws and/or regulations that encourage the substitution of drug products. These state laws generally require either that substitution be limited to drugs on a specific list (the positive formulary approach) or that substitution be permitted for all drugs except those prohibited by a particular list (the negative formulary approach). Because of the number of requests for FDA assistance in preparing both positive and negative formularies, it became apparent that the FDA could not serve the needs of each state on an individual basis. The agency also recognized that providing a single list based on common criteria would be preferable to evaluating drug products on the basis of differing definitions and criteria in various state laws. The therapeutic equivalence evaluations in this publication reflect FDA's application of specific criteria to the approved multi-source prescription drug products.

FDA classifies as therapeutically equivalent those products that meet the following general criteria:

1. They are approved as safe and effective.
2. They are pharmaceutical equivalents in that they (A) contain identical amounts of the same active drug ingredient in the same dosage form and route of administration and (B) meet compendial or other applicable standards of strength, quality, purity, and identity.
3. They are bioequivalent in that (A) they do not present a known or potential bioequivalence problem, and they meet an acceptable *in vitro* standard, or (B) if they do present such a known or potential problem, they are shown to meet an appropriate bioequivalence standard.

4. They are adequately labeled.
5. They are manufactured in compliance with Current Good Manufacturing Practice regulations.

This concept of therapeutic equivalence applies only to drug products containing the same active ingredient(s) and does not encompass a comparison of different therapeutic agents used for the same condition. The FDA considers drug products to be therapeutically equivalent if they meet the criteria outlined above, even though they may differ in certain other characteristics such as shape, scoring configuration, release mechanisms, packaging, excipients, expiration date/time, and minor aspects of labeling (e.g., the presence of specific pharmacokinetic information). The FDA believes that products classified as therapeutically equivalent can be substituted with the full expectation that the substituted product will produce the same clinical effect and safety profile as the prescribed product.

As described in this chapter, the concepts of bioavailability and bioequivalence testing are essential in the drug development process by creating the foundation for regulatory decision for both innovator and generic drug products.

# Chapter 6

## Dissolution

Vijai Kumar, MS, MBA and Praveen Hiremath, PhD

DEFINITION OF DISSOLUTION AND THEORETICAL CONCEPTS FOR THE RELEASE OF THE DRUG FROM DOSAGE FORMS 64

MATHEMATICS OF DISSOLUTION 64

DISSOLUTION PROFILE COMPARISONS 78

APPLICATION OF QUALITY BY DESIGN (QBD) PRINCIPLES IN DISSOLUTION TESTING 79

Dissolution is the process by which a solid enters into solution. The earliest reference to dissolution is the 1897 article by Noyes and Whitney, titled as “The Rate of Solution of Solid Substances in Their Own Solution.” The authors suggested that the rate of dissolution of solid substances is determined by the rate of diffusion of a very thin layer of saturated solution that forms instantaneously around the solid particle. They developed the mathematical relationship that correlates the dissolution rate to the solubility gradient of the solid. Their equation is still the basic formula upon which most of the modern mathematical treatments of the dissolution phenomenon revolve.

Interestingly, the work of Noyes and Whitney, together with the studies that followed in the early part of the 20th century, was primarily based on the physicochemical aspects of dissolution applied to chemical substances. The most prominent part of these investigations that deserve recognition are those of Nernst and Brunner, in 1904, for their application of Fick’s law of diffusion to the Noyes-Whitney equation, and those of Hixson and Crowell, in 1931, for their development of famous “Cube Root Law” of dissolution.<sup>1</sup> Hixson-Crowell equation is subsequently provided:

$$Q_0^{1/3} - Q_t^{1/3} = K_{HC}t \quad (1)$$

where  $Q_t$  is the amount of drug released in time  $t$ ,  $Q_0$  is the initial amount of drug in the dosage form/product, and  $K_{HC}$  is the rate constant for Hixson-Crowell cube root equation, which describes the surface area-volume relationship. This equation applies to products, such as powders and tablets, where the dissolution occurs in the planes that are parallel to the surface of the dosage form.

Two more alternative explanations were available, as reviewed by William Higuchi (1961),<sup>2</sup> by the 1950’s. The interfacial barrier model considered that interfacial transport, rather than diffusion through the film, is the limiting step, due to a high activation energy level for the former, first proposed by Wilderman in 1909. Another model was Danckwerts’ model, which appeared in 1951. According to this, constantly renewed macroscopic packets of solvent reach the solid surface and absorb molecules of solute, delivering them to the solution.

By the middle of the 20th century, emphasis started to shift to the examination of the effects of dissolution behavior of drugs on the biological activity of pharmaceutical dosage forms. One of the earliest studies, with this purpose in mind, was conducted by J Edwards, in 1951, on aspirin tablets. He reported, “because of its poor solubility, the analgesic action of aspirin tablets would be controlled by its dissolution rate within the stomach and the intestine.” No *in vivo* studies, however, were conducted by Edwards to support his postulate.

About eight years later, Shenoy and colleagues proved the validity of Edward’s suggestion of the *in vitro/in vivo* correlation by demonstrating a direct relationship between the bioavailability of amphetamine from sustained-release tablets and its *in vitro* dissolution rate. Other studies, especially those reported by Nelson, Levy, and others, confirmed, beyond doubt, the significant effect of the dissolution behavior of drugs on their pharmacological activities. Nelson, in 1957, was the first to explicitly relate the blood levels of orally administered

theophylline salts to their *in vitro* dissolution rates. Due to the importance of these findings, dissolution testing began to emerge as a dominant topic within both the pharmaceutical academia and the drug industry.

During this 20-year period, 1950–1970, a number of studies conducted, especially in the United States, confirmed the significance of dissolution- bioavailability relationship in the pharmaceutical product development. As a result, the basket-stirred-flask test (USP apparatus 1) was adopted as an official dissolution test in 6 monographs of the *United States Pharmacopeia (USP)* and *National Formulary (NF)*, in 1970. Also, due to the sustained interest in the subjects of dissolution and gastrointestinal absorption, an explosion in the number of monographs of the dissolution requirements in subsequent USP/NF editions was noted. Notable developments during this evolution are the adoption of the paddle method (USP apparatus 2) in 1978, the publication of a General Chapter on Drug Release in USP 21 (1985), the presence of 23 monographs for modified-release dosage forms in USP 22-NF 18 (1990), the adoption of the reciprocating cylinder (USP apparatus 3) for extended-release products in 1991, and the adoption of the flow-through cell in (USP apparatus 4) for extended-release products in 1995.

In the late 1960s, dissolution testing became a mandatory requirement for several dosage forms. The role of dissolution in the absorption of drug products, however, is still far from being understood completely. Although considerable efforts were made to establish *in vitro/in vivo* correlations between release of drug from the formulation and drug absorption, the limited knowledge of the complex composition and hydrodynamics of the gastrointestinal fluids remains a real barrier. In spite of the reported success of several *in vitro/in vivo* correlation studies, dissolution cannot be relied upon as a predictor of therapeutic efficiency. Rather, it is a qualitative tool that can provide valuable information about the biological availability of a drug, as well as batch-to-batch consistency. Another area of difficulty is the accuracy and precision of the testing procedure, which is dependent, to a large extent, on the strict observance of so many subtle parameters and detailed operational controls.

In spite of these shortcomings, dissolution is considered, today, as one of the most important quality control procedures performed on pharmaceutical dosage forms, and dissolution studies have become an essential part of drug applications to regulatory bodies worldwide. Whether or not it has been correlated with biological effectiveness, the standard dissolution test is a simple and inexpensive indicator of a product’s physical consistency. If one batch differs from the other in its dissolution characteristics or if the dissolution profiles of the production batches show a consistent trend upwards or downwards, it sounds a sure warning that some factor in the raw material, formulation, or process is out of control.<sup>1</sup> Additionally, dissolution data seems to be a useful tool in the early stages of drug development and molecular manipulation. In the early stages of research, steps may be taken to optimize characteristics that influence subsequent data concerning biological availability. Based on simple dissolution testing, selection of a proper salt for a new drug can be done at an early drug development stage.

## DEFINITION OF DISSOLUTION AND THEORETICAL CONCEPTS FOR THE RELEASE OF THE DRUG FROM DOSAGE FORMS

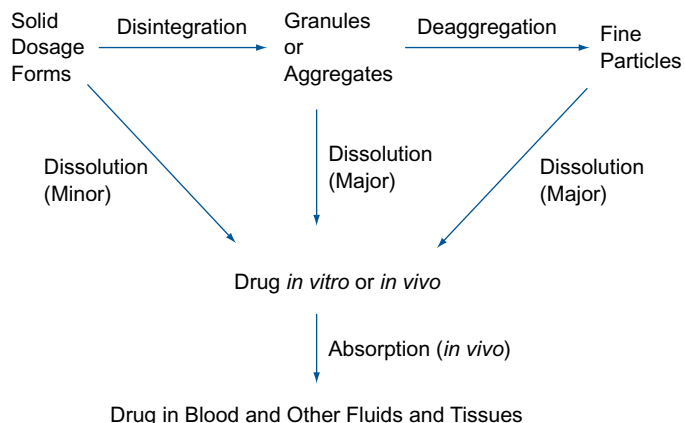

Dissolution is defined as the process by which solid substances enters in solvent to yield a solution. Stated simply, dissolution is the process by which a solid substance dissolves. Fundamentally, it is controlled by the affinity between the solid substance and the solvent.” The physical characteristics of the dosage form, the wettability of the dosage unit, the penetration ability of the dissolution medium, the swelling process, the disintegration, and the deaggregation of the dosage forms are a few of the factors that influence the dissolution characteristics of drugs. Wagner proposed a scheme, depicted in Figure 6-1, for the processes involved in the dissolution of solid dosage forms.

This scheme was later modified to incorporate other factors that precede the dissolution process of solid dosage forms. Carstensen proposed a scheme incorporating the following sequence:

1. Initial mechanical lag
2. Wetting of the dosage form
3. Penetration of the dissolution medium into the dosage form
4. Disintegration
5. Deaggregation of the dosage form and dislodgement of the granules
6. Dissolution and occlusion of some particles of the drug

Carstensen explained that the wetting of the solid dosage form surface controls the liquid access to the solid surface and, many times, is the limiting factor in the dissolution process. The speed of wetting directly depends on the surface tension at the interface (interfacial tension) and upon the contact angle between the solid surface and the liquid. Generally, a contact angle of more than  $90^\circ$  indicates poor wettability. Incorporation of a surfactant, either in the formulation or in the dissolution medium, lowers the contact angle and enhances dissolution. Also, the presence of air in the dissolution medium causes the air bubbles to be entrapped in the tablet pores and act as a barrier at the interface. For capsules, the gelatin shell is extremely hydrophilic, and, therefore, no problems in wettability exist for the dosage itself, although it may exist for the powders inside.

After the solid dosage form disintegrates into granules or aggregates, penetration characteristics play a prime role in the deaggregation process. Hydrophobic lubricants, such as talc and magnesium stearate, commonly employed in tablet and capsule formulations, slow the penetration rate and, hence, the deaggregation process. A large pore size facilitates penetration,

**Figure 6-1.** Schematics illustration of dissolution process of solid dosage forms.

but, if it is too large, it may inhibit penetration by decreasing the internal strain caused by the swelling of the disintegrant.

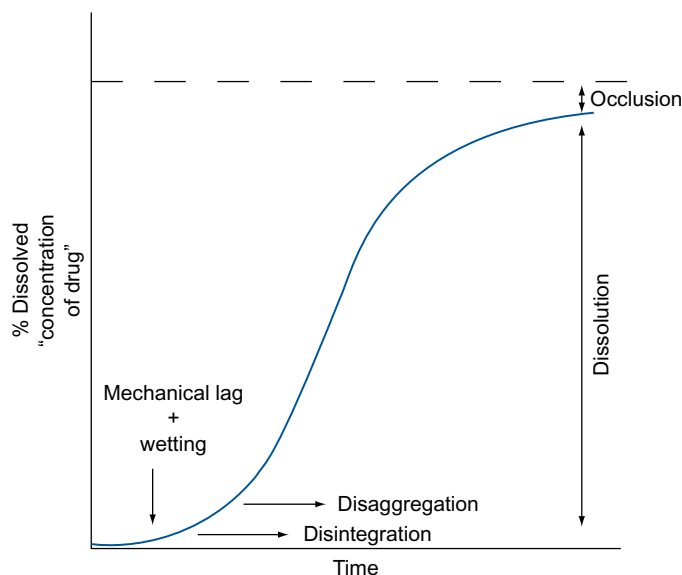

After deaggregation and dislodgment occur, the drug particles become exposed to the dissolution medium and dissolution proceeds. Figure 6-2,<sup>3</sup> graphically presents the model proposed by Carstensen.

It is apparent from Figure 6-2 that the rate of dissolution of the drug can become a rate-limiting step before it appears in the blood. However, when the dosage form is placed into the gastrointestinal tract in solid form, there are two possibilities for the rate-limiting step. The solid must first dissolve, and the drug in solution must then pass through the gastrointestinal (GI) membrane. Freely water-soluble drugs tend to dissolve rapidly, making the passive diffusion of the drug or the active transport of the drug rate-limiting step for absorption through the GI membrane. Conversely, the rate of absorption of poorly water-soluble drugs will be limited by the rate of dissolution of the undissolved drug or disintegration of dosage form.

The rate of dissolution of drug substance is determined by the rate at which solvent-solute forces of attraction overcome the cohesive forces present in the solid. This process is rate-limiting, when the release of solute into solution is slow and the transport into the bulk solution is fast. In this case, the dissolution is said to be interfacially controlled. Dissolution may also be diffusion controlled, where the solvent-solute interaction is fast, compared to transport of solute into the bulk solution. In diffusion-controlled process, a stationary layer of solute adjacent to the solid/liquid interface is postulated and is commonly referred to as the diffusion layer. The saturation concentration of solute develops at the interface and decreases with distance across the diffusion layer.

## MATHEMATICS OF DISSOLUTION

It has long been recognized that the release of the active drug from a drug product may be greatly influenced by the physicochemical properties of the drug, as well as the dosage form.<sup>4</sup> The availability of the drug is usually determined by the rate of release of the drug from the physical system (dosage form). The release of the drug from its dosage form is usually determined by the rate at which it dissolves in the surrounding medium. The rate of dissolution of a chemical or drug from the solid state is defined as the amount of drug substance that goes into solution per unit time under standardized condition of liquid/solid interface, temperature, and solvent composition. In biopharmaceutics, rate of dissolution usually refers to the rate at which

**Figure 6-2.** The S-shaped dissolution curve of solid dosage forms.

the drug dissolves from an intact dosage form or from fragments or particles from the dosage form during the test.<sup>5</sup>

The following section deals with the introductory concepts on mathematics of dissolution, focusing primarily on intrinsic dissolution.

## INTRINSIC DISSOLUTION

The rate of dissolution of a pure pharmaceutical active ingredient, when conditions, such as surface area, temperature, agitation or stirring speed, pH, and ionic strength of the dissolution medium is kept constant, is known as intrinsic dissolution rate. This parameter allows the screening of the drug candidates and aids in understanding their solution behavior under various biophysiological conditions.<sup>6</sup>

### Intrinsic Dissolution Rate Constants

The rate at which a substance dissolves in a liquid to form a solution is governed by physical parameters, such as the surface area of the substance at a given time during the process of dissolution, the shape of the substance, the characteristics of the solid/ liquid interface, and the solubility of the substance in the liquid. Hence, dissolution can be considered a specific type of certain heterogeneous reaction, which results in a mass transfer as a net effect between the escape and deposition of solute molecules at a solid surface. Mathematically, the process can be simply described as follows:

$$\frac{dM}{dt} = KA(C_s - C) \quad (2)$$

where  $M$  is the mass of the substance remaining to be dissolved,  $A$  is the surface area exposed to the dissolution medium,  $C_s$  is the saturation concentration referred to as solubility in the dissolution medium,  $C$  is the amount dissolved or the concentration of the drug in solution at time  $t$ , and  $K$  is the intrinsic dissolution rate constant or simply the dissolution rate constant.

The equation expresses the fact that, when  $C$  is small,  $C < 0.15C_s$ , then  $K$  is proportional to  $C_s$ , since  $(C_s - C)$  is large. If this applies, then to a good approximation we may write:

$$\frac{dM}{dt} = KAC_s \quad (3)$$

Equation 3 is commonly referred to as a sink-condition equation, which implies that sink conditions exist during the process of dissolution. It must be noted, however, that  $A$  is a constant, except initially, when only very small quantities of solute have dissolved and where there is an amount of solute far in excess of saturation.

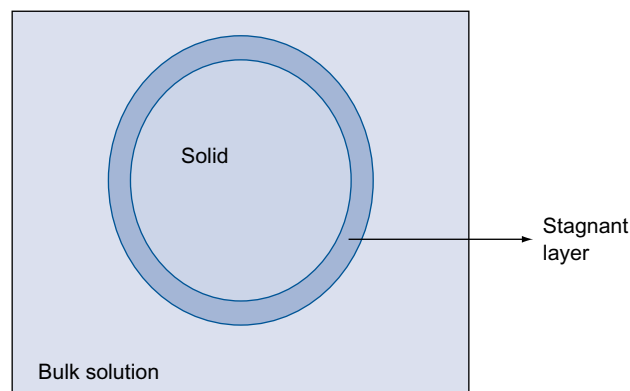

When the process of dissolution takes place under sink conditions, a stagnant film of liquid (dissolution medium) is adsorbed onto the solid, the thickness of this film being  $l$  cm. The liquid in the film in direct contact with the solid is saturated with drug in solution. The concentration of the drug in solution then drops as the distance from the dissolving solid surface increases. At the end of the film,  $l$  cm from the surface, the concentration in the film is the same as that in the bulk solution,  $C_b$ . The driving force behind the movement of solute molecules through the stagnant film is the concentration gradient that exists between the saturation concentration of the solute,  $C_s$ , in the stagnant layer at the surface of the solid and its concentration on the farthest side of the stagnant film,  $C_b$ . A schematic representation of dissolution as a physicochemical phenomenon is shown in Figure 6-3: the greater this difference in concentration, the faster the rate of dissolution.

Applying Fick's first law of diffusion to Equation 2, the flux,  $J$ , defined as the rate of flow of material through  $1 \text{ cm}^2$ , that is,

$$J = \frac{dM/dt}{A} \quad (4)$$

can be expressed as

$$J = -D \left( \frac{\delta C}{\delta x} \right) \quad (5)$$

**Figure 6-3.** Schematic representation of a physical model depicting a dissolution process.

where  $D$  is the coefficient of diffusion,  $x$  is the distance as shown in the Figure 6-3. If the concentration gradient,  $\delta C/\delta x$ , is linear, if  $C = C_s$  at the surface ( $x = 0$ ), and if  $C = C_b$  (the bulk concentration at the interface between the bulk solution and the film, where  $x = l$ ), then

$$\left( \frac{\delta C}{\delta x} \right) = \left( \frac{C_b - C_s}{l} \right) \quad (6)$$

Therefore,

$$\frac{1}{A} \frac{dM}{dt} = -D \frac{C_b - C_s}{l} = -K(C_s - C) \quad (7)$$

Or simply,

$$\frac{dM}{dt} = -KA(C_s - C) \quad (8)$$

If the agitation intensity of the system containing suspended particles is increased, the thickness of the film will decrease progressively. Hence,  $k$  is a function of the test as well. Additionally, if the product of  $A(C_s - C)$  is maintained constant for many drugs tested by the same test, the relative magnitude of  $k$  values will indicate the effective ease of dissolution. In practice,  $k$  also includes the dynamics of the shear rate between solid and the solvent, that is, the rate at which fresh solvent contacts the surface of the solid; highly complex processes, including diffusion rate through the boundary layers, depend upon this rate.

The shear rate depends on a multitude of variables that must be controlled, if the test is to be repeatable. Those variables include the flow pattern of solvent in the apparatus, turbulence, viscosity, surface tension, and dissolved gases, all of which are subject to uncontrolled input variables to the system, such as vibrations and system geometry. The theoretical basis for those inputs rests in the realm of chemical engineering's fluid flow and surface boundary theories, which are discussed elsewhere.<sup>7</sup>

The intrinsic dissolution rate has been used as a means to demonstrate the chemical purity and equivalency of the active pharmaceutical ingredient (API). The use of rotating disk system (USP Wood Apparatus), which is similar to USP procedure 1, is most common, although stationary disk systems, vertical diffusion cells, and enhancer cells can also be used to measure the intrinsic dissolution rates.<sup>8</sup>

### ROTATING DISK SYSTEM (USP WOOD APPARATUS)

The apparatus consists of steel punch, a die, and a base plate. The base of the die has three threaded holes for the insertion of the screws and the attachment to the base plate. The material is placed in the die cavity, the punch is inserted into the cavity, and the material is compressed. The die is screwed onto the shaft holder, and the shaft holder is mounted on the stirring device. The shaft is a stainless steel rod with hollow die holder. Pellet and die assembly are introduced at once, when the dissolution drive mechanism is lowered. The dissolution is achieved by shear-like motion of the pellet in the dissolution medium. The dissolution vessel is standard curved bottom 1-L flask. Care should be taken that the air bubbles do not form on the surface of the pellet or it will interfere with the dissolution rate (Fig. 6-4).

### STATIONARY DISK SYSTEM

The apparatus consists of a steel punch, a die, and a base plate. The die base has three holes for the attachment of the base plate. The three fixed screws on the base plate are inserted through the three holes on the die. Punch is inserted into the die cavity filled with the material, and the material is then compressed. The pellet and die assembly can then be inserted with the pellet side up, into the bottom of the dissolution vessel, which is flat bottomed. The USP Apparatus 2 is the stirring mechanism here. The advantage of this system is that no air bubbles are formed on the pellet surface. There is also no change in the temperature, as the device is small and is totally submerged into the dissolution medium (Fig. 6-5).

### CORRELATION BETWEEN THE DISINTEGRATION AND DISSOLUTION

The close correlation between disintegration and dissolution has been studied by many investigators. Both processes exhibit "S"-shaped curves, and a Probit or a Weibull function was suggested to explain the data. In general, however, disintegration has proved a poor indicator of bioavailability, due to the turbulent agitation maintained during the test. Several other factors, such as solubility, particle size, and crystalline structure, among others, have been found to affect the dissolution of the drug substance but have no relevance to disintegration.

Figure 6-4. Rotating disk system (USP Wood apparatus).

Figure 6-5. Stationary disk system (new apparatus).

### FACTORS AFFECTING THE RATE OF DISSOLUTION

The dissolution rate data can be meaningful, only if the results of successive test on the same dosage form are consistent within reason. The dissolution test should yield reproducible result, even when it is performed in different laboratories or with different personnel. To achieve high reproducibility, all variables that influence the test should be clearly understood and possibly controlled.

Factors affecting the dissolution rate of drugs from a dosage form include:

1. Factors related to the physicochemical properties of the drug
2. Factors related to drug product formulation
3. Factors related to dissolution test parameters
4. Miscellaneous factors

### FACTORS RELATED TO THE PHYSICOCHEMICAL PROPERTIES OF THE DRUG

#### Effect of Solubility on Dissolution

The physicochemical properties of the drug substance play a prime role in controlling its dissolution from the dosage form. The modified Noyes and Whitney equation shows that the aqueous solubility of the drug is the major factor determining its dissolution rate. Actually, some studies show that drug-solubility data could be used as a rough predictor of the possibility of any future problems with bioavailability, a factor that should be taken into consideration in the formulation design.

#### Effect of Particle Size on Dissolution

According to Nernst-Brunner theory, the dissolution rate is directly proportional to the surface area of the drug. Since the surface area increases with the decreasing particle size, higher dissolution rates may be achieved through the reduction of the particle size. This effect has been highlighted by the superior dissolution rate observed after "micronization" of certain sparingly soluble drugs, as opposed to the regularly milled form.

Several investigations have demonstrated an increased absorption rate for griseofulvin after micronization. Similar effects have been reported for chloramphenicol, tetracycline salts, sulfadiazine, and norethisterone acetate. In the case of chloramphenicol, it has been shown that formulations containing smaller particles (50–200  $\mu\text{m}$ ) were absorbed faster than formulations containing larger particles (400–800  $\mu\text{m}$ ). Figure 6-6 presents the effect of particle-size differences on the dissolution rate of phenacetin and phenobarbital.<sup>9</sup>

However, when employing this technique to enhance dissolution, it is important to recognize the fact that it is the

**Figure 6-6.** Effect of particle size on the dissolution rate of drugs from solid dosage forms.<sup>3</sup>**A.** Phenacetin: ○ particle size: 0.11-0.15 mm; △ particle size: 0.15-0.21 mm; ▲ particle size: 0.21-0.30 mm; □ particle size: 0.30-0.50 mm; △ particle size: 0.50-0.71 mm. **B.** Phenobarbital • particle size: 0.07-0.15 mm; △ particle size: 0.15-0.25 mm; • particle size: 0.25-0.42 mm; • particle size: 0.42-0.71 mm.

effective surface area that has to be increased. The effective surface area is the surface area available to the dissolution fluid. If the drug is hydrophobic and the dissolution medium has poor wetting properties, reduction of particle size may lead to decreased effective surface area and, hence, a “slower” rate of dissolution.

Physical properties of the drug particles, other than size, also indirectly affect the effective surface area by modifying the shear rate of the fresh solvent that comes in contact with the solid. These properties include the particle shape and the density.

The mechanism by which the reduction in particle size improves dissolution is usually through the enhancement of the drug solubility. It is assumed that the drug solubility is independent of particle size. However, the drug solubility and the surface area can be correlated by the Ostwald-Freundlich equation:

$$\ln S = \frac{2M\gamma}{\rho RT} \frac{1}{r} = \frac{\alpha}{r} \quad (9)$$

where  $M$  is the molecular weight,  $\rho$  is the density,  $\gamma$  is the interfacial tension or surface free energy of the solid,  $T$  is the temperature,  $R$  is the gas constant, and  $r$  is the radius of the particle.

From this equation,

$$S = S_{\infty} \cdot e^{\alpha/r} \quad (10)$$

The equation shows that the solubility is inversely proportional to particle radius. Therefore,  $S$  could be viewed as the solubility of the microparticles, and  $S_{\infty}$  as the solubility of the macro particles. However, it is obvious that the particle radius has to be reduced to a microlevel, before it can effect a change in solubility.

This extreme reduction in particle size usually cannot be achieved through regular milling or even micronization procedures, and, therefore, other methods have been recommended. One of these involves formation of a solid solution or molecular dispersion, where the molecules of the sparingly soluble drug either are dispersed interstitially in a water-soluble drug or replaced in its crystal lattice.

Another technique, which also produces extremely small particles but still larger than the those produced by solid solution, is by dispersion of the drug into a soluble carrier, such as polyvinylpyrrolidone (PVP) solution. These techniques are employed for the enhancement of dissolution rate of insoluble drugs.

### Effect of Solid Phase Characteristics of the Drug on Dissolution

Amorphicity and crystallinity, the two important solid-phase characteristics of drugs affect their dissolution profile. Numerous studies have demonstrated that the amorphous form of a drug usually exhibits greater solubility and higher dissolution rates, as compared to that exhibited by the crystalline form. For example, it was shown that the amorphous form of novobiocin has a greater solubility and higher dissolution rate than the crystalline form. Blood-level studies confirmed such findings, where administration of the amorphous form yielded about three to four times the concentration, compared to the administration of the crystalline form. Similar differences were demonstrated for griseofulvin, phenobarbital, cortisone acetate, and chloramphenicol. Chloramphenicol palmitate is one example that exists in at least two polymorphs. The B form is apparently more bioavailable. The recommendation might be that manufacturers should use polymorph B for maximum absorption. One contradictory example is that of erythromycin estolate, where the dissolution rate of amorphous form is markedly lower than the crystalline form of erythromycin estolate, as exemplified by Figure 6-7. However, a method of controlling and determining crystal form would be necessary in the quality control process.<sup>10</sup>

**Figure 6-7.** Dissolution performance of erythromycin estolate. (Dotted line, Crystalline form; Solid line, Amorphous form.)

### Effect of Polymorphism on Dissolution

Polymorphic forms of drugs have been shown to influence changes in solubilizing characteristics and, thus, the dissolution rate of the drug in question. Numerous reports have shown that polymorphism and the state of hydration, solvation, and/or complexation markedly influence the dissolution characteristics of the drug. The drugs that exhibit influence on the dissolution behavior include tolbutamide, chloramphenicol, and others.

### FACTORS RELATED TO DRUG PRODUCT FORMULATION

It has been shown that the dissolution rate of a pure drug can be altered significantly when mixed with various excipients during the manufacturing process of solid dosage forms. These excipients are added to satisfy certain pharmaceutical functions, such as diluents (fillers), dyes, binders, granulating agents, disintegrants, and lubricants. Generically identical tablet and capsule products, manufactured by different pharmaceutical manufacturers, were found to exhibit significant differences in dissolution rates for their active ingredients. In certain cases, several studies showed that poor tablet and capsule formulations have been shown to cause a marked decrease in bioavailability and impairment of the clinical response. Such findings, during the 1960s, especially in the case of digoxin and tolbutamide tablets, as well as chloramphenicol and tetracycline HCl (all life-saving drugs), were the triggering factors that compelled the drug-regulatory agencies and compendial authorities to institute the dissolution test as a legal requirement for most solid dosage forms.

### Effect of Granulating Agents and Binders

Solvang and Finholt<sup>11</sup> have shown that Phenobarbital tablets, granulated with gelatin solution, provide faster dissolution rate in gastric fluid than those prepared using sodium carboxymethylcellulose or polyethylene glycol 6000 as a binder. This observation was attributed to the fact that gelatin imparts hydrophilic characteristics to the hydrophobic drug surface, whereas PEG 6000 forms complex with poor solubility, and sodium carboxymethylcellulose is converted to its less soluble acid form at low pH of the gastric fluid (Fig. 6-8). Even gelatin obtained from various processes and origins has been shown to affect the dissolution rate of dosage forms.<sup>12</sup>

Various studies have been reported in the literature, evaluating the effects of various granulating agents and binders on the dissolution rate of tablets.<sup>13</sup>

### Effect of Disintegrants and Diluents

The type and amount of disintegrating agent employed in the formulation significantly controls the overall rate of dissolution of dosage form. Jaminet *et al.*<sup>12</sup> employed several disintegrating agents in manufacturing of Phenobarbital tablets, including Primojel (sodium glycolate of potato starch), Nymcel (polymerized water-soluble brand of sodium carboxymethylcellulose), and Copagel (low viscosity grade of sodium carboxymethylcellulose). The effect on the dissolution rate of tablets by the addition of disintegrants, before and after granulation, was assessed. When added before granulation, Copagel gave tablets with a remarkably slow dissolution rate. However, when added after granulation, Copagel did not result in lowering the dissolution rate. Primojel was not found as effective, particularly on addition after granulation. Levy, in 1963, studied the effect of starch, the most commonly used diluent, on the rate of dissolution of salicylic acid tablets manufactured by the dry, double-compression process (Fig. 6-9).<sup>14</sup> Increasing the starch content from 5% to 20% resulted in a dramatic increase in the dissolution rate, almost three-fold. This was attributed to better and more thorough disintegration. Later, however, Finholt suggested that the hydrophobic drug crystals acquire a surface layer of fine starch particles that imparts a hydrophilic property

**Figure 6-8.** Effect of binders and granulating agents on dissolution rate of tablets.<sup>5</sup> A. to the granular formulation and, thereby, increases the effective surface area and, hence, the dissolution rate (see Fig. 6-9).

### Effects of Lubricants

The nature, quality, and quantity of lubricants added can affect the dissolution rate. The effect of various lubricants on dissolution rate of salicylic acid was studied, and it was concluded that magnesium stearate, a hydrophobic lubricant, tends to retard the dissolution rate of salicylic acid tablets, whereas sodium lauryl sulfate enhances dissolution, due to its hydrophilic character combined with surface activity, which increases the microenvironment pH surrounding the weak acid and increases wetting, and better solvent penetration into the tablets<sup>15</sup> (Fig. 6-10) illustrates the effect of lubricants on the dissolution rate of tablets.

Effect of lubricants on the dissolution rate of drugs from dosage form depends on properties of the granules, the lubricant itself, and the amount of lubricant used. If granules are hydrophilic and fast disintegrating, a water-soluble surface-active lubricant will have an insignificant effect on the dissolution. Conversely, if the granules are hydrophobic, the surface-active lubricant will enhance dissolution. It was also found that hydrophobic lubricants, such as magnesium stearate, aluminum stearate, stearic acid, and talc, decrease the effective drug-solvent interfacial area by changing the surface characteristics of the tablets, which results in reducing its wettability, prolonging its disintegration time, and decreasing the area of the interface between the active ingredient and solvent.

## FACTORS RELATED TO THE DISSOLUTION TEST PARAMETERS

### Method of Granulation

Wet granulation has been shown to improve the dissolution rates of poorly soluble drugs by imparting hydrophilic properties to the surface of the granules. Additionally, the use of

fillers and diluents, such as starch, spray dried lactose, and microcrystalline cellulose, tends to increase the hydrophilicity of the active ingredients and, thus, improve dissolution. Consequently, wet granulation was considered superior to a dry or double-compression procedure. Figure 6-11 shows the effect of different granulation methods on the dissolution rate of tablets.<sup>16</sup>

It must be noted that, with the advent of newer tableting machines and materials, it becomes more evident that the critical formulation and proper mixing sequence and time of

**Figure 6-11.** Effect of manufacturing process on the dissolution rate of tablets.<sup>7</sup> B<sub>1</sub>, Direct compression with spray-dried lactose. B<sub>2</sub>, Wet granulation with ethylcellulose and lactose. B<sub>3</sub>, Acacia mucilage and lactose. B<sub>4</sub>, Starch paste and lactose.

Effect of lubricant on dissolution rate of salicylic acid contained in compressed tablets (formula A). ×, 3% magnesium stearate; •, no lubricant; ○, 3% sodium lauryl sulfate.

adding the several ingredients are the main criteria that affect the dissolution characteristics of the tablets, not the method of granulation.

### Effect of Compression Force on Dissolution Rate

In his early studies of the physics of tablet compression, T Higuchi, in 1953, pointed out the influence of compression force employed in the tableting process on the apparent density, porosity, hardness, disintegration time, and average primary particle size of compressed tablets. There is always a competing relationship between the enhancing effect, due to the increase in surface area, through the crushing effect and the inhibiting effect, due to the increase in particle bonding that causes an increase in density and hardness and, consequently, a decrease in solvent penetrability. The high compression may also inhibit the wettability of the tablet, due to the formation of a firmer and more effective sealing layer by the lubricant under the high pressure and temperature that usually accompanies a strong compressive force (Fig. 6-12).<sup>14</sup> The curve profile of the compressive force of the tablet, versus dissolution rate, can take one of several shapes, as is observed in Figure 6-13.<sup>9</sup>

## FACTORS RELATED TO THE DOSAGE FORM

### Drug Excipient Interaction

These interactions can occur during any unit operation, such as mixing, blending, drying, and/or granulating, resulting in a change in dissolution pattern of the dosage form in question.

The effect of magnesium stearate on the disintegration time of tablets containing either potato starch or sodium starch glycolate was found to depend on the swelling characteristics of the

**Figure 6-12.** Effect of precompression pressure on the dissolution rate of salicylic acid contained in compressed tablets.<sup>4</sup> ○, 715 kg; ×, 1430 kg; ●, 2860 kg; ■, 5730 kg pressure per cm.<sup>2</sup> (Average of five tablets each, formula D.)

**Figure 6-13.** Different types of relations between compressional force of tablets and dissolution rate.

disintegrants. These results were attributed to the formation of lubricant film during mixing, which resulted in an increase in disintegration time and, thus, delayed dissolution.<sup>17</sup>

It is essential that the formulator have a thorough understanding of these interactions, so that the most appropriate excipients can be selected to enable the formulator to perform optimally. By minimizing, if not eliminating, these interactions, adverse effects on the performance of the final product can be avoided. It must also be noted that better process control is also possible with non-interacting drug-excipient interactions.

### Deaggregation

Deaggregation is often a prerequisite for dissolution. In such cases, it can control dissolution. It was reported that two capsule formulations of sodium diphenylhydantoin showed significant deaggregation, dissolution, and thereby absorption rates. The formulation that deaggregated rapidly after the capsule shell was dissolved resulted in exposure of a larger surface area. This resulted in rapid dissolution at neutral pH, but less rapid dissolution when both preparations were exposed to 0.1N hydrochloric acid. Aggregation of other formulation inhibited the conversion of most of its sodium salt to the free acid in acidic medium, whereas such conversion occurred readily with the rapidly disintegrating formulation. As a result, after neutralization of the medium, the latter dissolved and absorbed more readily and rapidly than did the former.

## EFFECT OF TEST PARAMETERS ON THE DISSOLUTION RATE

### Eccentricity of the Stirring Device

USP 34/NF 29 specifies that the stirring shaft must rotate smoothly without significant wobble. Eccentricity can be measured with a machinist's indicator. It is measured in terms of total indicator reading (TIR), which determines the sum of the distance on both sides (180°) of the axis of rotation.

### Guiding the Shaft

One must remember that the shaft of the stirring device extends about 6 in beyond the chuck. An eccentricity of 0.005 in (0.11 mm) at a distance of 1 in (25 mm) from the chuck will be barely perceptible, but, at 6 in, it will amount to 0.30 in (0.75 mm), which is the maximum that can be tolerated.

The shaft mounting should not produce perfect concentricity, but also allow for ease of vertical adjustment. That can best be obtained with a hollow drive shaft and chuck grip on the output with a guide on the other hand. They must be held to close concentricity tolerances with the axis of rotation of the drive tube. The further apart such guides, the better the probability of minimum wobble at the end of the shaft, provided the shaft is straight. The simple trigonometry is illustrated in Figure 6-14.<sup>1</sup>

In the lower left view, the distance from the chuck to the basket is approximately 12 in (15 mm). If no guide bushing is used, any inherent eccentricity in the chuck is multiplied 12 times at the basket, which will certainly produce an eccentricity greatly exceeding the acceptable tolerances for eccentricity at the basket or paddle, if not when new, then after the chuck has been in use. In the lower right view, no guide bushing is used, but the shaft is supported at both ends of the hollow shaft from A to A, and the chuck is brought closer to the flask cover. The inherent eccentricity in the drive (A to A) can be held close at the factory, and the eccentricity of the basket cannot exceed it, if the shaft is straight. In this case, the distance from A to A is about 6 in and matches the distance from the chuck head to the basket, also about 6 in.

Even with a guide bushing, the system shown on the lower left is not recommended, because the chuck may have a twist corrected by the bushing, which might cause a whip in the shaft with attendant vibration. These problems can be minimized by using a resilient grip in the chuck, such as a rubber "O" ring.

**Figure 6-14.** The rotating shaft should be supported at two places (A) to minimize wobble, shown by the two arrangements depicted.

### Vibration

Vibration is a common variable introduced into the dissolution system from myriad causes. It has the effect of changing the flow patterns of the liquid and of introducing unwanted energy to the dynamic system. Both effects may result in significant changes in the dissolution rates. The speeds of the rotational device selected by official compendium are 50 rpm or 100 rpm. Other speeds are specified for certain drugs. Precise speed control is best obtained with a synchronous motor that locks into the line frequency. Such motors are not only more rugged, but are also far more reliable. Periodic variations in rpm that might result in possible disturbance in rotational devices is commonly referred to as torsional vibration. Such vibration indicates a variation in the velocity of rotation for short periods of time, although the average velocity is well within  $\pm 4\%$  of the specified rate.

### Alignment of the Stirring Element

There are two important factors to be considered here. These are as follows:

#### Tilt

USP 34/NF 29 states that the axis of the stirring element shall not deviate more than 0.2 cm from the axis of the dissolution vessel, which defines centering of the stirring shaft to within  $\pm 2$  mm. It also constrains tilt. A series of tests suggest that tilt in excess of 1.5 (degrees) may increase dissolution rates using Method 2 from 2% to 25%,<sup>18</sup> which is still a significant variation. The user should be able to adjust the equipment to obtain alignment of the vertical spindles to within 1 (degree) perpendicularly with the base of the drive to which the flasks are mounted. Such alignment cannot be ensured in the factory. Adjustments for perpendicularity must, therefore, be used to bring the equipment into alignment in its final position.<sup>19</sup>

### Agitation Intensity

The degree of agitation, or the stirring conditions, is one of the most important variables to consider in dissolution. Given the background of various theories of dissolution, it is apparent that agitation conditions can markedly affect diffusion-controlled dissolution, because the thickness of the diffusion layer is inversely proportional to agitation speed. Wurster and Taylor<sup>20</sup> employed the empirical relationship

$$K = a(N)^b \quad (11)$$

where  $N$  is the agitation rate,  $K$  is the reaction (dissolution) rate, and  $a$  and  $b$  are constants. For diffusion-controlled processes,  $b = 1$ . Dissolution that is interfacial-reaction-rate-controlled will be independent of agitation intensity, and, thus,  $b = 0$ .

Agitation intensity within and between various *in vitro* dissolution testing devices can be varied by the dimensions and geometry of the dissolution vessel, volume of dissolution medium, and the degree of agitation or shaking. It is safe to predict that the two dosage forms having particles of differing sizes and densities will not experience identical dissolution system, even though the containers are subjected to the same rate of rotation as oscillation.

### Temperature

Because drug solubility is temperature-dependent, careful temperature control during the dissolution process is very important and should be maintained within  $0.5^\circ$ . Generally, a temperature of  $37^\circ\text{C}$  is always maintained during dissolution determinations. The effect of temperature variations of the dissolution medium depends mainly on the temperature/solubility curves of the drug and excipients in the formulation (Fig. 6-15).<sup>21,22</sup>

**Figure 6-15.** Effect of temperature on dissolution and disintegration rates of tablets.<sup>15,16</sup> A. Dissolution and disintegration curves according to Equations 1 and 2 for position II of the USP basket.  $\Delta$ , dissolution at  $10^\circ$ ;  $\circ$ , dissolution at  $20^\circ$ ;  $\bullet$ , dissolution at  $30^\circ$ ; and,  $\circ$ , disintegration at  $5^\circ$ .<sup>16</sup> B. Dissolution of phenobarbital anhydrate at various temperatures (at 300 rpm).

For a dissolved molecule, the diffusion coefficient,  $D$ , depends on the temperature  $T$ , according to the Stokes equation:

$$D = kT/6\pi\eta r \quad (12)$$

where  $k$  is the Boltzmann constant and  $6\pi\eta r$  is the Stokes force for a spherical molecule ( $\eta$  is the viscosity in cgs or poise units, and  $r$  is the radius of the molecule).

### DISSOLUTION MEDIUM

Selection of suitable fluid for dissolution testing depends largely on the solubility of the drug, as well as mere economics and practical reasons.

#### pH of the Dissolution Medium

Great emphasis and effort was first placed on simulating *in vivo* conditions, especially pH, surface tension, viscosity, and sink condition. Most of the early studies were conducted in 0.1N HCl or buffered solutions with a pH close to that of the gastric juice (pH ~ 1.2). The acidic solution tends to disintegrate the tablets slightly faster than water and, thereby, may enhance the dissolution rate by increasing the effective surface area. However, due to the corroding action of the acid on dissolution equipment, currently, it is a general practice to use distilled water, unless investigative studies show a specific need for the acidic solution to generate meaningful dissolution data. Another approach for avoiding the deleterious effects of hydrochloric acid is to replace it with acidic buffers, such as sodium acid phosphate, to maintain the required low pH.

#### Surface Tension of the Dissolution Medium

Surface tension has been shown to have a significant effect on the dissolution rate of drugs and their release rate from solid dosage forms. Surfactants and wetting agents lower the contact angle and, consequently, improve penetration by the dissolution medium. Measurable enhancement in the dissolution rate of salicylic acid from an inert matrix was reported by Singh and coworkers, when the contact angle,  $\theta$ , was lowered from 92° (water) to 31°, using 0.01% dioctyl sodium sulfosuccinate (Fig. 6-16).<sup>23</sup> The surface tension was also correspondingly lowered from 60 to 31 dynes/cm. Similar findings were obtained in benzocaine studies when polysorbate 80 was used as the surface active agent (see Fig. 6-16).<sup>23</sup>

Other studies conducted on conventional tablet formulations and capsules also showed significant enhancement in the dissolution rate of poorly soluble drugs, when surfactants were added to the dissolution medium, even at a level below the critical micelle concentration, probably by reducing the interfacial tension. Low levels of surfactants were recommended to be included in the dissolution medium, as this seemed to give a better *in vivo* and *in vitro* correlation.

Finholt and Solvang compared the dissolution behavior of phenacetin and phenobarbital tablets in human gastric juice to that in dilute hydrochloric acid with and without various amounts of polysorbate 80 in the dissolution medium. The data showed that both pH and surface tension have significant influence on the dissolution kinetics of the drug studies. For example, they found that not only was the dissolution rate much faster in diluted gastric juice, but that it increased with decreasing particle size, whereas the opposite was the case when 0.1N HCl was used.

#### Viscosity of the Dissolution Medium

In case of diffusion-controlled dissolution processes, it would be expected that the dissolution rate decreases with an increase in viscosity. In the case of interfacial-controlled dissolution processes, however, viscosity should have little effect. The Stokes-Einstein equation describes diffusion coefficient,  $D$ , as a function of viscosity.

Braun and Parrott showed that the dissolution rate of benzoic acid is inversely proportional to the viscosity of the dissolution medium using various concentrations of sucrose and methylcellulose solutions (Fig. 6-17).<sup>24</sup>

**Figure 6-16.** Effect of surfactants on dissolution rate.<sup>17</sup> A. ### MISCELLANEOUS FACTORS

In addition to the factors discussed earlier, there are several other factors that can affect the dissolution characteristics of the drug product.

#### Adsorption

The adsorbent has an influence on the dissolution rate of a slightly soluble solid. It was also reported that the adsorbent is capable of increasing the dissolution rate observed in water under conditions of a decreased concentration gradient applying Nernst-Brunner film theory. Maximum dissolution rate can be obtained when a constant-concentration gradient is maintained. Adsorption isotherms can be employed to calculate the approximate amount of adsorbent required to increase the slower dissolution rate.

#### Sorption

The effect of water sorption on disintegration and dissolution properties, among other physical properties, of tablets containing microcrystalline cellulose was examined. It was concluded that water sorption from the atmosphere into the tablet containing microcrystalline cellulose is a very rapid first-order process, resulting in substantial changes in the physical properties. These changes are attributed to the breaking of the hydrogen bonds. The relative density of the tablets was found to decrease, resulting in increased disintegration time with increase in water sorption-rate constants. These changes were found irreversible.

#### Humidity

In relation to the dissolution rate of a drug substance, humidity is usually associated with storage effects. Moisture has shown

**Figure 6-17.** Effect of viscosity on dissolution rate.<sup>18</sup> A. Relationship of total solubility ( $C_s$ ) of benzoic acid at 25° to dissolution rate and concentration of polysorbate 80. •, rate; ○, concentration. B. Relationship of viscosity to dissolution rate of benzoic acid in aqueous methylcellulose solutions at 25°.

to influence the dissolution rate of many drugs from solid dosage forms. Environmental conditions to which dosage forms are exposed, moisture in particular, should be rigorously assessed, if reproducible and reliable dissolution data are to be obtained. Additionally, humidity during the manufacture of the dosage forms should be carefully controlled to reproduce the quality of the product from batch to batch.

### Detection Errors

Two most common variables leading to inter-laboratory disagreement are the failure to use standards during analysis and external vibration.<sup>25</sup> Extreme care must be exercised when laboratory methods are introduced into quality control to ensure that no part of the equipment interferes with sensitive determinations.

Despite the fundamental relationship between bioavailability and dissolution rate, the present evidence suggests that no single dissolution-rate test can be applied to all drugs. The possibility that a single test may be applied to drugs having similar physicochemical properties remains to be established. These observations are attributable, primarily, to the inability to assess and control the many variables affecting the dissolution process of a drug substance.

### Sources of Variability

#### Compendial Methods

When selecting apparatus for dissolution testing, routine quality control, new drug development, or complying with regulatory

requirements, the analyst must follow the latest issue of compendia, including revisions. The modifications introduced in the dissolution testing methods, during recent years, are so numerous that even revisions two or three years old may be outdated.

**USP/NF Method 1 (Rotating Basket Method)** The USP/NF rotating basket method of dissolution testing essentially consists of a  $25.0 \pm 3.0$  mm diameter  $\times$   $37.0 \pm 3.0$  mm high stainless-steel 40-mesh wire basket, rotated at a constant speed ranging from 25 to 150 rpm. It is immersed in 900 ml of dissolution medium in a vessel of 1000 ml capacity. The medium in the vessel is maintained at a constant temperature of  $37 \pm 0.5^\circ\text{C}$  by means of a suitable water bath. The environment in which the apparatus is placed should not contribute significant motion, agitation, or vibration to the assembly. A fitted cover may be used to retard evaporation. The shaft is positioned so that its axis is not more than 2 mm at any point from the vertical axis of the vessel and rotates smoothly without any significant wobble (Fig. 6-18).

The dosage unit is placed in a dry basket at the beginning of each test. Distance between inside bottom of the vessel and the basket is maintained at  $25 \pm 2$  mm during the test.

In case of non-disintegrating dosage forms, this apparatus is superior to Apparatus 2, since it constrains the dosage form in steady state fluid flow. This method may seem inferior for

**Figure 6-18.** USP Apparatus 1.

testing of dosage forms, which contain gums, due to the clogging of screen matrix. In case of floating dosage forms, this method performs well, but care should be taken that excipients do not clog the basket mesh.

**USP/NF Method 2 (Rotating Paddle Method)**—For all practical purposes, the compendial specifications outlined for this method are identical to method 1, except that the paddle is substituted for the rotating basket.

The metallic or suitably inert, rigid blade and shaft comprise a single entity. The paddle and blade shaft may be coated with suitable inert coating. The dosage form is allowed to sink to the bottom of the vessel before rotation of the blade is started. This apparatus is frequently used for both disintegrating and non-disintegrating dosage form at 50 rpm. Other agitation speeds are acceptable with proper justification.

USP/NF permits variation in the paddle method involving the use of a helix of non-reactive material as a “sinker” for floating dosage forms. Anchoring accomplished by such a device has been severely studied (Fig. 6-19).

In cases of basket and paddle methods, “cone formation” problem has been reported in cases of some of the products. A dosage form containing high amounts of insoluble excipients is expected to form a dense mass at the bottom of the vessel. This cone formation was observed for both poorly and highly soluble drugs, but it has more impact on poorly soluble drugs. The cone formation is less pronounced in cases of basket method, because the dosage is placed in the basket, instead of being dropped at the bottom of vessel, as in paddle method. To eliminate this problem mostly seen in paddle method and,

hence, to improve the reproducibility of the dissolution test, several modifications to the paddle method were suggested and investigated. They are the tilted vessel, the Peak™ vessel with a cone-shape molded into the bottom of the vessel, metal strip, crescent-shaped spindles, mega-paddle, and various propeller shapes. There was discussion regarding use of the peak vessel, because it is not standard equipment. Peak vessel use requires documented justification. It was pointed out that increasing paddle speed often eliminates the cone, but there are limits as to how high the paddle speed can go without losing discriminatory power. Although a comment was made that reducing the amount of excipients in the formulation could reduce or eliminate the cone, it was pointed out that cone formation and dissolution should not be the driving force to modify a formulation. A flow-through cell apparatus was suggested, as an alternative to minimize cone formation.

**USP/NF Method 3 (Reciprocating Cylinder)**—The assembly consists of a set of cylindrical, flat bottomed glass vessels; a set of glass reciprocating cylinders; stainless steel fittings (type 316 or equivalent) and screens that are made of suitable non-sorbing material and non-reactive material designed to fit the top and bottoms of the reciprocating cylinders; and a motor and drive assembly to reciprocate the cylinders vertically inside the vessels and, if desired, index the reciprocating cylinders horizontally to a different row of vessels. The vessels are immersed in suitable water bath of any size that permits holding the temperature at  $37 \pm 0.5^\circ\text{C}$  during the test. The components conform to the specifications, as shown in Figure 6-20, unless otherwise specified in the individual monograph.

One advantage of reciprocating cylinder is that gastrointestinal tract conditions can be easily simulated, as it is easy to make time dependent pH changes. This apparatus is most suitable for non-disintegrating (extended release) or delayed-release (enteric coated) dosage forms.

**USP Apparatus 4 (Flow-Through Cell)**—The assembly consists of a reservoir and a pump for dissolution medium; a flow-through cell; and a water bath that maintains dissolution medium at  $37 \pm 0.5^\circ\text{C}$ . The pump forces the dissolution medium upwards through the flow-through cell. The pump has a delivery range between 240 and 960 ml/hr, with the standard flow rates of 4, 8, and 16 ml/min. It must be volumetric to deliver constant flow independent of flow resistance in the filter device; the flow profile is sinusoidal with a pulsation of  $120 \pm 10$  pulses/min.

The components conform to the specifications, as shown in the Figure 6-21, unless otherwise specified in the monograph.

The advantages of flow through cell apparatus most often cited are the ability to test drugs of very low aqueous solubility in the open loop mode and the ability to change the pH conveniently during the test. The disadvantage associated with it might be the operational difficulties of preparing large volumes of medium for operation in the open loop mode and the added time in the system set up and cleaning.

**USP Apparatus 5 (Paddle Over Disk)**—The Apparatus 2 is used with the addition of a stainless steel disk assembly, designed for holding the transdermal system at the bottom of the vessel. Temperature is maintained at  $32 \pm 0.5^\circ\text{C}$ . A distance of  $25 \pm 2$  mm between the paddle and blade and the surface of the disk assembly is maintained during the test. The vessel may be covered during the test to minimize evaporation. Disk assembly for holding the transdermal system is designed to minimize any “dead” volume between the disk assembly and the bottom of the vessel. Disk assembly holds the system flat and is positioned such that the release surface is parallel with the bottom of the paddle blade. (For more specifications, refer to Fig. 6-22.)

**USP Apparatus 6 (Rotating Cylinder)**—The vessel assembly used is the same as Apparatus 1, except the basket and the shaft is replaced with a stainless steel cylinder stirring element to maintain the temperature at  $32 \pm 0.5^\circ\text{C}$  during the test. The shaft and cylinder components of the stirring element are fabri-

Figure 6-19. USP Apparatus 2.

**Figure 6-20.** USP apparatus 3. (All measurements are expressed in mm unless noted otherwise.)

cated of stainless steel to the specifications, as shown in Figure 6-23. The dosage units are placed on the cylinder at the beginning of each test. The distance between the inside of the vessel and the cylinder is maintained at  $25 \pm 2$  mm during the test.

**USP Apparatus 7 (Reciprocating Cylinder)**—The assembly consists of a set of volumetrically calibrated or tared solution containers made of glass or other suitable inert material; a motor and drive assembly to reciprocate the system vertically and to index the system horizontally to a different row of vessels automatically, if desired; and a set of suitable sample holders. (For details on specifications, refer to the Fig. 6-24.)

## DISSOLUTION OF IMMEDIATE RELEASE SOLID ORAL DOSAGE FORMS

*In vitro* dissolution tests for immediate release solid oral dosage forms, such as tablets and capsules, are used to (1) assess the lot-to-lot quality of a drug product; (2) guide development

of new formulations; and (3) ensure continuing product quality and performance.

For the drug approval process, it is essential to have the current knowledge about solubility, permeability, dissolution, and pharmacokinetics of a drug product. Based on drug solubility and permeability, the following Biopharmaceutical Classification System (BCS) is recommended in the literature:<sup>27</sup>

Class 1: High solubility-High permeability drugs

Class 2: Low solubility-High permeability drugs

Class 3: High solubility-Low permeability drugs

Class 4: Low solubility-Low permeability drugs

This classification can be used as a basis for setting *in vitro* dissolution specifications and *in vivo/in vitro* correlation (IVIVC). The BCS suggests that, for high solubility, high permeability (Class 1) drugs and, in some cases for high solubility, low permeability (Class 3) drugs, 85% dissolution in 0.1N HCl in 15 minutes can ensure that bioavailability is not limited by dissolution. In case of low solubility, high permeability drugs (Class 2), drug dissolution may be the rate-limiting step for drug absorption, and an IVIVC may be expected. A dissolution profile in multiple media is recommended for drug products in this category. In case of high solubility, low permeability drugs (Class 3), permeability is the rate controlling step, and a limited IVIVC may be possible, depending on the relative rates of dissolution and intestinal transit. Drugs in low solubility, low permeability (Class 4) present significant problems for oral drug delivery.

The regulatory acceptance of *in vitro* (dissolution) testing as a reliable surrogate for an *in vivo* bioavailability study is commonly referred to as “biowaiver.” Biowaiver may be granted for BCS Class 1 (high solubility, high permeability) drug products for bioequivalence studies, if the drug product is rapidly dissolving. The drug product is considered rapidly dissolving, if not less than 85% of the labeled amount of the drug substance dissolves within 30 minutes, using US Pharmacopeia (USP) Apparatus I at 100 rpm (or Apparatus II at 50 rpm) in a volume of 900 ml or less in each of the following media: (1) 0.1 N HCl or Simulated Gastric Fluid USP without enzymes; (2) a pH 4.5 buffer; and (3) a pH 6.8 buffer or Simulated Intestinal Fluid USP without enzymes.<sup>28</sup>

## DISSOLUTION OF POWDERS

There is no official method in the USP for dissolution testing of powders. The only application of powder dissolution in the USP is the evaluation of the intrinsic dissolution of powders in general chapter <1087> of the USP 34. However, in this method, the powder is pressed into a tablet, like a disk with a defined surface. The dissolution from the surface is evaluated. Dissolution testing of finely divided particles can be performed using paddle method or flow-through cell method.

## DOSAGE FORMS FOR ORAL CAVITY

Dosage forms for the oral cavity, such as sublingual tablets, buccal tablets, chewing gums, and chewable tablets, are solid dosage forms placed in the mouth, allowing the active ingredient to dissolve in the saliva and then absorb either via the oral route or by the buccal/sublingual mucosa within the mouth.<sup>29,30</sup>

- Chewable tablets: USP has stated the need to use paddle method for chewable tablets, with the exception of ampicillin chewable tablets where basket method is suggested, and for carbamazepine chewable tablets, where both USP apparatus 2 and 3 are suggested. There have been suggestions to use USP apparatus 3, a reciprocating cylinder, along with glass beads, to create a large amount of agitation within the dissolution medium.
- Buccal/Sublingual tablets: In general, the drug release studies from buccal/sublingual tablets has been carried out using USP apparatus 2 (paddle). Modified Franz diffusion cell also has been suggested for these dosage forms.
- Chewing Gums: The USP has not yet created an apparatus

**Figure 6-21.** USP apparatus . **A.** Large cell for tablets and capsules. to test the release of medication from chewing gums. However, the *European Pharmacopoeia* provides a description of a stainless steel 3-piston-apparatus that is required for testing of “medicated chewing gums.” The test is typically operated at  $37^\circ\text{C}$  and at 60 cycles/min. Test media with a pH of 6 are commonly used, since this pH corresponds to reported saliva pH values of 6.4 (adults) or 7.3 (children). However, to date, there has been insufficient international experience with this apparatus to draw a firm conclusion about its suitability.

### DISSOLUTION OF ORALLY DISINTEGRATING TABLETS<sup>31</sup>

Orally disintegrating tablets (ODT) are solid dosage forms that disintegrate in the oral cavity, leaving an easy to swallow residue. ODT have high porosity, low density, and low hardness. The time for disintegration for ODT is considered less than 1 min. Development of dissolution methods for ODT is comparable to the approach taken for conventional tablets, except when the tablets utilize taste masking. Media that can be used are 0.1 N hydrochloric acid, pH 4.5 and 6.8 buffers. The most commonly used apparatus for running dissolution test for ODT is USP Apparatus 2 (paddle method) with a paddle speed of 50 rpm. USP Apparatus 1 is less frequently used, due to the physical properties of these tablets, as the tablet fragments or disintegrated tablet masses may become trapped in the basket, yielding poorly reproducible dissolution profiles. Since dissolution for ODT is very fast, slower speeds are employed. In

**Figure 6-23.** USP apparatus 6. (All measurements are expressed in cm unless otherwise noted.)

**Figure 6-24.** USP apparatus 7.

the case of tablets exceeding 1 gram and containing relatively denser particles, larger mounds may be produced on dissolution, which may be prevented by using higher paddle speeds. These two situations expand the suitable range to 25–75 rpm.

### DISSOLUTION OF TOPICAL DOSAGE FORMS<sup>32</sup>

Drug-release studies from gels, creams, and ointments are becoming an important step, both during the developmental stages of new formulations and as a routine quality control test for assuring the uniformity of the finished product. Also, these studies can often provide useful information on some physicochemical parameters involved in the *in vivo* percutaneous absorption, such as the diffusion coefficient and the solubility of the drug in the specific vehicle used.

Although many investigators have conducted drug release-rate studies from topical dosage forms, it appears that no single apparatus or procedure has emerged as the most favored or accepted as a quasi-standard for others in the field. According to FDA guidelines, the most commonly used method is as follows:

*In vitro* dissolution method for topical dosage forms is based on an open chamber diffusion cell system, such as a Franz cell system, fitted usually with a synthetic membrane. The test product is placed on the upper side of the membrane, in the open donor chamber of the diffusion cell, and a sampling fluid is placed on the other side of the membrane, in a receptor cell. Diffusion of drug from the topical product to and across the membrane is monitored by assay of sequentially collected samples of the receptor fluid.

Aliquots removed from the receptor phase can be analyzed for drug content by high-pressure liquid chromatography (HPLC) or other analytical methodology.

### DISSOLUTION OF SUSPENSIONS

Although most dissolution studies during the last two decades have concentrated on tablets and capsules, some studies have pointed to the importance of the dissolution characteristics of drugs administered in suspension. This is hardly surprising, as suspensions are similar to the disintegrated form of tablets and capsules; if dissolution has become a priority for these formulations, it is logical to extend its concept to suspensions. Indeed, several studies show that the absorption of several poorly soluble drugs administered in suspension formulations are dissolution rate-limited.

Such *in vivo/in vitro* correlation studies have confirmed the importance and the viability of dissolution rate determinations of suspensions, as a discriminative test for rapid screening of new formulations and to control lot-to-lot variability within the same manufacturer and between different commercial manufacturers. In general, most of the dissolution apparatuses described for tablets and capsules could easily be used for suspensions.

The USP Apparatus 2 (paddle method) has frequently been used at a rotation speed between 25 to 50 rpm. However, the rotating filter apparatus by Shah has gained wide acceptance for suspensions, because it provides mild laminar liquid agitation and it functions as an *in situ* non-clogging filter. Sufficient volume of the dissolution medium should be used to maintain sink condition (about 900–1000 mL), and a temperature of 37°C should be maintained.

### DISSOLUTION OF SUPPOSITORIES

Although most of the early work on suppositories has been concerned with their physical characteristics, such as softening and liquefaction ranges, homogeneity, smoothness, and neutrality, several reports appeared in the early literature pointing to the direct correlation between their efficacy and the release characteristics of the active ingredients. It has been reported that fatty bases, such as cocoa butter, tend to release hydrophobic drugs, which are highly soluble in the oily base, very slowly. Emulsification of the fatty base significantly improved the drug-release rate. Incorporation of surface-active agents was found to improve the release rate of water-soluble drugs from the fatty suppository base dramatically.

Although many investigators have conducted extensive research on the release of drugs from suppositories, no single method or apparatus design has emerged as the standard procedure for the pharmaceutical laboratory. Many methods for the determination of the dissolution rate of suppositories are based on the dialysis technique, where the suppository is placed in a dialyzing bag made of special membrane or cellophane material. The bag is placed in a beaker or wide-mouth bottle, containing a known volume of distilled water, and then concentration of the drug outside the bag is measured as a function of time.

A slight variation of the basket method of the USP Dissolution Apparatus 1 is also used frequently. Hanson Research markets a basket apparatus for suppository dissolution testing. Hanson's modified basket uses slots, instead of mesh, to provide a suitable porosity. The use of such a basket avoids the blocking of the mesh opening of the regular USP basket, when oil-based

suppositories are used. The system also has the advantage of being capable of testing suppositories that float or have such low specific gravity that it interferes with the flow dynamics of the paddle method.

### DISINTEGRATION AND DISSOLUTION OF DIETARY SUPPLEMENTS<sup>33</sup>

USP 34/NF 29 contains a section on dietary supplements. One of the specifications appearing in the monographs for some of the supplement dosage forms is Disintegration and Dissolution, 2040. The dissolution procedures for the nutritional supplements use Apparatus 1 and Apparatus 2 and require measurement of one vitamin and folic acid, if applicable, and one mineral, if applicable. Oil-soluble vitamins are exempt from the dissolution requirement.

### DISSOLUTION OF MODIFIED RELEASE DOSAGE FORMS<sup>32</sup>

#### Extended Release

In addition to application/compendial release requirements, multipoint dissolution profiles should be obtained in three other media, for example, in water, 0.1N HCl, and USP buffer media at pH 4.5 and 6.8 for the drug product. Adequate sampling should be performed, for example, at 1, 2, and 4 hours and every 2 hours thereafter, until either 80% of the drug from the drug product is released or an asymptote is reached. A surfactant may be used with appropriate justification.

#### Delayed Release

In addition to application/compendial release requirements, dissolution tests should be performed in 0.1 N HCl for 2 hours (acid stage), followed by testing in USP buffer media, in the range of pH 4.5–7.5 (buffer stage) under standard (application/compendial) test conditions and two additional agitation speeds using the application/ compendial test apparatus (three additional test conditions). If the application/compendial test apparatus is the rotating basket method (Apparatus 1), a rotation speed of 50, 100, and 150 rpm may be used, and, if the application/compendial test apparatus is the rotating paddle method (Apparatus 2), a rotation speed of 50, 75, and 100 rpm may be used. Multipoint dissolution profiles should be obtained during the buffer stage of testing. Adequate sampling should be performed, for example, at 15, 30, 45, 60, and 120 min, following the time from which the dosage form is placed in the buffer, until either 80% of the drug from the drug product is released or an asymptote is reached.

## DISSOLUTION PROFILE COMPARISONS

In the presence of minor changes, single point dissolution tests have been employed in evaluating scale-up and post-approval changes.<sup>34</sup> For major changes, a dissolution profile comparison performed under identical conditions for the product before and after the change is recommended. Dissolution profile comparison may be carried out using the model dependent or model independent methods. One such model independent approach is subsequently explained.

### MODEL INDEPENDENT APPROACH USING A SIMILARITY FACTOR

This approach uses a difference factor ( $f_1$ ) and a similarity factor ( $f_2$ ) to compare the dissolution profiles. The difference factor ( $f_1$ ) calculates the percent (%) difference of the two curves at each time point and is a measurement of the relative error between the two curves:

$$f_1 = \left\{ \left[ \sum_{t=1}^n |R_t - T_t| \right] / \left[ \sum_{t=1}^n R_t \right] \right\} \cdot 100 \quad (13)$$

where  $n$  is the number of time points,  $R_t$  is the dissolution value of the reference batch (pre-change) at time  $t$ , and  $T_t$  is the dissolution value of the test (post-change) batch at time  $t$ .

The similarity factor ( $f_2$ ) is a logarithmic reciprocal square root transformation of the sum of squared error and is a measurement of the similarity in the percent (%) dissolution between the curves:

$$f_2 = 50 \cdot \log \left\{ \left[ 1 + (1/n) \sum_{t=1}^n |R_t - T_t|^2 \right]^{-0.5} \cdot 100 \right\} \quad (14)$$

To calculate the difference and similarity factor, first, the dissolution profile should be done for 12 units each of the pre-change and the post-change products. The difference factor ( $f_1$ ) and similarity ( $f_2$ ) can be calculated using the mean dissolution values from both curves at each time interval. For the curves to be considered similar,  $f_1$  values should be close to 0, and  $f_2$  values should be close to 100. This model independent method is most suitable for dissolution profile comparison, when three or four more dissolution time points are available.

### AUTOMATION IN DISSOLUTION TESTING

Due to the large amount of testing required in determining dissolution rate of drugs, automation of the process seemed almost a necessity, not simply a convenience to the analyst. Also, because of modular nature of the dissolution apparatus, automation can be easily accomplished in different ways and by various techniques.

At present, however, the setup of the apparatus, media preparation, and introduction of the dosage forms are mostly done manually. The rest of the process—including the withdrawal of samples, maintenance of a certain pH or of sink conditions, assay performance, and data acquisition and calculations—is, in most cases, fully automated. The automation process not only saves money, time, and effort on the part of the analyst, but, more significantly, it improves the overall reliability and enhances the reproducibility of testing procedures.

Several commercial companies have also introduced semi- and fully-automated dissolution systems. Some of these are the Hanson Research Dissolution System (Northridge, CA; Dissoette and Dissograph apparatuses), Technicon (Tarrytown, NY; Sasdra apparatus), and Applied Analytical (Wilmington, NC).

Millipore's Waters Chromatography Division has introduced a fully automated dissolution system, using a Waters pump, detector, and autosampler, combined with a Hanson Research's dissolution bath and sample transfer system. Samples are analyzed by HPLC, which provides better specificity than ultraviolet (UV) methods of analysis.

Hewlett-Packard manufactures a fully automated dissolution sampling and UV analysis system that can analyze samples from three dissolution baths. One such system is model 2100 C dissolution test system (Fig. 6-25).<sup>35</sup> The Model 2100C combines enhanced features with advanced communications to ensure reproducibility and control throughout the dissolution testing process. The operations are technician-friendly. Its convenient vessel layout simplifies manual or automatic sampling. It has built-in height adjustment and permanent centering, which reduces operator errors. It also has chuckless spindles to reduce setup time. The precision control of variables provides most accurate and repeatable results. The unique water bath flow characteristics maintain vessel temperature to better than  $\pm 0.1^\circ\text{C}$ . It has versatile SystemLink™ for PC communication and printer output and can be configured for use with both basket and paddles.

### VALIDATION OF DISSOLUTION METHOD

In general, the approach to validation of a dissolution method is similar to that of any other method. The following discussion briefly summarizes the approach to dissolution assay validation.<sup>36</sup>

#### Specificity/Placebo Interference

It is necessary to demonstrate that the results are not unduly affected by placebo constituents, other active drugs, or degradates.

Figure 6-25. Distek dissolution system.

### Linearity, Range, Filter Bias, and Recovery Studies

The linearity of the detection method, range, the filter bias, and the recovery of drug from dissolution fluid containing placebo should be determined. System suitability tests for UV-Vis and chromatographic methods are also identified at this stage.

### Precision and Ruggedness

Precision testing of the dissolution method should be performed on at least two lots of six tablets each on two days. The average of each run, as well as the standard and relative standard deviations, should be computed. Precision of the dissolution method is usually expressed as the standard deviation for a data set obtained on a single day.

### Robustness

The evaluation of robustness, which assesses the effect of making small, deliberate changes to the dissolution conditions, typically, is done later in the development of the drug product. The number of replicates (typically, 3 or 6) is dependent on the intermediate precision.

### Effect of Dissolved Gases

Air dissolved in the media may form bubbles that, in turn, could coat the tablets or other dosage form. This is most likely to happen as the medium is heated to test temperature (37°C). The coating can affect the drug release by altering the dissolution and disintegration or dissolution of the tablet. Accordingly, the effect of deaeration on the dissolution rate should be evaluated, or deaerated medium should be specified in the procedure. Effective methods of deaeration include vacuum filtration, helium sparging, hot water placed under a vacuum with or without sonication, and the use of a commercially available medium dispensing device.<sup>37</sup>

### Automation

Validation for automated systems is the same as for manual sampling. A simple experiment should be done to verify the drug does not adsorb to the apparatus tubing and to quantify system carryover.

## APPLICATION OF QUALITY BY DESIGN (QbD) PRINCIPLES IN DISSOLUTION TESTING

The main purpose of QbD is to understand and control the critical process parameters (CPP) and critical material attributes (CMA) that have significant influence on the target product quality (TPQ). There has been tremendous interest and discussion surrounding the application of quality by design (QbD) principles in dissolution testing. The future goal is to eliminate

dissolution altogether, with the help of scientifically defined and properly executed experiments. For example, if particle size correlates with dissolution during development, then particle size measurement could be used in lieu of the latter. Similarly, granule size could be used as a future surrogate test for particle size distribution, which could then be used to replace dissolution testing.<sup>38</sup>

It is not feasible to test various batches produced during process and product establishment in the clinic. Under QbD, variants would be deliberately made at the extremes of the proposed design space to look for variability, rather than trying to make all batches equivalent. It is recognized that the dissolution test can be used as a surrogate for *in vivo* bioavailability studies. The present bioequivalence guidelines and biopharmaceutical classification system (BCS) provide a platform for application of *in vitro* dissolution, as a surrogate for clinical quality (Fig. 6-26). However, to support using a dissolution test as a surrogate for clinical quality in QbD, a much higher level of understanding, which incorporates a link to clinical quality in regulatory documentation, is required. It is, especially, essential to establish a link between *in vitro* tests and the safety and efficacy (volunteer PK). Once this link has been established, the *in vitro* (dissolution) test can be used as a surrogate of clinical performance, and the clinical performance of all variants from the design space establishment can be evaluated (Fig. 6-27). To use a dissolution test as a surrogate tool in QbD, it is very

		Solubility	
		High	Low

		Solubility	
		High	Low
Permeability	High	<b>Complete dissolution within 30 minutes in most discriminating 'simple' media (physiological pH range). If slower: bioavailability data</b> <b>1</b>	<b>Limit set based on clinical 'bioavailability' data</b> <b>2</b>
	Low	<b>Complete dissolution within 15 minutes in most discriminating 'simple' media (physiological pH range). If slower: bioavailability data</b> <b>3</b>	<b>Limit set on case by case basis</b> <b>4</b>

Figure 6-27. Importance of BCS class of the drug in setting dissolution specifications.

important to have an *in vitro* dissolution test that has best possible relevancy to *in vivo*. In this direction, several important developments have been made in understanding the dissolution medium composition to establish *in vivo* relevancy, so that it may play a role in QbD in the future. However, modeling of intestinal hydrodynamics, *in vivo* drug precipitation/solid state conversions and conditions for dissolution in the more distal parts of the GI tract still need to be effectively addressed to develop *in vivo* relevant dissolution methods to make QbD application in dissolution testing a reality.<sup>39</sup>

### INTRODUCTION

Medical and pharmaceutical research provides a basis for the development of new therapeutic approaches to human and animal disease. This process of drug discovery research can be basic (seeking an understanding of biological phenomena that are unknown) or applied (using principles that are known to produce a desired new product or effect). In either case, drug discovery research results from an unmet clinical need, a recognized deficit in treatment options. Drug discovery is the process by which drugs are discovered or designed. In the past most drugs were discovered either by identification of the active ingredient from traditional remedies or by serendipitous discovery. Today we know how disease and infection are controlled at the molecular and physiological level. Drug discovery involves the identification of candidates, synthesis, characterization, screening, and assays for therapeutic efficacy. Drug discovery is still a lengthy, expensive, difficult, and inefficient process with a low rate of new therapeutic discovery. The outcome of a successful drug discovery program is the generation of a therapeutic entity where none previously existed or the replacement of established therapies in favor of a newer modality that is safer and more efficacious.<sup>1</sup> The main function of the pharmaceutical industry is to create products (i.e., drugs that have an impact on health care). Drug development is the process of bringing a new drug to the market once a lead compound has been identified through drug discovery. Drug development includes preclinical research (microorganisms/animal) and clinical trials (human). Products of this type can be foreseen to some extent through knowledge and study and thus are amenable to planned research and development (R&D). For example, if the cause of a disease has been identified as an infection by a microorganism, a search can be undertaken for an agent that will prevent or cure the infection. However, in some instances, the etiology of a disease is unknown despite intensive investigation. In this situation, the pathway to a satisfactory cure or method of prevention cannot be foreseen or forecast. In such cases, products may only be developed after application of careful investigations, from a revolutionary new approach, or perhaps from a serendipitous finding.

Although much of the drug discovery research in the United States is carried out by major pharmaceutical manufacturers and biotechnology companies, this research is dependent on a vast and growing background of scientific knowledge generated by diverse organizations. Universities, private institutes, governmental laboratories, and industrial research all play significant roles in developing new technologies and knowledge that provides the basis for discovery and the ultimate generation of a new product. This new knowledge may involve development of a new technology, improved scientific methodology and instrumentation, or increased understanding of the basic molecular or cell biology underlying a disease.

The major objective of research in the pharmaceutical industry is to produce safe drugs that prevent, cure, or ameliorate disease. Interim research goals that lead to this major objective are to

- Understand the molecular basis of biological mechanisms in health and disease.
- Develop new biological testing procedures relevant to human and veterinary medicine.
- Develop a quantitative understanding of the interaction of drugs with key biological systems, leading to the more rational design of drugs.
- Understand the absorption, transport, and mode of action of drugs.
- Develop drugs of low toxicity, reproducible delivery, and high specificity for a given pathological state or target organ.

This chapter will touch on the above points to illustrate how drug discovery research is used to develop new products that fulfill clinical needs.

### EVOLUTION OF 21ST-CENTURY PHARMACEUTICAL RESEARCH

The search for medicines to treat disease began with natural products. Up until the early part of the 20th century, pharmaceuticals were mainly derived from natural products, and the practice of gathering and preparing dried herbs was commonplace. A remedy such as menthol was extracted from peppermint and used for treating coughs and colds. Boneset tea reduced fevers, peppermint relieved an aching tooth or a colicky baby, and foxglove could revive a failing heart. Early challenges associated with natural products were the ability to develop and manufacture drugs of uniform strength and quality. Quality often varied with the raw materials or the skills of the pharmacist. Current challenges for natural products relate more to mining natural biodiversity<sup>2</sup> and meeting the synthetic challenges.<sup>3</sup>

Until World War I, most synthetic drugs and chemicals used in the United States were discovered and produced in Europe. When supplies were curtailed by the war, the impetus was provided for the establishment of an independent US chemical and pharmaceutical industry. Accordingly, production of chemicals and drugs was undertaken, which stimulated the development of industrial research. In the following years, the US pharmaceutical industry made major contributions through discovery and development of new drugs, and it assumed a place of leadership in the world.

Toward the mid-20th century, chemical research on the isolation, identification, and synthesis of drugs began to yield many important drug substances. During this time the synthesis and

manufacturing of vitamins was a major focus of companies such as Roche and Merck. Among the major drugs discovered and/or developed in the United States during this period were insulin, sulfonamides, penicillin and broad-spectrum antibiotics, cortisone and other steroid compounds, isoniazid, diuretics, and tranquilizers (now commonly referred to as anxiolytics or antipsychotics). Discovery and development of the sulfonamides, antibiotics, and other anti-infective agents dramatically reduced the death rates from a number of infectious diseases. Use of drugs like isoniazid led to a decline in the United States tuberculosis death rate between 1945 and 1984 from 39 per 100,000 people to 0.7 per 100,000 people. Since a large proportion of the deaths from these diseases had occurred prior to adulthood, these drugs allowed more individuals than ever before to mature and assume productive roles in society.

Since the early 1980s, new classes of drugs that treat hypertension and dyslipidemias have emerged and made inroads in reducing morbidity and mortality from cardiovascular disease. These are now some of the world's most efficacious, safe, and profitable drugs. According to a 2010 update by the American Heart Association (AHA), the death rate for cardiovascular disease fell 28 percent between 1997 and 2007.<sup>4</sup> Cancer medicines are moving from cytotoxic agents to cytostatic agents, but there is still much work to be done in this complex area of cell signaling and rampant proliferation. New challenges have emerged in areas of dementia, given our expanded lifespan and increased awareness.

In its broadest definition, biotechnology refers to the use of living organisms, such as cells, tissues, or biological molecules such as enzymes or antibodies in the production of products having beneficial use. Biological products include a wide range of agents such as vaccines, blood and blood components, allergenics, somatic cells, gene therapy, tissues, and recombinant therapeutic proteins. In contrast to most drugs that are chemically synthesized and whose structure is known, most biologics are complex mixtures that are not easily identified or characterized. A recent survey found that America's biopharmaceutical research companies have in development 900 biotechnology medicines and vaccines, targeting more than 100 diseases. These include 352 medicines for cancer, 188 for infectious diseases, 69 for autoimmune diseases, and 39 for AIDS/HIV and related conditions.<sup>5</sup> Many already approved biotechnology medicines treat or help prevent heart attacks, strokes, hepatitis, heart failure, kidney cancer, cystic fibrosis, diabetes, and various types of leukemia.

Of increasing importance as lifespan improves and the world population grows are the classes of drugs that have marked effects on quality of life without significantly affecting longevity. Beginning in the early 1990s, a new term appeared in the evolution of pharmaceuticals. The term *lifestyle drugs* appeared when insurance companies were faced with the decision of paying for products that might improve one's life, function, or appearance, as opposed to a drug one might take to manage an illness or cure a disease.<sup>6,7</sup> The question was, do insurance companies pay for treatments or happiness? Looking back in time, many consider alcohol to be one of the oldest and most widely used of the lifestyle drugs. Its use can be considered an attempt to increase happiness through pharmacological activity. A turning point in the era of modern lifestyle drugs was the launch of sildenafil citrate (Viagra) in 1998 as a drug of choice for erectile dysfunction.

There are as many different definitions of "lifestyle drugs" as there are people involved in the discussion. It is very difficult to define absolutely. An operational definition of "lifestyle drugs" that has gained some traction is as follows: drugs that could modify or change non-medical or non-health-related goals or conditions at the margins of health and well-being.<sup>8</sup>

The term "lifestyle drugs" generally encompasses pharmaceuticals that do the following:<sup>6</sup>

- Treat conditions resulting from personal responsibility or behavior choices
- Aid in smoking cessation (e.g., bupropion)

- Enhance life or performance
- Treat erectile dysfunction (e.g., sildenafil citrate)
- Treat problems falling outside the medical or social definition of health
- Address male-pattern baldness (e.g., finasteride)
- Straddle medical, social, and environmental domains
- Treat social anxiety disorder (e.g., selective serotonin reuptake inhibitors (SSRIs))

An increasing number of lifestyle drugs can be expected to reach the marketplace in the near future. The debate over who will pay for them will intensify. A looming question for all society is whether pharmaceutical research dollars will be diverted from seeking those medications to treat or mitigate disease to drugs that are designed to increase happiness, pleasure, and a personal sense of well-being. All elements of society—government, industry, health care professionals, patients, and consumers—should participate in these discussions.<sup>9</sup>

The applications of nanotechnology and pharmacogenomics are among the newest evolutions in pharmaceutical research and could have far-reaching and paradigm-shifting implications for drug discovery. Nanotechnology came into its own in 2000 with the birth of the National Nanotechnology Institute. To date more than \$14 billion has been invested by the US government in nanotechnology. Nanotechnology is a science that involves the design and building of structures and devices smaller than 100 nanometers. It is currently being applied to all stages of drug development, from formulation chemistry for targeted drug delivery to diagnostic applications. Nanotechnology is capable of improving drug research and development by providing researchers more information about drugs and targets, allowing high content screening, decreasing volumes of expensive reagents, and enhancing solubility and selective tissue targeting. The largest share of opportunities is emerging in pharmaceutical applications, and this is expected to reach \$18 billion in 2014.<sup>10</sup> The US National Science Foundation predicts that nanotechnology will produce half of the pharmaceutical industry product line by 2015.<sup>11</sup>

The old adage of the right drug for the right patient was traditionally based on the trial and error method of matching patients with the appropriate treatment protocol. In the evolving scientific principle of pharmacogenomics, health care providers will prospectively analyze a patient's genetic profile and prescribe the best available drug therapy, based on biomarkers that will predict drug response or drug toxicity.

Sometimes referred to as "personalized medicine," pharmacogenomics is the fusing of classical pharmacology with human genetics, using a patient's genotype to optimize drug therapy and minimize toxicity.

Anticipated benefits of this new discipline include the following:<sup>12</sup>

- Pharmaceutical companies will produce entities with a high specificity to defined conditions, based on the proteins, enzymes, and RNA molecules associated with genes and diseases.
- Accurate determination of appropriated drug dosages will replace basing dosages on weight and age. Dosages based on a patient's genetics will maximize the therapy's value and, in all likelihood, will decrease the risk of overdosing.
- Knowledge of an individual's genetic code will allow the person to make lifestyle and environmental changes to avoid or lessen the severity of a genetic disease. This will also allow for careful monitoring and treatments that can be started at the optimal time to maximize patient benefit.
- Drug therapy, from the first dose, will be safer, speeding recovery time. It is likely that pharmacogenomics may reduce the estimated 100,000 deaths and 2 million hospitalizations that occur each year in the United States as the result of adverse drug response.<sup>13</sup>
- Vaccines, made of DNA or RNA, will activate the immune system but will be unable to cause infections.

Pharmacogenomics presents barriers which must be overcome before full benefits can be realized. All healthcare providers will need to gain or develop a deeper understanding of genetics in order to correctly interpret the genetic testing results and their applicability to the patient. The process adds an extra diagnostic step before providers can determine which drug will provide the most appropriate treatment option.

One latest example of personalized medicine is a genetic test that will help the practitioner predict which patient with acute coronary syndrome (ACS) requires a higher dose of clopidogrel. A study published in the *Journal of the American Medical Association* concluded that “among patients with stable cardiovascular disease, tripling the maintenance dose of clopidogrel to 225 mg daily in CYP2C19\*2 heterozygotes achieved levels of platelet reactivity similar to that seen with the standard 75-mg dose in noncarriers; in contrast, for CYP2C19\*2 homozygotes, doses as high as 300 mg daily did not result in comparable degrees of platelet inhibition.”<sup>14</sup> This finding is but an example of the future that will allow practitioners to treat patients appropriately from the first dose, instead of by trial and error, thus potentially preventing a dangerous and costly negative outcome.

In June 2010 the FDA listed 6 medications for which diagnostic genetic testing was required prior to prescribing. Today there are approximately 30 drugs for which the FDA recommends diagnostics testing and more than 200 medications that contain pharmacogenomics data within the drug’s labeling.

## PHARMACEUTICAL RESEARCH ORGANIZATIONS

The pharmaceutical and biotechnology industries are leaders among all US industries with respect to support of R&D. The industry finances almost its entire R&D with its own funds; no other industry spends as high a percentage of R&D funds for basic and applied research. A significant portion of every sales dollar is devoted to drug research activities (Table 7-1). For instance, in 2010 US pharmaceutical companies devoted 20.5 percent of their sales revenues to R&D.<sup>15</sup> In 2010 the average R&D spending for the top 20 pharma companies was US \$4.4 billion, or 18.2 percent of sales.<sup>16</sup> This expenditure in part underlies the cost of prescription drugs because only 2 of 10 marketed drugs return revenues that match or exceed R&D costs.<sup>15</sup>

Technological advances have led to an explosion of small biotechnology companies that specialize in one or more steps in the preclinical and clinical processes. Often large pharmaceutical companies contract to the smaller outside companies as a way of extending their internal resources, to mitigate capacity fluctuations and to decrease costs. The trend among large

pharmaceutical companies toward outsourcing has led to the growth of many contract research organizations (CROs) that are contracted to produce biopharmaceuticals.<sup>16</sup> Additionally, there is a movement by large pharmaceutical companies to outsource the production of early-phase clinical study drugs to compounding pharmacies. This trend is being driven in part by economics and in part by drug shortages that are affecting patient care worldwide.

The academic community plays a vital role in the development of new drugs. Its role includes, but is not limited to, research on a basic understanding of disease states, development of biochemical or physiological rationales for drug targets, the initial evaluation of new drugs, consultantships with companies to use their academic and scientific expertise to guide pharmaceutical research, and, certainly not least, the training of scientists. During the late 1980s and early 1990s, scientists at universities made many basic advances toward identification of enabling technologies, which led to the founding of many biotechnology companies that continue to flourish today. Over time, platform technologies were used to enable the biotechnology-focused<sup>17</sup> company to become a product-focused company, the true endpoint of pharmaceutical research. Examples of platform technology to product conversion are the following: (1) Ligand Pharmaceuticals, founded by Dr. Ron Evans of the Salk Institute, was based on the discovery of novel intracellular receptors and their role in gene transcription, focusing on the identification of agonists and antagonists, primarily of steroid hormone receptors. Ligand and its sister company X-Ceptor continue today to work on these important drug target families. Ligand markets ONTAK, Targretin capsules, Targretin gel, and Panretin gel. Ligand’s newer product, AVINZA, is a treatment for chronic, moderate-to-severe pain. In addition, Ligand’s pharmaceutical partners develop products for men’s and women’s hormone-related diseases, osteoporosis, metabolic disorders, and cardiovascular and inflammatory diseases. (2) Vertex was founded by Dr. Joshua Boeger, using the structure-based design that relies on the high-resolution molecular imaging of the active site of a disease molecule. Vertex has had several major pharmaceutical relationships, including GlaxoSmithKline, for the development and marketing of Agenerase (amprenavir) for HIV, and Kissei for p38 MAP Kinase inhibitors for use in inflammatory disease. (3) In contrast to the target-family focus brought by Ligand and X-Ceptor or the structure-based design brought by Vertex, PharmacoPeia, a combinatorial chemistry company founded by Drs. Michael Wigler and Clark Still, employs chemical and biological diversity and high-throughput screening approaches to lead drug discovery. PharmacoPeia has a drug pipeline based on its collaborations with key pharmaceutical partners, such as Schering-Plough, Bristol-Myers Squibb, Celgene, and Cephalon. Thus, partnerships between academia and biotechnology, as well as between biotechnology and large pharma, have propelled both the genesis and evolution of biotechnology. It is likely that change will continue to occur at a faster pace in the smaller and more opportunistic biotechnology areas than within large pharma partners.

Clinicians and clinical scientists often lead the discovery of new uses for drugs and new directions for research based on observations made in the clinical setting. Chlorpromazine was originally synthesized as an antihistamine but was found to be useful as an antipsychotic. The clinical use of this compound, and of other central nervous system drugs, has resulted in a marked reduction in the number of mentally ill patients needing hospitalization.

Research in the academic community has been supported to a major extent by agencies of the US government, such as the Public Health Service (PHS), the National Institutes of Health (NIH), the Centers for Disease Control and Prevention (CDC), and the National Science Foundation (NSF). The pharmaceutical industry also contributes financial support to academic laboratories where research of general or specific interest to the industry is conducted. Institutes established by private

**Table 7-1. Leading Pharmaceutical Companies Ranked by R&D Spending (US\$ in Billions) in 2010**

Company	R&D Spending	Pharma Sales	R&D as % of Sales
Merck	11	39.8	27.6
Pfizer	9.4	58.5	16.0
Roche	8.6	39.1	22.0
Novartis	7.1	42.0	16.9
GlaxoSmithKline	6.1	36.2	16.9
Sanofi-Aventis	5.1	40.3	12.7
Eli Lilly	4.9	21.1	23.2
Johnson & Johnson	4.4	22.4	19.6
AstraZeneca	4.2	33.3	12.6
Abbott	3.7	19.9	18.6

From Cacciotti J, Clinton P. The Lull between two Storms, *Pharmaceutical Executive*, May 2011. [www.oliverwyman.com/media/2011\\_PharmExec\\_50.pdf](http://www.oliverwyman.com/media/2011_PharmExec_50.pdf); accessed 20 April 2012.

endowment such as the Sloan-Kettering Institute, Shriners Children's Hospitals, the Institute for the Study of Aging, and the Gates Foundation all pursue basic and applied research in many fields related to the public health. Many hospitals also maintain research clinics and/or privately or publicly endowed foundations to pursue causes and treatment of specific diseases, a related group of diseases, diseases endemic to a certain geographical area, or groups of diseases affecting a certain organ of the body. Because research does not depend on the vending of items or services, it is not immediately self-supportive and must be supported by public as well as private funds.

Interest in pharmacoepidemiological research has prompted the development and need for review criteria in this area. *The Hartzema Guide*<sup>18</sup> makes use of case-controlled and cohort studies as major methodologies in this field. Generally, the evaluation criteria for case-controlled and cohort studies address proper sample-frame definition, compatibility of cases and controls, drug-exposure validations, unintended-effect ascertainment procedures, and related considerations. Although these can be confusing, Hartzema provides interpretation of the statistics used in reporting case-controlled and cohort studies and gives review criteria for meta-analysis, an approach to integrating the pharmacoepidemiological literature.

## THE SEARCH FOR NEW DRUGS

Until the early 20th century, most useful drugs, such as morphine, quinine, digitalis, ergot, and atropine, to name a few, were derived from plant sources, and their therapeutic uses were based on serendipitous discoveries. As the science of medicinal chemistry has evolved, screening of natural products has become more methodical. Screening of natural products is based on the concept that evolution favors molecular conservation. However, the future of natural product screening for drug discovery is currently limited by speed and compound diversity.

In the mid-20th century, useful drugs were derived from natural products, chemical syntheses, or combinations of both sources. The approaches used to identify lead molecules that evolved to drugs covered the spectrum from molecular diversity to rational design. Molecular diversity is the differences in physical properties that exist among different molecules. These properties can be expressed as differences in shape or size, polarity and charge, lipophilicity, polarizability, or flexibility.<sup>19</sup>

The application of molecular diversity techniques to drug discovery is a multidisciplinary effort requiring the skills of people of varied backgrounds, ranging from computational chemistry to engineering to organic synthesis to molecular biology.<sup>20</sup>

Rational, or structure-based, drug design refers to a process that begins with a high-resolution map to the active site of a disease target. With an x-ray crystal structure or a nuclear magnetic resonance image, medicinal and protein chemists can engineer molecules to fit, or better fit, the active site. This approach is appealing, has been applied by biotechnology companies in a more high-throughput fashion, and has been successful in the field of HIV protease inhibitors and chemotherapy protein-tyrosine kinases inhibitors.

Structure-based design is not currently applicable to all classes of drug targets, however. Guanine nucleotide-coupled receptors (GPCRs), which have proven to be one of the most feasible classes of drug targets, intertwine between the extra- and intracellular surface seven times. Because of their architecture in the lipid bilayer of the cell membrane, the structure of these "heptahelical receptors" has not been solved. However, using processes described below, many successful drugs have been found that work through GPCRs.

The advent of combinatorial chemistry in the 1980s and 1990s greatly impacted drug discovery. This technology refers to the generation of compounds in sets, or libraries, that are typically chemically related and made by combining sets of reactions, such that the chemical steps are efficiently conducted. Combinatorial chemistry was initially applied to amino acids

and nucleotides by Affymax and NeXagen, respectively. Since then, several companies, predominantly Pharmacoepia and Arqule, have applied this technology to small molecules. Having large numbers of compounds allows for increases in subtle alterations in chemical relatedness as well as chemical diversity. This point is critical since the biological target is the true measure of a successful chemical interaction and use of descriptors to capture chemical diversity does not discriminate in the relevant ways that biology does. This point was well made by Jurgen Drewes<sup>21</sup> when he wrote, "It is, however, by no means certain to what extent molecular diversity, as viewed by chemists and as calculated by structural descriptors, resembles diversity as 'seen' by a biological target molecule."

Collections of compounds can be designed to be "drug-like" in that they have favorable physicochemical properties in common with known drugs. These properties were first elucidated by Dr. Chris Lipinski of Pfizer and have become known as the "Lipinski Rule of Five." Based on his analysis of drugs developed predominantly at Pfizer, Dr. Lipinski described key traits necessary for a molecule to have suitability as a drug.<sup>22</sup> These traits are less than 5 hydrogen-bonds, less than 10 hydrogen-bond acceptors, an octanol-water partition coefficient less than 5, and a molecular weight less than 500. It is important to note, however, that approximately 25 percent of the drugs in the Comprehensive Medical Chemistry (CMC) database do not follow the "Rule of Five." Typically, these exceptions are antibacterials, antineoplastics, or CNS drugs. The large percentage of exceptions would advise against overly strict adherence to these guidelines as rules. Indeed, it is rare to identify a drug in a high-throughput screen (HTS) and best to think of compound collections as sources of leads that can be optimized to drugs by medicinal chemists, biologists, and pharmacologists.

The testing of compound collections in HTSs is another area where key advancement has occurred in the pharmaceutical industry in the last 25 years. HTS allows scientists to devise biochemical assays around a molecular target using new technologies. With more sensitive high-throughput technologies focused on identification of activity at a precise molecular target, the likelihood that a compound will be identified in a high-throughput screen increases. One of the primary impacts of combinatorial chemistry and its HTS counterpart has been more efficient identification of leads from chemical libraries. However, despite its promise and efficiency, over the past 15 years, technology and HTS have not met the expectations of the pharmaceutical industry in producing significantly higher numbers of lead compounds that resulted in new chemical entities or new drug products.

## CHEMICAL LIBRARIES AND SAMPLE COLLECTIONS

Prior to the advent of combinatorial chemistry, organic chemists in the pharmaceutical industry synthesized new compounds one at a time. The collection of these compounds was not particularly diverse but led to hundreds of thousands of compounds in a company's sample collection. Combinatorial chemistry has greatly increased the efficiency of compound synthesis, leading to significantly larger compound collections. The explosion in synthesis of chemical libraries necessitated more efficient testing of biological activity.

Initial screening of thousands of compounds is accomplished rapidly by the use of *in vitro* enzymatic or receptor screens. Typically, several unique active lead compounds emerge, which are studied in a variety of secondary assays, either confirming or refuting the original hypothesis.

The small molecular weight of compounds in a chemical library favors the chance of their oral availability. The Lipinski guideline recommends that compounds be about 500 daltons to optimize oral absorption across the gastrointestinal tract.<sup>22</sup> Other guidelines include recommendations for polar surface area and hydrophobicity measures.<sup>23</sup> Orally available drugs are highly desirable; thus, small molecule drug discovery remains the focus of pharmaceuticals over their biological counterparts.

Whether a molecular diversity or rational design approach was followed to identify the lead molecule, drug discovery tends to proceed thereafter through an iterative process of chemical modification and biological testing. Teams of scientists improve the characteristics of their lead compound in an optimization process. If successful in building the appropriate characteristics, this process results in a drug candidate.

## NATURAL PRODUCT SOURCES

In addition to compound collections, organic chemists and biochemists derive leads from natural product sources. Natural products can be derived from plant and animal sources; in the latter category microbial and marine organisms often are considered separately from ordinary domestic animals. Digitalis glycosides, such as digitalis and digoxin, derive from the foxglove plant and are powerful cardiac stimulants. The poppy plant has provided opium alkaloids (morphine, codeine) used in analgesia; and the belladonna plant provides the belladonna alkaloids (atropine and scopolamine) used as parasympathetic blockers. In addition to the plant alkaloids mentioned earlier, some important natural products include antibiotics, steroid and peptide hormones, vitamins, enzymes, prostaglandins, and pheromones.

Although serendipity plays a relatively large role in the search for natural products, rational biological inputs based on deficiency syndromes, replacement therapy, or known biological effects clearly influence the development of these drugs. Nutritionists, endocrinologists, pharmacologists, microbiologists, biochemists, and physiologists all play a vital role in understanding the underlying biological mechanisms. Antibiotics, steroids, and prostaglandins provided fertile new fields for chemical modification, leading, in all three cases, to drugs that are more useful than the parent compounds. Much research is being undertaken by the NIH and private companies on unique natural products that have anticancer properties. For example, Taxol (paclitaxel), derived from the bark of a Pacific yew tree (*Taxus brevifolia*), was developed for the treatment of ovarian cancer by Bristol-Myers Squibb. As mentioned earlier, current challenges for natural products research relate to mining natural biodiversity<sup>2</sup> and meeting the synthetic challenges.<sup>3</sup>

## FUNCTIONS OF RESEARCH SCIENTISTS

The pharmaceutical industry is an outstanding example of successful collaboration between scientists of biological and physical science disciplines. Chemists and other physical scientists predominantly have been responsible for synthesis, isolation, and characterization of medicinal agents. However, biological scientists have played an equally essential role in originating meaningful screening and testing models and in the overall evaluation of new agents. Qualified specialists in many fields, including pharmacy, physics, statistics, chemistry, biology, engineering, pharmacology, physiology, medicine, and many others, take part in the tremendous research effort in pharmaceuticals. Cooperation is a major feature of today's scientific investigations. Multidisciplinary teams are essential in industrial research requiring collaboration and effective communication; frequently a hundred or more scientists may be involved in discovering and developing a compound into a useful drug.

Some industrial research laboratories are organized according to scientific disciplines, such as departments of organic chemistry or pharmacology. Other companies may use a project-team style, wherein chemists, biologists, and pharmacologists are organized into a project unit for the purpose of discovering drugs useful for a particular disease state. Frequently the latter organizational approach is focused on therapeutic areas, such as diseases of the cardiovascular, immunological, or central nervous systems. Irrespective of the organizational style, problems in drug discovery and development have become so complex that a multidisciplinary approach to research nearly always is

used. For the sake of simplicity, this section will outline the functions of scientists with particular backgrounds who play leading roles in pharmaceutical research; however, the reader should understand that drug development is a cooperative venture among all scientists.

## ORGANIC CHEMISTRY

As noted previously, organic chemists synthesize new drug candidates as well as isolate and characterize natural products, such as alkaloids. In each case, there is interest in the complex relationships between chemical structure and pharmacological action. These structure-activity-relationships (SARs) are fundamental to drug discovery. Once synthesized, compounds are evaluated for numerous types of biological and pharmacological action. Observation of interesting and repeatable biological activity opens pathways for additional chemical research effort in the expansion of the series and often leads to significant new medicinal products. Determination of the pharmacological activity of a compound is an involved process, with very small changes in structure frequently yielding profound changes in the pharmacological effect. Many of the currently used anti-spasmodics, anticonvulsants, local anesthetics, nonnarcotic analgesics, chemotherapeutic agents, and hypnotics have been products of this approach.

Another research approach is to identify, isolate, and purify compounds from biologically active mixtures. The determination of the structure of a biologically active molecule provides a twofold benefit to pharmacy and medicine. It makes possible research leading to synthesis and modification of the structure. Changes in structure usually are accompanied with changes in biological activity, and occasionally vast improvement is accomplished. For example, our current knowledge of adrenal corticosteroids began with the study of the various components in an extract of the adrenal cortex. The components were characterized structurally, and biological activities were assessed. Eventually, cortisone was synthesized from bile acids. Today, some synthetic analogs of cortisone are available that are superior therapeutically to the naturally occurring steroids.

A second example of slight chemical changes leading to improved biologic activity comes from the tetracyclines, a clinically important group of antibiotics. The first of these, 7-chlorotetra-cycline, was isolated in 1948 from *Streptomyces aureofaciens*. Shortly thereafter, a group of scientists isolated 5-hydroxyte-tracycline from *Streptomyces rimosus*, and in 1953 its structure was established. Once the chemical structure of this antibiotic was known, the way was opened for systematic variation of the basic nucleus to obtain new drugs with improved properties. Specifically, the catalytic removal of chlorine from 7-chlorote-tracycline gave tetracycline itself, which proved to be superior to either of the above-mentioned antibiotics, and has replaced them to a large extent. Although tetracycline initially had been isolated from a *Streptomyces* species, this useful antibiotic is prepared more readily by semisynthetic methods.

Studies on the structure and synthesis of penicillins led to the development of the semisynthetic penicillins and, later, to cephalosporins and monobactams. These new compounds have made possible major improvements in antibiotic therapy. Total synthesis is made possible by knowledge of chemical structures and, in many instances, is important economically in reducing the cost of the drug. Chloramphenicol, which can be obtained from cultures of *Streptomyces venezuelae*, combats bacteria-produced typhoid dysentery and Rocky Mountain spotted fever. A commercially feasible chemical synthesis has replaced the fermentation process for production of the antibiotic.

## MICROBIOLOGY

Since the discovery and development of penicillin during World War II, the search for new antibiotics among the metabolic products of microorganisms has constituted a major research effort in the pharmaceutical industry. The proven clinical

usefulness of antibiotics in treating many bacterial infections has fully justified this effort. Microbiologists have searched among a wide variety of fungi and bacteria, looking for antibiotic substances. In this search, microorganisms from plant tissues, animal sources, the sea, many types of soil, and many other ecological niches have been examined. There are more than 16,500 antibiotics produced by microorganisms that have been reported in the scientific literature, approximately 90 percent of which have been characterized and have had molecular structures assigned.<sup>24,25</sup> More than 1000 antibiotic substances have been detected and at least partially characterized. A combination of microbiological and chemical methods is required to distinguish the new antibiotics from the host of older ones that have already been discovered.

After a culture has been found to produce a new antibiotic, microbiologists then turn their attention to the biosynthesis of the compound, seeking to improve yields in order to produce quantities of the compound for testing and evaluation. An effort also is made to understand biosynthetic pathways, improve yields further, and facilitate the biosynthetic production of the isotope-labeled antibiotic for pharmacological and toxicological evaluation.

New antibiotics are being evaluated for application in an increasing number of disease conditions. Tests are conducted to determine activity of new antibiotics against a variety of yeasts, molds, and protozoa, as well as against normal and antibiotic-resistant bacterial pathogens. The antibacterial drugs have contributed to major advances in the control of bacterial and other microbial diseases. However, impetus for continued research is provided by problems of drug resistance, patient sensitivity, and the inability to control certain infections.

Microbiologists are concerned not only with the microorganisms that produce antibiotics but also with the microbial pathogens that the antibiotics are expected to control. The mode of transmission of disease and the pathogenicity, virulence, and invasiveness of the infectious microorganisms are under investigation. A serious problem in drug resistance involves the transfer of drug resistance among gram-negative bacteria by means of an episome bearing one or more antibiotic resistance factors. Agents that prevent the emergence of the resistance factor, or that prevent its transfer, have been sought. Current research is being directed toward agents that enhance host resistance.

Integration of microbiological research and organic chemical research resulted in the production of a series of semisynthetic penicillins and cephalosporins. These antibiotics are chemically modified derivatives of biosynthetically produced antibiotics, which possess improved spectra of action or other advantageous chemical and biological properties.

## BIOCHEMISTRY, CELL BIOLOGY, AND MOLECULAR BIOLOGY

Pharmaceutical research in biochemistry, cell biology, and molecular biology has exploded in the past 25 years. These areas include investigations of specific mechanisms of action for biologically active compounds. Biochemistry and cell biology are focused on understanding the underlying biochemical and cellular processes that are involved in the wonderfully complex mechanism of living things: the signal transduction processes, the energy-yielding systems, and the synthetic systems for generation of proteins, nucleic acids, and other macromolecules. Normal cellular communication and metabolic patterns are determined, and efforts are made to define the abnormal conditions that occur in various disease states. Biochemists also are involved in the isolation, purification, and characterization of small and large biologically active molecules.

The increasing sophistication of research demands that an understanding of the molecular bases of diseases emerge as a primary goal. This knowledge has strongly influenced both the methodology of testing new drugs and the choice or design of compounds to be tested. Biological targets (i.e., the molecular locations where drugs act) are identified, isolated, and

characterized. Usually this involves the cloning and expression of the target proteins from human tissue as well as from various other species that may serve as model systems in drug testing. Some of the receptor systems for which drugs have been developed include those for catecholamines, opiates, steroids, and various peptide hormones such as bradykinin, angiotensin II, and endothelin. The discovery of the enkephalins, natural brain polypeptides that bind the opiate receptor, has opened new horizons in CNS pharmacology. This information has been useful in acquiring new knowledge of the interaction between drugs and their receptor sites and in understanding the requirements for specific spatial orientation of essential structural features of drugs. Drug design also makes provision for those characteristics that will assure absorption, transport to the receptor site, and elimination of the therapeutic agent.

Biochemists and cell biologists develop the biomedical rationale to guide medicinal chemists in the design of drugs that are more selective for specific aspects of disease. For example, knowledge of the structure and biochemical function of coenzymes stimulated chemists to synthesize a large number of analogs of coenzymes, some of which have proven to be useful compounds in the chemotherapy of cancer; methotrexate is an example of such a compound.

Increasing emphasis is being placed on studies of enzymatic processes, such as those related to the biosynthesis of cholesterol, fatty acids, and triglycerides; regulation and control of protein and nucleic acid synthesis; absorption processes; and biochemical mechanisms in central nervous processes and ischemia. The significance of elevated blood levels of cholesterol and certain other lipids in atherosclerosis has focused attention on drugs affecting cholesterol biosynthesis. Several of these drugs, such as Livalo, Lipitor, Crestor, Zocor, Pravachol, and Mevacor, are now available. These drugs have had a dramatic impact in reducing serum cholesterol, and more cholesterol-reducing drugs may be expected.

Acute problems associated with atherosclerosis often are caused by thrombi. Current antithrombolytic approaches are directed at inhibiting platelet aggregation through warfarin (Coumadin); heparins; aspirin; Integrilin (eptifibatide) or Reo-Pro (abciximab)—inhibitors of gpIIb/IIIa; or clopidogrel, prasugrel, and ticagrelor. The desire to inhibit the clotting cascade makes thrombin a good drug target for direct inhibition. This approach involves the investigation of thrombin receptor inhibition. The first direct thrombin inhibitor, Pradaxa (dabigatran etexilate), was approved in 2010 for reducing the risk of stroke and blood clots in people with atrial fibrillation not caused by a heart valve problem. Enzymes that are capable of dissolving a recently formed blood clot, such as streptokinase, tissue plasminogen activator (tPA), and urokinase, have been approved and are useful under specific primary care circumstances in the treatment of stroke.

Major advances have been made in the field of gastrointestinal physiology; many new gastrointestinal polypeptide hormones have been isolated and characterized, and their primary functions have been determined. Evidence for many years pointed to the existence of gastric receptors for histamine in addition to the vascular receptors. More recently, proton-pump inhibitors (PPIs), such as omeprazole, pantoprazole, lansoprazole, esomeprazole, and rabeprazole, have been designed to block specifically the H<sub>2</sub> receptor and have been very effective in the treatment of peptic ulcers when used with appropriate antibiotic treatment.

Molecular biological research has impacted every area of drug discovery. Molecular biology provides insight into the organism's fundamental genetic composition. Genetic testing of a patient may prevent a known toxic effect of a drug, such as abacavir. Abacavir is in a class of medications called nucleoside reverse transcriptase inhibitors (NRTIs) and is used in combination with other medications to treat HIV infection. Hypersensitivity reaction to abacavir is strongly associated with the presence of the HLA-B\*5701 allele. Therefore, a prospective HLA-B\*5701 screening might spare a patient from a hypersensitivity reaction to the drug.

Of note to pharmaceutical research is the use of recombinant expression as a source of scarce or valuable human proteins, such as growth hormone, antibodies, interferon, and insulin. This science also allows dissection of cell pathways and the generation of reagents for better assays. A major objective of research is the design of satisfactory model systems in animals, cell culture, and other innovative means to give reliable predictions of the safety and efficacy of new drugs in humans. Molecular biology has advanced the reduction in the numbers of animals used in drug research. Tests for biological activity at the molecular level are done first, after which animal tests using standardized, controlled experiments are conducted.

## VIROLOGY AND IMMUNOLOGY

The search for antiviral agents, which has depended on the development of methodology for propagation and assaying of viruses in tissue culture, has led to more precise procedures of testing compounds for antiviral activity. Tissue-culture techniques have made possible the production of large quantities of viruses for vaccine manufacture. New and improved vaccines represent a major objective of biologic research. New separation methods developed in biochemistry and physical chemistry have been applied to the isolation and purification of viruses and have led to preparation of highly purified and concentrated vaccines. Such vaccines are more effective and produce markedly fewer side-effects.

The discovery of HIV and its epidemiological implications has opened new avenues of research to develop suitable therapies. In combinations with cocktails of other drugs, HIV protease inhibitors are the main avenue of therapeutic approach for controlling HIV today. The discovery that chemokines and chemokine receptors are involved as coreceptors for HIV defined new pharmaceutical strategies toward small-molecule drug discovery.

New viral threats will surely emerge. Currently, the world is working to understand a new corona virus which has led to the severe acute respiratory syndrome (SARS) threat. New viruses will threaten the world, due to global travel, and could be used in bioterrorism. Advances in virology will add new understanding, disease controls through treatment, and eventually cures.

Recent immunological research has focused attention on a number of important diseases with an autoimmune component, such as rheumatoid arthritis, lupus, inflammatory bowel disease (IBD), and multiple sclerosis. These diseases continue to be poorly treated over time. Suppression of immune functions or induction of immune tolerance may be of great importance. A more detailed knowledge of the molecular basis of B and T differentiation, signal transduction, and leukocyte trafficking is needed to search for drugs that either enhance or inhibit these immune responses.

In addition, a clearer picture of the molecular basis of immune disease is required to improve the probability that additional drugs will be found to alleviate allergic reactions.

Immunological research has also been directed toward cancer. The existence of tumor-specific antigens in both viral- and chemical-induced tumors, as well as new evidence for host reactions to the tumor, increase the possibility of useful immunological approaches against cancer. One of the most important developments in the past decade has been the isolation and production of monoclonal antibodies. These agents can be used to identify tumor-specific antigens and thus serve as powerful *in vitro* diagnostic and therapeutic tools. The technique can be applied to other antigens as well. These substances are being developed as carrier systems for drugs by virtue of their ability to deliver the antibody-drug complex directly to the antigen-producing cell or tissue.

## PHARMACOLOGY

The role of pharmacological research in drug discovery continues to evolve. Initially, the pharmacologist was a whole animal biologist who developed animal models of disease to the extent

possible and tested compounds in animals to measure efficacy. Classical pharmacology contributed in two major areas<sup>26</sup>: (1) the design and operation of animal model for detecting and evaluating the activity of compounds, and (2) determination of the dosage, toxicity, mode of action, metabolism, and fate of a drug candidate in the body. More recently, the molecular pharmacologist is involved in the discovery and validation of new targets for drug discovery, as well as the generation of new assays, both *in vitro* and *in vivo*. Classic pharmacological methods using intact animals, whole organs, and isolated tissues were used more than 15 years ago. These have evolved to more automated and molecular-oriented methods, in which purified or recombinant enzyme and receptor systems are used in initial phases of discovery pharmacology, followed with *in vivo* testing as needed. Potential drug candidates are examined early on for specificity against other unrelated molecules, a means of reducing side-effects in individuals. Safety assessments are done earlier in the discovery process, allowing the physicians and clinical pharmacologists to work together to set the starting points for dosing drugs with minimal side-effects, to monitor what form of toxicity might appear, and to determine contraindications for drug use.

The study of drug absorption, distribution, metabolism, and excretion is frequently referred to as ADME. Drug therapy requires an elaborate and thorough knowledge of the kinetics of these processes after intravenous, oral, topical, sublingual, or intraorifice administration of the drug. Initial studies are often conducted using *in vitro* experimental systems, such as Caco-2 cell permeability, to determine the likelihood of oral absorption, or human liver microsome to determine the likelihood of metabolic stability. Common next steps are to test suitable compounds in animals to determine if the experimental systems are accurate for a particular chemical series and to extend the data set to a whole organism. Experiments are often performed with radioactive forms of the drug to determine the amounts of drug and its metabolites that appear in blood, urine, and tissues. Animals can be used to determine the manner in which a living organism assimilates a drug; however, human pharmacokinetic studies are essential to determine the fate of the compound in humans: Is it accumulated in specific organs, is it excreted into bile or urine, and is it metabolized? To determine the concentration of drugs in biological fluids or tissues requires special separation techniques, as well as sensitive, accurate, and precise instrumental measurements. Accurate quantitation and identification of the drug and its metabolites usually requires the use of chromatographic techniques coupled with mass spectrometry. Sensitive liquid-chromatography mass-spectrometry (LC/MS) methods provide powerful data on early drug candidate molecules, which influence the direction of new chemical synthesis.

## TOXICOLOGY

To be certain that a new drug is safe, detailed studies are made of the effects of varying doses and prolonged administration of that drug. The pharmacologist provides acute toxicity data; however, the toxicologist then must refine the acute toxicity measurement in laboratory animals and begin subacute and chronic studies. The latter are conducted in a variety of species, at several dosage levels of the drug, and over periods of time ranging from 3 months up to 30 months. During the test period, animals are observed carefully for all adverse symptoms. At the end of this period, and occasionally during its progress, the animals are sacrificed, and their vital tissues (such as liver, heart, kidney, intestine, or brain) are removed and studied grossly and microscopically by a pathologist.

In addition to gross and microscopic pathology, biochemical and physiological responses are measured as an indication of liver function, kidney function, or endocrine function. During recent years, metabolic investigations have become more sophisticated and have been brought to bear on the comparative effects of drugs on various animals and on humans. In some

instances, the metabolism of drugs or the therapeutic effects of drugs vary from species to species. Such variability can be the basis for differences in toxicity as well as efficacy. For these reasons, increasing emphasis is being given to studies of comparative metabolism in humans and animals to determine which laboratory animal handles the drug in a manner similar to humans. Selection of that species for extensive toxicity testing increases confidence that the toxic reactions that may occur in humans can be predicted by the animal tests.

Reproductive studies to determine the potential effects of the new drug on the reproductive processes and on subsequent generations are performed. Teratological studies are done to determine whether the new drug affects the fetus. Special toxicity tests have been designed to detect specific toxic reactions, such as nerve damage resulting in hearing loss. Ultimately, drugs reaching the marketplace will be assigned an FDA Pregnancy Category (A, B, C, D, X).

Carcinogenicity trials, which are lifelong studies in animals carried out at doses approximating the maximum (tolerated) human dose, provide evidence of a new drug's potential to produce human cancer. Several newer methods of toxicity are evolving in the biotech industry using gene activation methodology whereby one can evaluate if a candidate drug is transcriptionally active at a number of genes involved in liver metabolism or stress responses. These methods are likely to transform toxicological testing in the future.

In 1992, a global effort aimed at establishing uniform standards for toxicology testing of new drugs began, under the auspices of the International Conference on Harmonization (ICH). Guidelines were first published on toxicology testing for drugs and updated in 1998. Biologicals were not covered by those initial guidelines. Product-specific toxicology programs normally are required for biologicals. Toxicological studies are assuming increasing importance in the world of pharmacy and medicine. As knowledge and skills increase, and the ability to measure toxic reactions improves, greater safety and efficacy of new drugs may be ensured.

During the 1990s and continuing into the 2000s, significant progress has been achieved in the concept of replacing animals in toxicology/safety assessment with numerous *in vitro* systems. These are attempts to reduce the number of animals used and to refine the manner in which they are used. A review of available data, from 1973 to 2006, shows a decline in the number of animals used in research, experimentation, teaching, or testing: from just under two million in the 1970s and 1980s to just over one million in 2006.<sup>27</sup> Overall, multiple *in vitro* systems have been developed for screening and testing for eye and skin irritation, skin sensitization, teratology, and other endpoints; and a scientific consensus has been reached on the requirements and processes for validation for these *in vitro* tests. However, the use of these newer test systems in place of existing *in vivo* tests is not yet a reality. Much progress and dialog have taken place in the 1990s and 2000s on modification of both US and international requirements and guidelines for testing and for defining an approval process for alternatives and innovations.

Communication between scientists and the literature also have evolved with the explosion of information systems (IS) technologies and access to the Internet. Attention and access to the scientific and patent literature has accelerated. Formerly, the individual scientist subscribed personally to a few journals and depended on a scientific library for coverage of additional new scientific findings. With the tremendous growth of the scientific and patent literature and the emergence of interdisciplinary investigations, individual scientists can conduct desktop searches to stay abreast of the literature. Despite increasing use of various kinds of alerting services and facilities, many of them computer-based, for retrieval or retrospective search of pertinent information, personal perusal of literature remains critical, and the ability to initiate desktop searches is fundamental to independent scientific research.

## PHYSICAL CHEMISTRY

Modern research in pharmacy and medicine is supported and expedited by instrumentation. Modern instruments make possible the rapid and accurate measurement of physical and chemical properties of molecules. Separation and characterization of molecules are sometimes possible today in a matter of hours or a few days; only a decade or two ago, such work often required many days, weeks, or even months. Examples of specialized physicochemical and computational methods that are applicable to structural research are electron microscopy, nuclear magnetic resonance (NMR) spectroscopy, mass spectrometry, and crystallography.

NMR spectra identify chemical groups and indicate the nature of neighboring chemical groups in the molecule. Mass spectrometry permits determination of the molecular weight and empirical formula of an organic molecule and of the major fragments of the molecule. With this information, it is often possible to deduce the entire structure of a molecule rapidly and precisely. X-ray crystallographic analysis enables the physical chemist to determine the precise position of each atom of a molecule as it exists in the crystalline form. Structures of both the drug target and a potential drug in the active site of an enzyme have been critical to the discovery of HIV protease inhibitors.

Physicochemical studies are directed at the chemical groups and stereochemical configuration of biologically active molecules; these studies can describe molecules in terms of energy and electron distributions and can approximate the influence of the chemical environment on these distributions. The spatial and electronic conformation of drugs and the changes in conformation that occur in various environments govern the absorption, transport, distribution, and reaction with the receptor site. If description of molecules in these functional terms is achieved, correlation of electronic structure with function may be possible, and the design of safer, specific, and more effective drugs on a rational basis may occur.

## INFORMATION SCIENCE

The information systems have spearheaded a great amount of data generation, assimilation, and scientific communication. IS departments are now commonplace in academic, government, and industrial settings. The amount and sophistication of chemical and biological information have led to the critical role of bench-top and desktop computers in assimilating data. Computer-assisted chemistry, computer graphics, and relational databases have added a new dimension in structure and activity relationships. The computer-based monitoring and analysis of animal studies is routine. Online signal processing allows investigators to interact more fully with their experiments. Computer-assisted automation permits collection of more data with increasing accuracy; sophisticated software packages are available commercially or may be developed in-house.

## DRUG DEVELOPMENT

Before a new drug candidate can proceed to toxicological or clinical evaluation, considerable analytical chemical development is required to lay the groundwork for subsequent quality control and stability studies. Drug standards are established, and analytical methods for the bulk drug and the proposed final product are devised. Tentative chemical, physical, and biological specifications of the candidate drug are established. Simultaneously with analytical development, pharmaceutical chemists begin formulation studies toward the goal of a stable, highly acceptable product that delivers the correct amount of drug in a reproducible, effective manner. Sometimes a new drug must be modified chemically via esterification to a pro-drug in order to provide a form that is pharmaceutically acceptable and effective. Accelerated and long-term stability studies are started to estimate the conditions in which the product will be stable.

If a compound has desirable activity in an experimental testing system and appears to be safe upon toxicological examination, it becomes a candidate for clinical trial. Two additional tasks must be accomplished before a clinical trial can be undertaken. First, the drug candidate must be in a suitable, stable dosage form, and the candidate compound must be available for absorption and transport to the site of action. The stabilization of a drug candidate must preclude physical or chemical change (discoloration, precipitation, or decomposition). These components, or excipients, must often meet the standards outlined in the US Pharmacopeia/National Formulary (USP/NF), European pharmacopeias, or other national compendia. Because of the many physical forms in which pharmaceuticals are presented, the research necessary is broad in scope and not only involves the principles of physical pharmacy but also requires the application of principles from the allied fields of chemistry and biology.

The second task at this stage is to file an Investigational New Drug (IND) application with the FDA. The IND is, in fact, a document that gives a full description of the new drug, the location and manner of its manufacture, all quality control information and standards, stability, analytical methods, pharmacology, toxicology, documentation of efficacy in animals, qualifications of investigators who will be doing the clinical studies, and the complete protocols of the proposed clinical studies.

A new drug is administered to humans for the first time by a physician or clinical pharmacologist. These Phase I studies are carried out most often in healthy male volunteers in order to study the safety and pharmacokinetics of a new drug. The first trial of a drug in humans is done with great caution and on a very limited basis.

When dosing limits have been established and are found acceptable, the drug is made available to a larger number of practicing specialists for the Phase II study, which principally is concerned with the determination of safety and efficacy in patients having the primary disease for which the drug is to be tested. The minimum effective dose, the maximum tolerated dose, and the dose response (intermediate doses) also must be determined.

If after Phase II the drug still looks promising, it is distributed more widely to selected practicing physicians in the Phase III study. The purpose of the Phase III stage is to secure data from a larger number of patients on efficacy and incidence of side effects.

Finally, before the new drug can be marketed, a New Drug Application (NDA) is filed with the FDA and approval obtained. The NDA contains most of the information included in the IND, revised and updated, as well as all the results of the clinical studies proving safety and efficacy. Almost all clinical, laboratory, and patient history data are processed on computers. These medical data are updated in computerized retrieval systems and are designed to provide timely information during the FDA review. These systems also provide an additional information resource for premarketing and post marketing queries. Only after FDA approval of the NDA can distribution and marketing of the new drug begin.

Depending on the nature of the disease and the clinical endpoints that are monitored, some drugs require long-ranging and expensive clinical trials. Some trials by necessity monitor mortality rates. Clinical trials are carefully designed with the input of statisticians to determine numbers of patients and duration of the studies. Trials cost hundreds of millions of dollars (Figure 7-1) over multiyear periods, and they demand careful monitoring throughout.

Figure 7-1 also depicts the clinical research effort on a new drug and represents the culmination of many years of effort by large numbers of scientists of many disciplines and skills. Clinical research is the proving ground where the intelligence, creativity, and perseverance of laboratory researchers come to fruition. Of the candidate drugs that come to clinical research, only 20 percent survive as safe and efficacious and are added to the portfolio of therapeutics. Indeed, the 2011 report from the Pharmaceutical Manufacturers of America (PhRMA), titled 2011 Profile Pharmaceutical Industry<sup>15</sup> revealed the following information on the drug discovery research process:

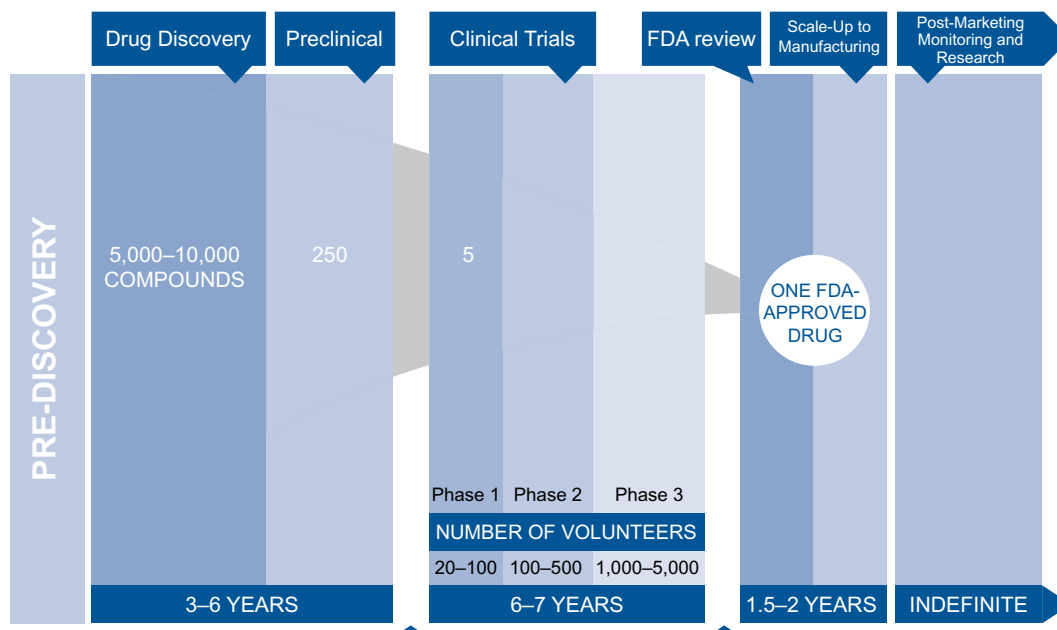

- One in 5000 compounds screened is approved for patient use.
- The estimated cost to create one new medicine is \$1.2 to \$1.3 billion.
- It takes an average of 10 to 15 years to develop a new medicine.
- Only 2 of 10 marketed drugs return revenues that meet or exceed the R&D costs (Figure 7-2).

Together with the cost of conducting R&D (Table 7-1), the above data explain the rising costs of prescription drugs. The top 25 selling drugs are listed in the twelfth Annual Pharma

**Figure 7-1.** The rise in drug development costs. The average cost to develop one new approved drug—including the cost of failures—increased approximately 50% between the late 1990s and the early 2000s. (From Pharmaceutical Research and Manufacturers of America. Chart Pack: Biopharmaceuticals in Perspective. 2010. [http://www.phrma.org/sites/default/files/159/phrma\\_chart\\_pack.pdf](http://www.phrma.org/sites/default/files/159/phrma_chart_pack.pdf), Accessed 8 May, 2012. The cost of biopharmaceutical R&D: is biotech different? *Managerial and Decision Economics* 2007; 28: 469–479; JA DiMasi *et al.* The price of innovation: new estimates of drug development costs, *Journal of Health Economics* 2003; 22:151–185. Note: Data for early 2000s is adjusted to 2000 dollars based on correspondence with study author.)

Developing a new medicine takes an average of 10–15 years

**Figure 7-2.** The research and development process. (From Pharmaceutical Research and Manufacturers of America, Pharmaceutical Industry Profile 2011. Washington, DC: PhRMA, April 2011.)

Executive report.<sup>16</sup> The top 10 of these are “blockbuster drugs” (i.e., over \$1 billion in sales (Table 7-2)<sup>16</sup>) and account for \$48 billion of sales in a \$593 billion market, or 8.1% of the market. Another factor in rising costs that cannot be discounted is the fact that overall research productivity and investment in

innovative research for new approaches and new medicines in the large pharma tier of companies has declined.<sup>28</sup> This may in part be attributable to merger and acquisition (M&A) consolidation in the industry. Of the top 10 companies, all are the result of M&A (Table 7-3).<sup>16</sup>

**Table 7-2. The Top-Selling Drugs in 2010**

Rank	Drug	Company	Type of Drug	2010 Sales (US \$ in billions)
1	Lipitor	Pfizer	Cholesterol reducer	7.2
2	Nexium	AstraZeneca	Antiulcer	6.3
3	Plavixq	Bristol-Myers Squibb	Antiplatelet	6.1
4	AdvairDiskus	GlaxoSmithKline	Antiasthmatic	4.7
5	Abilify	Otsuka	Antipsychotic	4.6
6	Seraquel	AstraZeneca	Antipsychotic	4.4
7	Singulair	Merck	Antiasthmatic	4.1
8	Crestor	AstraZeneca	Cholesterol reducer	3.8
9	Actos	Takeda	Antidiabetic	3.5
10	Epogen	Amgen	Erythropoiesis-stimulating agent	3.3

(From Cacciotti J, Clinton P. The Lull between two Storms, *Pharmaceutical Executive*, May 2011. www.oliverwyman.com/media/2011\_PharmExec\_50.pdf; accessed 20 April 2012.)

**Table 7-3. Top 10 Pharmaceutical Companies Worldwide in Prescription Sales (US\$ in billions) for 2010**

Rank	Company	Pharma Sales	Increase (%)
1	Pfizer	58.5	28.9
2	Novartis	42.0	9.2
3	Sanofi-Aventis	40.3	-4.1
4	Merck	39.8	58.0
5	Roche	39.1	4.1
6	GlaxoSmithKline	36.2	-4.2
7	AstraZeneca	33.3	1.4
8	Johnson & Johnson	22.4	-0.4
9	Eli Lilly	21.1	5.4
10	Abbott	19.9	27.7

(From Cacciotti J, Clinton P. The Lull between two Storms, *Pharmaceutical Executive*, May 2011. www.oliverwyman.com/media/2011\_PharmExec\_50.pdf; accessed 20 April 2012.)

The drug discovery research effort represents the culmination of, on average, 10 to 15 years of research and development by many scientists from multiple disciplines. Of the candidate drugs that come to clinical research, only about 20 percent survive as safe and efficacious and are added to the portfolio of therapeutics. The great investment in pharmaceutical research in the early part of the 20th century that has led to advancements in pharmaceutical therapies needs to be remade in the 21st century in support of helping patients to live longer, healthier, and more productive lives.

# Chapter 8

## The New Drug Approval Process

Linda A. Felton, PhD and Dennis W. Raisch, PhD, RPh

THE FOOD AND DRUG ADMINISTRATION 93

POST-APPROVAL ACTIVITIES 98

OVERVIEW OF THE US DRUG APPROVAL PROCESS 93

SUMMARY 98

The research and development efforts needed to ensure the safety and efficacy of new drugs are complex, time consuming, and financially risky. Thousands of compounds undergo extensive testing for every one new chemical that receives marketing approval.<sup>1</sup> Research and development costs for each new drug product are estimated at approximately \$1 billion.<sup>2</sup> It has been reported that only 30% of drugs that reach the marketplace generate sufficient revenue to recover the average cost of development.<sup>3</sup> This chapter discusses the stages of new drug development and approval in the United States with a focus on clinical trial design and methodology. Readers are encouraged to refer to specific Food and Drug Administration (FDA) guidance documents for more detailed information ([www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/default.htm](http://www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/default.htm)). Note that other countries have similar regulatory authorities that oversee drug approvals.

### THE FOOD AND DRUG ADMINISTRATION

The Food and Drug Administration (FDA) oversees the new drug approval process in the United States. The initial legislation, the Pure Food and Drug Act of 1906, was passed in response to Upton Sinclair's exposé of the meat packing industry, *The Jungle*, which described deplorable practices resulting in contamination. Over time, the authority of the agency expanded, but it remained relatively powerless to effectively assure the safety and efficacy of medicines. Subsequently, a sulfanilamide product containing diethylene glycol as a solvent to enhance the aqueous solubility of the drug was developed. Diethylene glycol, however, is a highly toxic agent used in antifreeze solutions, and numerous deaths resulted from its ingestion. Based on these tragic events, Congress passed the Food, Drug, and Cosmetic Act of 1938, which increased the regulatory authority of the FDA to oversee the development of new drug products.<sup>4</sup> The Act required disclosure of the ingredients and formulation, assay methods, manufacturing processes, and all animal and human testing to the FDA prior to the distribution of drug products.

Although the Act of 1938 required new drug products to be safe, efficacy standards were not established until another tragedy occurred in the early 1960s. Thalidomide, a synthetic sedative/tranquilizer, had been sold in Europe without a prescription and was viewed as a possible alternative to the more toxic barbiturates.<sup>5</sup> Prior to FDA approval of thalidomide, several incidences of toxicity in Europe were reported. Severe birth defects were noted when the drug was administered to pregnant women, the most common being phocomelia or arrested limb development. These events brought about the Kefauver-Harris Amendments of 1962, which strengthened existing laws and emphasized the need for the safety of approved drugs.<sup>6</sup> These Amendments required manufacturers to establish both safety and efficacy of new drug products prior to approval and required investigators to file Investigational New Drug Applications (INDs) prior to testing drugs in humans. As a side note, thalidomide is currently approved in the United States for the treatment and prevention of painful skin lesions associated

with erythema nodosum leprosum and multiple myeloma. Other potential uses of this drug under investigation include several types of cancer, Crohn's disease, and autoimmune deficiency-associated diseases.<sup>5,7</sup>

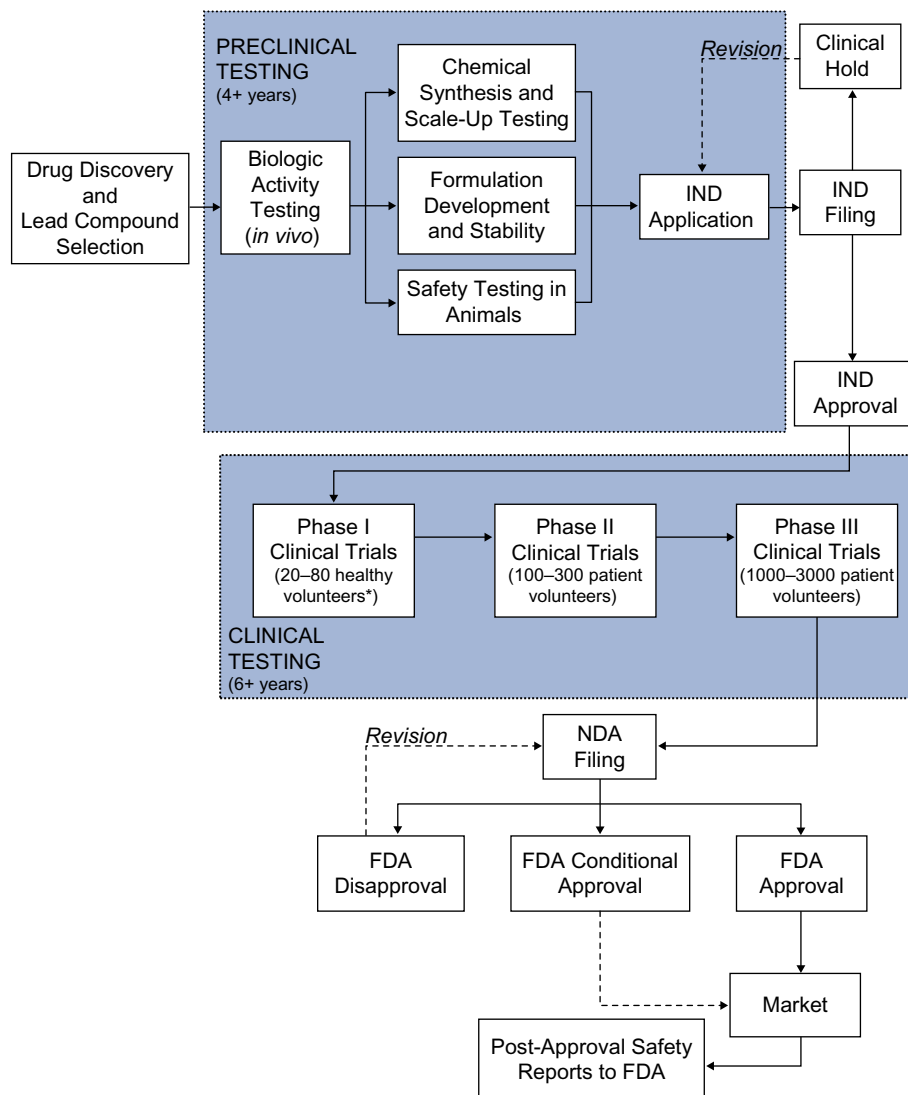

The role of the FDA is to promote and protect the health of Americans. A multidisciplinary staff, consisting of pharmacists, physicians, pharmacologists, chemists, statisticians, attorneys, and other scientists, as well as administrative personnel, is employed at the FDA to achieve this goal. The FDA consists of several Centers, each designated with specific responsibilities. The Center for Food Safety and Applied Nutrition oversees food and cosmetic products. The Center for Veterinary Medicine is responsible for animal feed and drugs. The Center for Devices and Radiological Health covers the safety and efficacy of medical devices. This Center also oversees radiation-emitting devices, such as lasers, x-ray systems, microwave ovens, and cellular telephones. The Center for Biologics Evaluation and Research (CBER) supervises biologics. Finally, the Center for Drug Evaluation and Research (CDER) is responsible for drugs and drug products. In addition to reviewing the safety and efficacy of all prescription and over-the-counter drug products prior to marketing, the Center for Drug Evaluation and Research is responsible for monitoring drug safety after initial market approval and has the authority to withdraw drugs posing significant health risks from the market. The Center for Drug Evaluation and Research provides health care professionals and consumers with drug-related information and screens television, radio, and print ads for truthfulness and balance.

Other countries have similar regulatory authorities that oversee the approval of new drug products. For example, the European Medicines Agency (EMA) regulates most European markets. The pharmaceutical industry and regulatory authorities, including the FDA, have been working closely with the International Conference on Harmonization (ICH) to develop standardized regulatory processes for the major markets and allow results of international clinical trials to be used to support approvals across countries.

### OVERVIEW OF THE US DRUG APPROVAL PROCESS

As mentioned previously, drug discovery and development is a complex and expensive endeavor. The next several sections of this chapter discuss the new drug development and approval processes in the United States. Although focused specifically on the Center for Drug Evaluation and Research and new drugs/drug products, similar requirements exist for biologics. Medical devices are approved in a different manner, depending on how they are used and their invasiveness on human functions. Devices require an approved Investigational Device Exemption (IDE) prior to beginning clinical studies. The drug approval process is divided into two sections: (1) preclinical testing (lead compound selection and animal testing of new chemicals) and (2) clinical testing (administration of new chemicals to humans). Figure 8.1 shows a schematic of these steps.

**Figure 8-1.** Schematic of the new drug approval process in the United States. For life-threatening illnesses such as cancer, patients enrolled in Phase I studies may suffer from the disease.

## DRUG DISCOVERY AND LEAD COMPOUND SELECTION

Pharmaceutical companies begin the discovery process by targeting a broad disease category (for example, cancer or cardiovascular disease) or a specific disease state (for example, breast cancer or hypertension). A chemical with potential therapeutic benefit(s), known as a lead compound, must first be identified, and researchers use various high-throughput assay techniques to rapidly screen large numbers of chemicals for biological activity.

Random screening, as the name implies, requires biological testing of a large variety of diverse compounds from existing chemical libraries. Although less up-front financial investment is needed, thousands of compounds may be screened and tested before one agent with significant biochemical activity is identified. A more mechanism-based drug design is targeted synthesis, where researchers focus on one step in a disease process as the target for drug intervention. Although an extensive knowledge of the disease state is required, this more directed approach increases the likelihood of successfully identifying a lead compound. In combinatorial chemistry, one compound is used as a base chemical and various functional groups are randomly added to enhance biological activity. This technique is a more expensive, more complex method of identifying potential lead agents. Another method to enhance biological activity is

drug modeling, where computers are used to manipulate virtual structures and calculate protein binding capabilities. Although initial costs are significant, drug modeling techniques show a great deal of promise for future drug discovery as more research is conducted to identify biochemical pathways. Generally, these discovery techniques are used in combination to identify lead compounds.<sup>8-10</sup>

## PRECLINICAL TESTING

A multidisciplinary team of researchers works to determine many of the lead compound's critical properties. This team might continue to work with the compound throughout the entire development process or the development responsibilities might be transferred to another group of scientists during the clinical testing phase. Preclinical testing includes:

- discovery testing to ensure biological activity *in vivo*
- chemical synthesis and scale-up to ensure adequate quantities of high purity can be made
- formulation development and stability testing to characterize various chemical properties, develop the initial drug delivery system, and determine the stability of the compound
- animal safety testing to ensure limited toxicities of the lead agent.

At this stage of the development process, good laboratory practices (GLPs) are followed. These regulations, in the Code of Federal Regulations (CFR) 21 Part 58, provide standards for the design and conduct of preclinical studies. Qualifications of personnel and requirements for standard operating procedures are specified.

During discovery testing, the specifics of the compound's properties, such as the mechanism of action in animal models, compound specificity, duration of action, and structure-activity relationships, are determined. Adequate quantities of the new chemical compound must be produced at a high level of purity. Impurities present at concentrations greater than 0.1% must be characterized and tested for toxicity. The physicochemical properties of the active compound are determined, and development of the drug delivery system to be used in human testing begins. Animal testing provides initial data regarding the absorption, distribution, metabolism, and excretion (ADME) in a living system. Possible side effects and toxicities are noted. Toxicity studies of at least the same duration as the proposed human testing and a minimum of two weeks must be completed. Active and inactive metabolites must be characterized. Often, the most appropriate animal model to predict human response is not known, thus toxicity studies are conducted in at least 2 animal species, one rodent and one nonrodent, to obtain a comprehensive view of the potential toxicity. Early absorption, distribution, metabolism, and excretion or toxicity problems may be corrected by slight modifications in the chemical structure of the new entity.

Animals should be given the new drug product by the same route intended for humans. Certain dosage forms, such as aerosol, nasal, or buccal delivery systems, might be difficult to administer to animals. In these circumstances, alternative drug delivery routes may be used, and the selected route of administration should ensure sufficient exposure to the new chemical entity. During animal safety testing, dosing studies are conducted, and the highest no-effect dose is determined. In addition to dose, plasma concentrations of the drug are followed, and noted toxicities are correlated to dose and/or plasma concentration.

Generally, once discovery testing shows therapeutic promise, the chemical synthesis, formulation development, and animal safety testing occur concurrently (see Figure 8.1). Although resources may be wasted on earlier failures, successful candidates will be ready for human testing more quickly. The administration of drugs in humans at the earliest time possible ultimately saves valuable resources, as highly toxic compounds can be eliminated and alternative lead compounds can be developed.

Additional preclinical studies may be conducted during clinical testing to support larger trials and, eventually, the marketing of the drug product. Formulation development continues throughout the process, and the data gained from both animal and human testing allow for optimization of the drug delivery system. It is imperative to identify and resolve formulation problems early in the development process, as unresolved problems will surely reemerge later, costing the company both time and money as clinical testing is delayed. More chronic animal exposure experiments are conducted to support further clinical testing.

### Pre-IND Meetings

Pre-IND meetings may be held prior to submission of an Investigational New Drug application (IND) and at the request of the sponsor, during these early stages of development to discuss testing plans and data requirements. These meetings are especially useful when a drug has been developed overseas and a great deal of preclinical and clinical data is readily available. During pre-IND meetings, the sponsor and FDA should agree on the acceptable phase of the initial clinical investigation. Clinical data from other countries, if obtained following International Conference on Harmonization requirements, may eliminate the need for Phase I human safety testing in the United States.

FDA guidance documents provide an overview of procedures for requesting formal meetings. These meetings are not intended to replace informal discussions with the FDA.

### INVESTIGATIONAL NEW DRUG APPLICATION (IND)

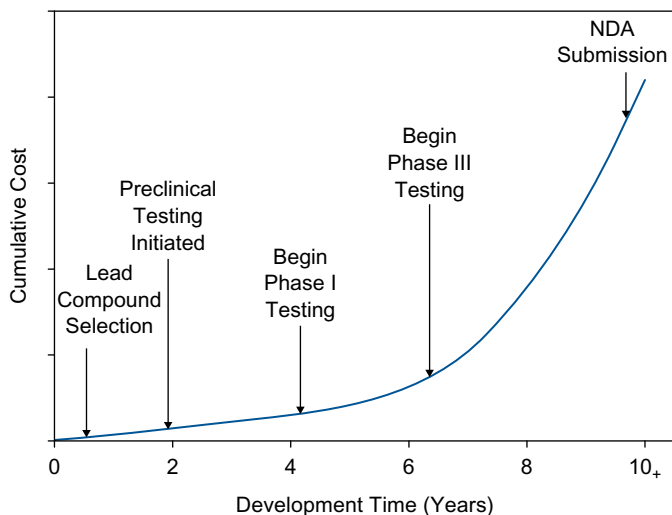

An Investigational New Drug application (IND) must be filed with the FDA and approved prior to administering new drug products to humans. The guidelines for preapproval of all clinical testing are specified in 21 CFR Part 312. FDA guidances for INDs can be found on its website. The name and chemical description of the active components, a list of active and inactive components, and the manufacturers of these components must be provided. The method of preparation and the dosage form to be administered is required. The IND includes all preclinical animal data and the names and locations of the investigators performing the planned clinical trials. Data from clinical trials conducted in other countries should also be included. A major component of the IND is the study protocol(s) implemented to evaluate the drug. The protocol must address all aspects of the trial, including study procedures, informed consent, data collection, and analysis, as well as mechanisms for subject selection, follow-up, and safety monitoring to protect the patient. Upon receipt, an IND number is assigned by the FDA, which is used to track all subsequent communication between the study sponsor and the FDA. The IND is assigned to the appropriate division of the Center for Drug Evaluation and Research, and the contents are thoroughly reviewed. The FDA has 30 days from receipt of the IND to decide if the proposed clinical trial should proceed. Rather than "approving" an IND, the FDA must provide notification if the trial is placed on "clinical hold" pending clarifications or changes to the study protocol. If no further communication is received from the FDA, the sponsor is allowed to begin the study by enrolling patients. Each facility's Institutional Review Board (IRB) must approve the protocol(s) conducted under the IND.

Although the trial may proceed, reviewers at the FDA may place a "clinical hold" on the trial at any time. A "clinical hold" prevents human testing under the IND until FDA concerns have been adequately addressed. Reasons for placing an IND under a clinical hold include unreasonable or significant risk of illness or injury to trial subjects, insufficient information or procedures to assess and minimize patient risks, inadequate qualifications of the clinical investigators, or a misleading, erroneous, or incomplete Investigator's Brochure (a document containing all relevant information about the drug). Revisions to clinical protocols, as well as new protocols or substudies, are submitted to the FDA as amendments to the IND. Progress reports regarding the trial must also be provided annually. The contents of the annual report are specified in the regulations. Furthermore, the sponsor must report any unexpected, serious adverse drug events that occur during the trial must be reported to the FDA and the IRB within specified time periods.

Not all clinical trials require INDs. A sponsor proposing a trial with a commercially available, FDA-approved drug product is exempt, if the trial (1) is not intended to be submitted to the FDA to support labeling changes or a new indication; (2) is not intended to support a major change in advertising; and (3) does not involve a route of administration, dose, or patient population that significantly increases the risk of the drug. An IND is not required, if the trial is exempt according to the above criteria, regardless whether a placebo (inert or inactive treatment) is employed as a control group. Independent investigators, rather than pharmaceutical companies, often conduct these types of clinical trials.

### CLINICAL INVESTIGATIONS

Clinical investigations involve the administration of a drug product to humans. This segment of the drug development process requires substantial financial and time commitments.<sup>11</sup> Figure 8.2 shows the considerable increase in development costs associated with the initiation of clinical trials. Human

**Figure 8-2.** Relationship between the time devoted to new drug development and dollars invested.<sup>6</sup>

testing is divided into four phases, each phase having specific objectives. The following sections discuss the various phases of clinical testing.

### Phase I Clinical Trials

The first series of experiments performed in humans occurs during Phase I clinical testing. A small number of healthy volunteers (approximately 20–80 people) are exposed to the new drug product in closely monitored trials primarily to assess the compound's safety. For the investigation of drugs to treat life-threatening diseases, such as cancer or Acquired Immune Deficiency Syndrome (AIDs), patients afflicted with the disease may be enrolled.<sup>12</sup> In Phase I trials, the starting dose is low, often one-tenth of the highest no-effect dose in the animal models. After the initial treatment is completed, additional subjects may be recruited, and higher doses may be administered to determine the maximum dose tolerated without significant side effects. During this phase of testing, preliminary absorption, distribution, metabolism, and excretion data of the parent drug and all metabolites should be evaluated. Data regarding pharmacokinetic and pharmacological effects are used in the design of future Phase II trials.

### Phase II Clinical Trials

Phase II clinical testing shifts the focus of the trials from safety to efficacy. In comparison to Phase I trials, a larger number of people (100–300 patients) are enrolled, and the majority of these participants suffer from the target illness. Side effects from the new drug product are also investigated. These clinical trials are closely monitored and well-controlled (see Clinical Trial Planning and Design section). Failure during Phase II testing is common, as the human body is more complex than a test tube or animal testing. As with any study conducted in humans, clinical protocols for Phase II trials must be sent to the FDA prior to beginning the trial. They may be included as amendments to the IND approved for a Phase I study.

### Phase III Clinical Trials

At the end of Phase II testing, sponsors are encouraged to meet with the FDA personnel who are assigned to the review division for the therapeutic area (for example, Division of Psychiatry Products, Division of Neurology Products, Cardiovascular Renal Products, etc.). These meetings involve review of the acceptability of past trials, the design of future trials, and the general drug development plan. Scientists at the FDA carefully review preclinical and clinical data in evaluating proposed Phase III protocols. Specific areas of the proposed Phase

III trials that are scrutinized include the study objectives, informed consent, inclusion/exclusion criteria, dosing regimens, methods and timing of data collection, duration of treatment and follow-up assessment, blinding of the drug products and plans for maintaining the blind, plans to assess compliance with the protocol, identification of primary outcome variables, and methods to account for dropouts. Addressing these key areas of proposed Phase III protocols is expected to limit the bias of trial results. An overall goal of the meeting is a good-faith agreement between the sponsor and the FDA regarding data required for submission of a New Drug Application (NDA), the final regulatory hurdle before the drug product can be marketed.

Phase III clinical trials are the longest and most comprehensive evaluation of new compounds. Significantly larger numbers of patients (1000–3000) who are afflicted with the target illness are tested. Patients are often recruited, tested, and monitored by several major hospitals and clinics throughout the country. Phase III trials may also be conducted internationally. In addition to determining efficacy, these trials monitor adverse reactions. The new drug may be compared to existing therapeutic regimens (that is, comparator products) or a placebo. The final market formulation for the drug product should be optimized prior to the start of Phase III trials. Compounds that successfully complete Phase III testing have a 95% chance of being approved by the FDA.<sup>1</sup>

Prior to the completion of Phase III testing and New Drug Application (NDA) submission, sponsors are encouraged to meet with the appropriate review division of the FDA again. These meetings help establish the format of the submission, so that the review proceeds smoothly and to determine whether additional animal or human trials are necessary. The meeting should be held sufficiently in advance of the tentative New Drug Application (NDA) filing date to allow ample time to incorporate recommended changes or perform additional trials.

### Phase IV Clinical Testing

Phase IV trials are post-approval clinical trials designed for one of several reasons. The FDA may mandate Phase IV testing in a specific patient population to further assess efficacy and side effects. Companies may also choose to conduct additional clinical tests to more fully understand how their product compares to other commercially available therapeutic regimens. Since duration of exposure and number of patients treated are often limited during Phase III testing, Phase IV trials may be required to assess long-term safety of the drug.

## THE NEW DRUG APPLICATION

Once the Phase III trials have been completed, all preclinical and clinical data are compiled into a New Drug Application (NDA), which is submitted to the FDA for review. The FDA also reviews the product's labeling and package insert. The NDA approval process is the last hurdle prior to marketing. An NDA document typically consists of hundreds of thousands of pages and contains highly detailed information. Regulation guidelines, including the information required for an NDA, are provided in 21 CFR Part 314 Subpart B. Primary items include:

1. safety and efficacy of the drug treatment(s)
2. components of drug product(s)
3. description of methods and controls used in manufacturing the active ingredient and drug delivery system and its packaging
4. proposed labeling.

According to the Center for Drug Evaluation and Research, the time for a standard NDA review has been reduced from a median of 22 months in 1992 to approximately 13 months in 2008 (6 months for priority review).<sup>13</sup> The faster review times have been attributed to the Prescription Drug User Fee Act (PD-USA) of 1992.<sup>14</sup>

When an NDA is submitted, relevant sections of the document are distributed to the appropriate reviewers and evaluated first for completeness. If the document is sufficiently complete, the NDA is accepted for review and assigned a priority status. NDAs for new chemical entities are classified as either “P” for priority review or “S” for standard review. A “P” rating is given to new drug products with improved therapeutic effects, safety, and/or side effects in comparison to currently marketed drugs. NDAs assigned a “P” rating are expected to be reviewed in a more timely manner than those assigned an “S” rating. If the NDA is deemed too incomplete to review, it is not filed. The decision to accept the NDA is made within 60 days of the date of submission.

Once the NDA is accepted, detailed evaluation continues, and the FDA has 180 days from submission to complete the review. Each reviewer submits written comments of his or her assigned section and makes a recommendation. The NDA may also be presented to an Advisory Committee for comment. All documents are then compiled and ultimately submitted to the Director of the Office of Drug Evaluation. The FDA may approve the product for market, approve with specific conditions attached (Conditional Approval), or disapprove the drug product. Primary reasons for disapproval include lack of demonstrated safety and efficacy, issues with the manufacturing/processing procedures, or false/misleading labeling. If not approved, a letter is sent to the sponsor detailing deficiencies in the application. If the NDA is approved, an approval letter, along with a draft of the product labeling, is sent to the sponsor. The label is a combination of the draft submitted by the sponsor and revisions provided by the reviewing section of the FDA. Standardized labeling requirements are provided in 21 CFR Part 201.57.

Prior to NDA approval, the FDA conducts an inspection of the sponsor’s facilities to ensure compliance with current Good Manufacturing Practices (cGMPs) as set forth in 21 CFR Parts 210 and 211. These are industry standards to ensure consistent quality of manufactured drug products. Preapproval inspections are conducted within 45 days of the NDA acceptance. If deficiencies are noted, a letter (FDA Form 483) is sent to the sponsor delineating the problems. Once the deficiencies are resolved, the company must provide written certification, and the FDA will then clear the application within 45 days, if the corrections are adequate. As this step is critical in the approval process, companies often hold mock preapproval audits.

The NDA approval process is complicated and challenging, and the process may involve several revisions. In 2008, 70% of priority reviews were approved and 60% of standard reviews were approved as their original submissions (<http://www.fda.gov/downloads/AboutFDA/ReportsManualsForms/Reports/UserFeeReports/PerformanceReports/PDUFA/UCM243358.pdf>).

In response to the FDA Modernization Act of November 1997, the National Institutes of Health (NIH), in collaboration with the FDA, established the Clinical Trials Website ([www.clinicaltrials.gov](http://www.clinicaltrials.gov)). This website is a searchable database that provides information on clinical trials, including the purpose of the study, recruiting status, criteria for participation, study drug(s), and the location of the trials. Investigators are required by law to provide results on the website once the trial is completed. This process was established to ensure that the results of nonsignificant or negative studies were made public. Most medical journals require proof of registry at [clinicaltrials.gov](http://clinicaltrials.gov) prior to publication of clinical trial results.

## THE ABBREVIATED NEW DRUG APPLICATION (ANDA)

In addition to approving new drug products for the United States, the FDA is charged with the approval of generic drug products (21CFR Part 314). This work is accomplished through the Center for Drug Evaluation and Research’s Office of Generic Drugs. A generic drug product must be bioequivalent in comparison to an approved proprietary drug product. The review process for generic drugs is specifically focused on bioequivalence testing rather than safety and efficacy. Thus, conventional

clinical testing is not required. To be considered bioequivalent, both the rate and extent of drug absorption must be within established parameters in comparison to the reference drug. *In vivo* (within a biological system) bioequivalence testing is required for most dosage forms. Applicants may request a waiver from performing *in vivo* bioequivalence studies for certain drug products where bioavailability may be established by submitting (1) a formulation comparison for products whose bioavailability is evident (that is, oral solutions, injectables) or (2) comparative dissolution. The FDA provides guidance on establishing bioequivalence. If any portion of the application is not acceptable, a letter of deficiency that details the insufficiencies and requests additional information and data to resolve these concerns is issued. A tentative approval letter delaying the marketing of the generic product may be issued, if approval of the generic occurs prior to the expiration date of patents or exclusivities of the reference drug product.

## RAPID ACCESS TO NEW DRUG PRODUCTS

As a result of the demand for more rapid access to new drug products, the FDA has written several regulations and policies specifically designed for drugs intended to treat severely debilitating or life-threatening illnesses. Subpart E (21 CFR 312.80-.88) regulations expedite the development and approval process. For example, treatment INDs (21 CFR 312.34) are intended to make drugs relatively far along in the development process available to seriously ill patients and are typically made available during Phase III clinical trials.

Accelerated approval is a mechanism whereby products are approved for marketing based on limited data and exposure of small numbers of patients to the product. Approvals may be granted when studies have been performed using surrogate endpoints, such as laboratory finding or physical signs that may not directly measure patient response yet is considered likely to predict therapeutic benefit or delays in disease progression rather than ultimate endpoints, such as mortality. The process is limited to life-threatening indications, such as HIV and cancer. When a drug is approved via accelerated approval, the FDA requires specific post-approval studies be performed within a predetermined amount of time. However, often, these studies are difficult to perform, because patients may not be willing to participate in trials in which the new treatment may not be given. Thus, completion of these post-approval commitments is often delayed.<sup>15</sup> For example, from December 1992 to July 2010, the FDA approved 47 new oncology indications for 35 drugs, but only 26 were converted to regular approval, within a median of 3.9 years. Delays in completing post-marketing studies have been as much as 10.5 years.<sup>15</sup> Lack of completion of confirmatory trials was cited as the reason for not moving to regular approval among 14 of the 21 indications. Furthermore, as with other FDA approved products, the use of accelerated approval products often extends beyond the approved indications, because prescribers are allowed to utilize them in off-label settings.

## Orphan Drug Approval

Orphan drugs are drugs used to treat rare diseases or conditions that affect less than 200,000 people in the United States. Orphan drugs go through the same FDA review process previously described. However, the review is expedited, as the majority of orphan drugs are used in the treatment of serious or life-threatening disease. The process by which a company can file an application for orphan drug designation is described in 21 CFR Section 316.20. Due to substantial drug development costs, orphan drugs provide limited opportunities for companies to recoup their investments. The United States federal government, through the Orphan Drug Act of 1983, established tax incentives, reduced user fees, and created exclusivity agreements to encourage research in the orphan diseases.<sup>16</sup> Grants are also available through the FDA to support clinical research, and annual requests for applications may be found in

the Federal Register. Eight new products (new chemical entities and new biologic license applications) for orphan diseases were approved in 2009.<sup>17</sup>

### OVER-THE-COUNTER DRUG APPROVAL

The approval process for over-the-counter (OTC) drugs is considerably different from prescription medications, and their review is not held to the same standards as an NDA. The first phase of the approval process involves an advisory panel consisting of a multidisciplinary group of scientists that review data provided by manufacturers and other previously published research. The findings are submitted to the FDA, and these reports are subsequently summarized in the Federal Register. Interested parties are given an opportunity to comment. Next, the FDA reviews all statements and publishes a tentative final monograph. The FDA also publishes the nature of the comments received and provides further opportunity for feedback. Then, the final monograph is published in the Federal Register and goes into effect one year after publication. The monographs establish conditions under which over-the-counter drugs are recognized as safe and effective and are not misbranded. By following a monograph, a company can then market an over-the-counter drug without additional FDA approval. For any unsubstantiated claims that a company wishes to make (that is, claims not approved in the monograph), data must be presented to the FDA to justify revision of the monograph or the sponsor may submit a NDA.

### POST-APPROVAL ACTIVITIES

#### SAFETY MONITORING

After an NDA has been granted and marketing is initiated, drug safety is still monitored. Sponsors of the NDA must periodically submit reports of adverse events. For newly approved drugs, these reports are filed quarterly for the first three years, then annually thereafter. For adverse events that are considered serious and unexpected (that is, fatal or life-threatening, permanently disabling, or requiring or prolonging hospitalization), the sponsor must provide a report to the FDA as soon as possible (a written report within 15 days of receipt of the information and a telephone or facsimile report within 7 calendar days). The FDA's MedWatch program (see <http://www.fda.gov/Safety/MedWatch/default.htm>) encourages health-care providers and patients to directly report serious adverse reactions to drugs to the FDA. The program also provides alerts to practitioners regarding actions and recommendations by the FDA. Serious adverse events may require minor labeling changes or the addition of warning or precaution statements. If serious safety concerns arise, the FDA may withdraw approval of the NDA. Another alternative is the addition of a "Boxed Warning" in the product label. Boxed warnings are usually accompanied by a "Dear Health Professional" letter that is sent directly to licensed health providers to increase awareness of the potential problem. The boxed warnings may specify a newly identified risk or provide additional guidelines for use of the products in certain patient groups. Often, an FDA Advisory Committee reviews the NDA in light of the new data prior to an official NDA withdrawal. In some instances, manufacturers have withdrawn drug products prior to FDA action.<sup>18</sup>

For certain medications that pose a serious and significant public health concern, the FDA requires the distribution of approved patient medication information. This Medication Guide is intended to ensure patients' safe and effective use of the drug products. The FDA Amendments Act of 2007 further requires a risk evaluation and mitigation strategy (REMS) from manufacturers to ensure that the benefits of a drug or biological product outweigh its risks. A draft guidance on the subject of REMS and Medication Guides was recently issued by the FDA and can be found on its website, along with a list of products subject to a risk evaluation and mitigation strategy.

### CHANGES TO AN APPROVED PRODUCT

Any change made to an FDA-approved drug product, including component or composition, chemical synthesis, analytical methods, manufacturing site, manufacturing process, batch size, or labeling, must be submitted to the FDA. Some of the so-called scale-up and post-approval changes (SUPAC) require FDA approval prior to the implementation of the change. Depending on the type of change made and the impact the change may have on the quality of the drug product, notification to the FDA may be provided through annual reports or supplemental new drug applications (SNDA).

### SUMMARY

New drug products must be shown as safe and effective before they are approved by the FDA for marketing in the United States. Other countries have regulatory authorities similar to the FDA that oversee new drug approvals. This chapter, focused on drug approval in the United States, outlined the various stages involved in new drug development, including the milestones of Investigational New Drug Application and New Drug Application submission. The costs associated with the development of new drug products are substantial, and the most significant expenditures occur during clinical testing. Thus, the design and conduct of clinical trials are critical to successful drug product development. Several considerations in clinical trial design have been highlighted. The reader is encouraged to refer to specific FDA guidance documents and other referenced materials for further information.

DENSITY AND SPECIFIC GRAVITY 113

PHARMACEUTICAL CALCULATIONS 114

LOGARITHMS 115

PHARMACEUTICAL PROBLEMS 116

ANSWERS TO PROBLEMS 129

APPENDIX A 132

One of the first technical operations that the student of pharmacy must learn is the manipulation of balances, weights, and measures of volume. This entails a study of the various systems of weights and measures, their relationships, and a mastery of the mathematics involved. This chapter considers the fundamental principles of metrology underlying the testing, manufacturing, and compounding of pharmaceutical preparations:

- **Weights and measures**—An accumulation of facts concerning the various systems, with tables of conversion factors and practical equivalents. The relationships among the various systems of weights and measures are clarified.
- **Weighing and measuring**—A discussion of the various types of balances, particularly prescription balances and methods of using, testing, and protecting them; also of various devices and methods for measuring large or small volumes of fluids.
- **Density and specific gravity**—A consideration of the mass/volume ratio of a substance (density), and the ratio of the weight (mass) of one substance to the weight (mass) of another substance taken as the standard (specific gravity).
- **Pharmaceutical calculations**—A review of basic mathematical principles and their use in solving pharmaceutical problems.

### WEIGHTS AND MEASURES

*Weight* is a measure of the gravitational force acting on a body; weight is directly proportional to the body's mass. The latter, being a constant based on inertia, never varies, whereas weight varies slightly with latitude, altitude, temperature, and pressure. The effect of these factors is usually not considered unless very precise weighing and large quantities are involved.

*Measure* is the determination of the volume or extent of a body. Temperature and pressure have a pronounced effect, especially on gases or liquids. These factors, therefore, are considered when making precise measurements.

All standard weights and measures in the US are derived from or based on the United States National Prototype Standards of the Meter and the Kilogram. The standards are made of platinum-iridium, and are in the custody of the National Institute of Standards and Technology (NIST) in Washington, DC.

### HISTORY

A brief outline of the origin of the many systems of weights and measures may help clarify the essential distinctions between them. The sense of the weight of a body cannot be conveyed intelligibly to the mind unless a means of comparison is chosen. As weight is the measure of the gravitational force of a body, this force is expressed in terms of standards of resistance, which exactly balance the body and keep it in equilibrium when used with a mechanical device constructed for this specific purpose. Such standards are termed *weights* and the mechanical devices are called *balances* or *scales*.

The standards that have been chosen by various nations are arbitrary, and instances are common where different standards are in use at the same time in the same country. Many of the ancient standards clearly are referable to variable parts of the human body, such as nail, foot, span, pace, cubit (length of the forearm), and fathom or faethm (stretch of the arms). In the history of metrology three periods may be traced:

- The *Ancient* period, during which the old classical standards originated, terminated with the decline of the Roman Empire. The unit of distance used by all nations for maritime measurements, the *nautical* or *meridian* mile (1/60 of a degree of the earth's equatorial circumference) is exactly equal to 1000 Egyptian fathoms or 4000 Egyptian cubits. These Egyptian measurements, which have persisted for more than 4000 years, were based on astronomical or meridian measurements that were recorded imperishably in the great Pyramid at Ghizeh, whose perimeter is exactly 500 of these fathoms, or 1/2 nautical mile.
- The *Medieval* period extended to the sixteenth century. During this period the old standards were lost, but their names were preserved, and European nations adopted various independent standards.
- The *Modern* period extends from the sixteenth century to the present. Since the seventeenth century, the efforts of most enlightened nations have been directed toward scientific accuracy and simplicity, and during the present century toward international uniformity.

Historical metrology, also referred to as *documentary metrology*, is concerned with the study of monuments and records of ancient periods. *Inductive metrology* is concerned with the accumulation of data concerning the measurement of large numbers of objects that have been referred to as standards but which have no exact measure except by statutory regulation.

### The English Systems

In Great Britain, in 1266, the 51st Act of the reign of Henry III declared:

that by the consent of the whole realm of England the measure of the King was made—that is to say, that an English silver penny called the sterling, round and without clipping, shall weigh *thirty-two grains of wheat*, well dried and gathered out of the middle of the ear; and twenty pence (pennyweights) do make an ounce and twelve ounces a pound, and eight pounds do make a gallon of wine, and eight wine gallons do make a bushel, which is the eighth of a quarter.

The 16-ounce pound (*avoirdupois pound*), undoubtedly of Roman origin, was introduced at the time of the first civilization of the British island. However, according to Gray, the word

“haberdepous” was first used in English laws in 1303. A statute of Edward I (AD 1304) states:

that every *pound* of money or of *medicines* is of *twenty shillings weight*, but the pound of all other things is *twenty-five shillings weight*. The *ounce of medicines* consists of *twenty pence*, and the *pound* contains *twelve ounces* [the troy pound], but in other things the pound contains *fifteen ounces*, in both cases the ounce weighing twenty pence.

These laws unfold the theory of the ancient weights and measures of Great Britain, and reveal the standards (i.e., a natural object, grains of wheat). A difference existed then between the troy and the avoirdupois pound, but the weights now in use are 1/16 heavier than those of Edward I, due to the change subsequently made in the value of the coin by the sovereign. In addition, the true pennyweight standard was lost, and, in the next revision of the weights and measures, the present troy and avoirdupois standards were adopted.

The troy *weight* is of still earlier origin. The great fairs of the eighth and ninth centuries were held at several French cities, including Troyes, the gathering place of traders from all countries. Coins were frequently mutilated, so they were sold by weight, and the standard weight of Troyes for selling coin was adopted for precious metals and medicines in all parts of Europe. The troy ounce and the avoirdupois ounce were originally intended to have the same weight, but after the revision it was found that the avoirdupois ounce was lighter by 42½ gr (grains) than the troy ounce. The subsequent adoption of troy weight by the London College of Physicians in 1618, on the recommendation of Sir Theodore Turquet de la Mayerne who compiled their first pharmacopeia, has entailed upon all apothecaries who are governed by British customs to this day the very great inconvenience of buying and selling medicines by one system of weights (the *avoirdupois*) and compounding them by another (the *apothecary* or *troy*).

In the next century efforts were made toward reforming the standards, and in 1736 the Royal Society began the work that ended in the preparation, by Mr. Bird under the direction of the House of Commons, of the standard *yard* and standard *pound* troy in 1760. Copies of these were prepared and no intentional deviation has been made since.

The growing popularity of the French metric system—and the desirability of securing a standard that could be recovered easily in case of loss or destruction, and that should be commensurable with a simple unit—prompted steps in England to secure these advantages in 1816. The labors of English scientists led to the adoption of the *imperial* measures and standards, which were legalized on January 1, 1826; imperial standards are now in use in Great Britain, thus introducing another element of confusion into an already complicated subject. In this system the *yard* is equivalent to 36 inches, and its length was determined by comparison with a pendulum beating seconds of mean time, in a vacuum, at a temperature of 62°F at the level of the sea in the latitude of London, a length that was found to be 39.1393 inches. The *pound troy* (containing 5760 gr) was determined by comparison with a given measure of distilled water under specified conditions. Thus, a cubic inch of distilled water was weighed with brass weights in air at 62°F, the barometer at 30 inches, and it weighed 252.458 gr. The standard for measures of capacity in Great Britain (either dry or liquid) is the *imperial gallon*, which contains 10 lb avoirdupois (each 7000 gr) of distilled water weighed in air at 62°F, the barometer standing at 30 inches. The *bushel* contains eight such gallons.

George Washington, in his first annual message to Congress, in January 1790, recommended the establishment of uniformity in currency, weights, and measures. Action was taken with reference to the currency and recommendations were made by Thomas Jefferson, then the Secretary of State, for the adoption of either the currently used English systems or a decimal

system. However, nothing was accomplished until 1819–1820, when efforts again were made in the United States to secure uniformity in the standards that were in use by the several states. Finally, after a lengthy investigation, on June 14, 1836, the Secretary of the Treasury was directed by Congress to furnish each state in the Union with a complete set of the revised standards, and thus the *troy pound* (5760 gr), the *avoirdupois pound* (7000 gr), and the *yard* (36 inches) are all identical with the British standards. However, the *US gallon* is quite different; the old wine gallon of 231 inch<sup>3</sup>—containing 58 372.2 gr of distilled water at its maximum density, weighed in air at 62°F, the barometer standing at 30 inches—was retained. The bushel contained 77.274 lb of water under the same conditions, thus making the dry quart about 16 percent greater in volume than the liquid quart.

In 1864 the use of the metric measures was legalized in Great Britain, but was not made compulsory, and in 1866 the United States followed the same course. By the US law of July 28, 1866, all lengths, areas, and cubic measures are derived from the international meter equivalent to 39.37 inches. Since 1893 the US Office of Standard Weights and Measures has been authorized to derive the yard from the meter: one yard equals 3600/3937 m, and the customary weights are referred to the kilogram by an Executive Order approved April 5, 1893. Capacities were to be based on the equivalent; dm<sup>3</sup> equals one liter, the decimeter being equal to 3.937 inches. The gallon still remains at 231 inch<sup>3</sup> and the bushel contains 2150.42 inch<sup>3</sup>. This makes the liquid quart equal to 0.946 liter and the dry quart equal to 1.1013 liter, whereas the imperial quart is 1.1359 liter. The customary weights are derived from the international kilogram, based on the value that one avoirdupois lb equals 453.5924277 g and that 5760/7000 avoirdupois lb equals one troy lb.

Avoirdupois weight is used in general in the United States for commercial purposes, including the buying and selling of drugs on a large scale and occasionally on prescription orders.

### The Metric System

The idea of adopting a scientific standard for the basis of metrology that could be reverified accurately was suggested by a number of individuals after the Renaissance. Jean Picard, the seventeenth-century French astronomer, proposed that the length of a pendulum beating one second of time at sea level, at latitude 45° should be taken as a unit.

In 1783, the Scottish inventor James Watt first suggested the application of decimal notation, and the commensurability of weight, length, and volume. The French National Assembly in 1790 appointed a committee to decide the preferability of the pendulum standard or a terrestrial measure of some kind as a basis for the new system. The committee reported in 1791 in favor of the latter, and commissions were appointed to measure an arc of meridian and to perfect the details of the commensurability of the units and of nomenclature. However, certain inaccuracies were inherent in the early standards, so they do not bear the intended exact relationships to each other. The present accepted standards are defined in publications of the National Institute of Standards and Technology (NIST).

In its original conception, the meter was the fundamental unit of the metric system, and all units of length and capacity were to be derived directly from the meter, which was intended to be equal to one ten-millionth of the earth's quadrant. Furthermore, it originally was planned that the unit of mass, the kilogram, should be identical with the mass of a cubic decimeter of water at its maximum density. At present, however, the units of length and mass are defined independently of these conceptions.

For all practical purposes, calibration of length standards in industry and scientific laboratories is accomplished by comparison with the material standard of length: the distance between two engraved lines on a platinum-iridium bar, the *International Prototype Meter*, which is kept at the International Bureau of Weights and Measures.

The *kilogram* is defined independently as the mass of a definite platinum-iridium standard, the *International Prototype Kilogram*, which also is kept at the International Bureau of Weights and Measures. The *liter* is defined as the volume of a kilogram of water, at standard atmospheric pressure, and at the temperature of its maximum density, approximately 4°C. The *meter* is thus the fundamental unit on which are based all metric standards and measurements of length and area and of volumes derived from linear measurements.

Of basic scientific interest is that on October 14, 1960, the 11th General Conference on Weights and Measures, meeting in Paris, adopted a new international definition for the standard of length: the meter is now defined as the length equal to 1,650,763.73 wavelengths of the orange-red light of the krypton-86 isotope. This standard will be used in actual measurements only when extreme accuracy is needed.

The kilogram is the fundamental unit on which all metric standards of mass are based. The liter is a secondary or derived unit of capacity or volume. The liter is larger by about 27 ppm (parts per million) than the cube of the tenth of the meter (the cubic decimeter): 1 liter = 1.000027 dm<sup>3</sup>.

The conversion tables in this publication that involve the relative length of the yard and meter are based on the relation: 1 m = 39.37 inch, contained in the Act of Congress of 1866. From this relation it follows that 1 inch = 25.40005 mm (nearly).

In recent years engineering and industrial interests the world over have urged the adoption of the simpler relation, 1 inch = 25.4 mm exactly, which differs from the preceding value by only 5 ppm. This simpler relation has not as yet been adopted officially by either Great Britain or the United States but is in wide industrial use.

In the United States, the abbreviation "cc" (for cubic centimeter) still persists in general use and is taken as synonymous for the more correct milliliter. The US Pharmacopeia (USP) IX and National Formulary (NF) IV adopted the term *milliliter* with its abbreviated form *mil*, but it proved so unpopular in practice that the following pharmacopeial convention directed the return to the older term cubic centimeter (cc). However, in 1955, USP XV and NF X once again adopted the term *milliliter* with the abbreviation mL.

National jealousies and the natural antipathy to changing established customs interfered greatly with the adoption of the metric system during the early part of the nineteenth century. At present the metric system is in use in every major country of the world. In the United States and Great Britain it is legalized for reference to and definition of other standards, and it is in exclusive use by nearly all scientists and by increasing segments of industry and the public. In the United States the metric system was legalized in 1866, but not made compulsory; in the same year the international prototype meter and kilogram were adopted as fundamental standards. The US silver coinage was based upon the metric system, the half dollar being exactly 12.5 g and the quarter and the dime being of the proportionate weights.

As corporations became more international, the need for a universal standard increased. Since 1875 there has been established and maintained an International Bureau of Weights and Measures, with headquarters in Paris. This Bureau is managed by an international committee that enjoys universal representation. One objective of the committee is to make and provide prototypes of the meter and kilogram for the subscribing nations; approximately 40 such copies have been prepared.

The US prototype standards of both the meter and the kilogram mass, constructed of a platinum-iridium alloy, were brought from Paris in 1890 and are now in the custody of the NIST in Washington, DC. They have been reproduced and distributed by the US government to the various states having bureaus needing such replicas. The original US prototype meter was taken back to Paris in 1957 for reverification and was found to have altered only 3 parts in 100,000,000 after 67 years of use. Thus, there was no demonstrable change within the limits

of experimental error. With the adoption of the krypton-86 wavelength of light definition for the meter the different countries have the means to check their prototype meter bars without returning them to Paris at periodic intervals for comparison with the international meter bar.

## ORTHOGRAPHY AND READING

### Orthography

There are two methods of orthography of the metric units in use. In the original French, the units are spelled *metre*, *litre*, and *gramme*; in the method proposed by the American Metric Bureau, the units are spelled *meter*, *liter*, and *gram*. For three decades after the original adoption of the metric system, the USP and NF adopted *meter* and *liter*, but used the French *gramme*. Now these official compendia use the spelling *gram*.

### Reading

Some difficulty is usually experienced by those unfamiliar with the metric system in reading the quantities. In the linear measures in pharmacy, centimeters and millimeters are used almost exclusively; thus, 0.05 m would not be read five hundredths of a meter, but rather five centimeters (5 cm); if the millimeter column contains a unit, as in 0.055 m, it is read 55 millimeters (55 mm) in preference to fifty-five thousandths of a meter.

Fractions of a millimeter must be read decimally, as 0.0555 m, fifty-five and five-tenths millimeter (55.5 mm). In measures of capacity, cubic centimeters (cc) or milliliters (mL) are used exclusively for quantities of less than a liter. The terms half-liter, quarter-liter, 100 milliliters, and one milliliter are denoted by 500 mL, 250 mL, 100 mL, and 1 mL respectively.

In weight, when the quantity is relatively large and in commercial transactions, the *kilogram* is abbreviated to *kilo*. When less than a *kilogram* and not less than a *gram*, the quantity is read with the *gram* for the unit. Thus, 2000 g would be read either as 2000 grams or as 2 kilos, and 543 g would be read as 543 grams; 2543 g is sometimes read as 2 kilos and 543 grams, although 2543 grams usually is preferred.

For quantities below the *gram*, decigram and centigram usually are not used, but rather *milligram* has been regarded as the most convenient unit. With the increase in the use of extremely small doses of very potent drugs and the wide application of more delicate analytical procedures, the term *microgram* (mcg, µg, or γ), for thousandths of a milligram, is frequently used to designate quantities up to 999 µg (less than 1.000 mg).

Both the metric and English systems of weights and measures are in use in the United States. Even though the metric system has nearly replaced the English system, the pharmacist must have a practical knowledge of both.

## WEIGHTS

### The Metric System

The USP of 1890 adopted the metric system of weights and measures to the exclusion of all others except for equivalent dosage statements, and the British Pharmacopoeia of 1914 did likewise. In 1944 the Council on Pharmacy and Chemistry of the American Medical Association adopted the metric system exclusively. The advantages of the metric or decimal system, and its simplicity, brevity, and adaptability to everyday needs are now conceded universally.

### FRACTIONAL AND MULTIPLE PREFIXES

In many experimental procedures, including some in the pharmaceutical sciences, very small (and occasionally very large) quantities of weight, length, volume, time, or radioactivity are measured. To avoid the use of numbers with many zeros in such cases, the NIST recognizes prefixes to be used to express fractions or multiples of the International System of Units (SI), which was established in 1960 by the General Conference on

Weights and Measures (see the foregoing discussion). The recognized prefixes, which in use are adjoined to an appropriate unit (as, for example, in such quantities as nanogram, picomole, microcurie, microsecond, or megavolt) are defined in Table 9-1.

Table 9-2 lists some metric weights. The prefixes, which indicate multiples, are of Greek derivation: deka, 10; hecto, 100; kilo, 1000. Fractions of the units are expressed by Latin prefixes: deci, 1/10; centi, 1/100; milli, 1/1000.

Only a few of the most convenient denominations are employed in practical work. Whole numbers from one to 1000 are usually expressed in terms of grams, while the kilogram is used as the unit for larger quantities. Quantities between one milligram and one gram are usually referred to in terms of milligrams; microgram ( $\mu\text{g}$  or mcg) is used in quantitative analysis, biological studies, and for minute dosage statements.

### The English Systems

In the United States, both the avoirdupois and apothecary systems of weight measurement sometimes are used in handling medicines. It must be emphasized that *pharmacists may buy their drugs by avoirdupois weight*. These two systems differ:

1 pound avoirdupois = 7000 gr and is abbreviated lb.

1 pound apothecary = 5760 gr and is abbreviated tb.

1 ounce avoirdupois = 437.5 gr and is abbreviated oz.

1 ounce apothecary = 480 gr and is abbreviated ℥.

The *grain avoirdupois* is exactly the same as the *grain apothecary*. The apothecary pound is therefore 1240 gr lighter than the avoirdupois pound, and the apothecary ounce is therefore 42.5 gr heavier than the avoirdupois ounce.

The abbreviations of the denominations of apothecary weight are represented by the signs ounce, ℥; dram, ℥; scruple, ℥; and grain, gr. These have been in use for a long time but possibly may be mistaken for one another in rapid or careless writing. The abbreviations or signs of avoirdupois weight differ from those of apothecary weight, and care should be used not to confound them; they are lb (sometimes written #), pound: oz, ounce: gr, grain. Tables 9-3–9-5 show three English systems of weight.

**Table 9-1. Prefixes for Fractions and Multiples of SI Units**

Fraction	Prefix	Symbol	Multiple	Prefix	Symbol
10 <sup>-1</sup>	deci	d	10	deka	da
10 <sup>-2</sup>	centi	c	10 <sup>2</sup>	hecto	h
10 <sup>-3</sup>	milli	m	10 <sup>3</sup>	kilo	k
10 <sup>-6</sup>	micro	μ	10 <sup>6</sup>	mega	M
10 <sup>-9</sup>	nano	n	10 <sup>9</sup>	giga	G
10 <sup>-12</sup>	pico	p	10 <sup>12</sup>	tera	T
10 <sup>-15</sup>	femto	f	10 <sup>15</sup>	peta	P
10 <sup>-18</sup>	atto	a	10 <sup>18</sup>	exa	E

**Table 9-2. Metric Weight**

1 microgram $\mu\text{g}$	= 0.000001 g
1 milligram mg	= 0.001 g
1 centigram cg	= 0.01 g
1 decigram dg	= 0.1 g
1 gram g	= 1 g
1 dekagram dag	= 10 g
1 hectogram hg	= 100 g
1 kilogram kg	= 1000 g

Note: The abbreviation  $\mu\text{g}$  or mcg is used for microgram in pharmacy, rather than gamma ( $\gamma$ ) as in biology.

**Table 9-3. Avoirdupois Weight**

Pounds	Ounces	Grains
1 =	16 =	7000
	1 =	437.5

Note: 2000 lb = 1 ton, and 2240 lb = 1 long ton.

**Table 9-4. Apothecary Weight**

Pounds	Ounces	Drams	Scruples	Grains
1 =	12 =	96 =	288 =	5760
	1 =	8 =	24 =	480
		1 =	3 =	60
			1 =	20

**Table 9-5. Troy Weight**

Pounds	Ounces	Pennyweights	Grains
1 =	12 =	240 =	5760
	1 =	20 =	480
		1 =	24

Jewelers evaluate precious stones with troy weight, which is very similar to apothecary weight. The apothecary and troy grain, ounce, and pound are identical, but the ounces are subdivided differently. The *carat*, used by jewelers, is equal to 3.168 troy grains or four carat grains. When used to express the fineness of gold, one carat signifies 1/24 part. A 14-carat ring is 14/24 pure gold.

As indicated in the footnote to Table 9-6, a number of special metric system units are used in various pharmacopeial and nonofficial descriptions, tests, and assays of drugs and other substances to express linear measurements of very small dimension. These units and their symbols or abbreviations are listed in Table 9-7, together with their equivalents in terms of the other metric units and the inch.

**Table 9-6. Metric Linear Measure**

1 nanometer (nm)	= 0.000000001 m (0.001 $\mu\text{m}$ : 10 <sup>-9</sup> m: 10 Å)
1 micrometer ( $\mu\text{m}$ )	= 0.000001 m (0.001 mm: 10 <sup>-6</sup> m: 10 000 Å)
1 millimeter (mm)	= 0.001 m
1 centimeter (cm)	= 0.01 m
1 decimeter (dm)	= 0.1 m
1 meter (m)	= 1 m
1 dekameter (dam)	= 10 m
1 hectometer (hm)	= 100 m
1 kilometer (km)	= 1000 m

Although the meter (m) is observed to be the initial unit, it is seldom necessary to use it in pharmaceutical practice, and the same holds true for a number of the above measures. The micrometer ( $\mu\text{m}$ ), millimeter (mm), and centimeter (cm) are employed in the description of many official drugs. Measurements pertaining to spectrometric and colorimetric tests and assays of many official drugs are recorded in micrometers ( $\mu\text{m}$ ) or reciprocal centimeters ( $\text{cm}^{-1}$ ) for infrared and in nanometers (nm) for ultraviolet and visible wavelengths of light, respectively.

**Table 9-7. Equivalent Linear Measurements**

Unit	Inches	mm	$\mu\text{m}$	nm	$\text{\AA}$
1 inch	1	25.4	25 400	$2.54 \times 10^7$	$2.54 \times 10^8$
1 mm (millimeter)	0.0394	1	1000	$10^6$	$10^7$
1 $\mu\text{m}$ (micrometer)	$3.94 \times 10^{-5}$	$10^{-3}$	1	1000	10 000
1 nm (nanometer)	$3.94 \times 10^{-8}$	$10^{-6}$	$10^{-3}$	1	10
1 $\text{\AA}$ (angstrom unit)	$3.94 \times 10^{-9}$	$10^{-7}$	$10^{-4}$	0.1	1

## MEASURES

### Systems

Two systems of linear measure are used in the United States: English and metric. Two systems of liquid measure are used: apothecary (also called the wine measure or US liquid measure) and metric. The units of the English system of linear measure (inch, foot, yard, and mile) are well known, and need not be described here. The units of the metric systems of linear and liquid measure, and of the apothecary (wine, US liquid) system of liquid measure, with their respective equivalents, are given in Tables 9-7, 9-8, and 9-9.

Pharmacists who fill Canadian or British prescriptions should also be familiar with the substantially different British imperial liquid measure system; the units, with their equivalents, are given in Table 9-10.

The following facts concerning the US system of liquid measure (see Table 9-9) should be noted:

- The apothecary fluid ounce (f ℥) of distilled water weighs 455 gr at 25°C.
- The apothecary pint contains 16 f ℥.
- The US gallon contains 128 f ℥ or 231 inch<sup>3</sup>. One gallon of distilled water weighs 8.337 avoirdupois lb at 62°F. The US pint therefore weighs 1.04 avoirdupois lb and the pound of distilled water measures only 0.96 pt. *One pound does not measure one pt.*

The following facts concerning the imperial system (see Table 9-9) should be noted:

- The imperial fluid ounce of distilled water weighs 437.5 gr at 15.6°C (60°F). It therefore weighs one avoirdupois oz.
- The imperial pint contains 20 f ℥.
- The imperial gallon contains 160 f ℥. One gal of distilled water weighs 10 avoirdupois lb; 16 f ℥ in this system therefore weighs one avoirdupois lb.

From the above, one can deduce the following:

- The US fluid ounce and minim are larger than the imperial fluid ounce and minim (<imperial>). One US minim or fluid ounce equals 1.04 imperial minims or fluid ounces.
- The imperial pint and gallon are much larger than the US pint and gallon.

*It is, therefore, inaccurate to use measuring devices calibrated in the US system in measuring quantities directed in English prescriptions when the imperial measure is intended. Conversely, devices calibrated in the imperial system should not be used to measure quantities directed in US prescriptions when the US measure is intended.* For example, Canadian pharmacists using American graduated cylinders should calculate percentage solutions on the basis of 454.6 gr of distilled water to the fluid ounce. This is one more argument in favor of adoption internationally by all pharmacists of the metric system of weights and measures.

## THE RELATIONSHIPS OF WEIGHTS AND MEASURES

When the systems of weights and measures in use in the United States are examined, the lack of close relation between the different units is appreciated at once. Nevertheless, if the following points are used carefully, many pharmaceutical problems will be greatly simplified.

- Pharmacists may weigh themselves, buy merchandise, sell over the counter, and calculate postage, etc., using avoirdupois weight, which contains 437.5 gr in 1 oz.
- Pharmacists may compound formulas by apothecary weight, which contains 480 gr in 1 ℥.
- One apothecary fluid ounce of water weighs 455 gr at 25°C. Since 480 minim weigh 455 gr, 1 minim weighs  $455/480 = 0.95$  gr. 1 minim does *not* weigh 1 gr. 1 f ℥ does *not* weigh 1 ℥.

### Practical Equivalents

Tables of weights and measures and a table of practical equivalents should be kept in a conspicuous and convenient place

**Table 9-8. Metric Liquid Measures**

1 microliter ( $\mu\text{L}$ )	= 0.000001 L
1 milliliter (mL)	= 0.001 L
1 centiliter (cL)	= 0.01 L
1 deciliter (dL)	= 0.1 L
1 liter (L)	= 1 L
1 dekaliter (daL)	= 10 L
1 hectoliter (hL)	= 100 L
1 kiloliter (kL)	= 1000 L

Note: The standard of capacity is the liter, which is the volume of 1 kg of distilled water at its maximum density (approx. 4°C). Microliters ( $\mu\text{L}$ ) are used to measure volumes of solutions used in chromatographic procedures for the separation and quantitative determination of some official drugs.

**Table 9-9. Apothecary or Wine Measures (US)**

Gallon	Pints	Fluid ounces	Fluidrams	Minims
1	8	128	1024	61 440
	1	16	128	7 680
		1	8	480
			1	60

**Table 9-10. Imperial Measure (British)**

Gallon	Pints	Fluid ounces	Fluidrams	Minims
1	8	160	1280	76 800
	1	20	160	9 600
		1	8	480
			1	60

in the prescription department, and the following equivalents, which are given with practical accuracy, should be committed to memory. Other equivalents may be calculated from these.

### LINEAR MEASURE

1 meter = 39.4 inches  
 1 inch = 2.54 cm = 25.4 mm  
 1 micrometer = 1/1000 mm = 10<sup>-6</sup> m = 1/25, 400 inch

### LIQUID MEASURE

1 milliliter = 16.2 minim  
 1 fluid ounce = 29.6 mL  
 1 pint = 473 mL  
 1 gallon = 3790 mL

### WEIGHT

1 kilogram = 2.20 lb avoird  
 1 pound avoird = 454 g  
 1 ounce avoird = 28.4 g  
 1 ounce apothecary = 31.1 g  
 1 pound apothecary = 373 g  
 1 gram = 15.4 gr  
 1 grain = 64.8 mg

A table of metric doses with approximate apothecary equivalents is given in Appendix 9A.

### Approximate Measures

In apportioning doses for a patient, the practitioner is usually compelled to order the liquid medicine to be administered in certain quantities that have been established by custom, and estimated as shown in Table 9-11.

In almost all cases, careful tests have found that modern teacups, tablespoons, dessertspoons, and teaspoons average 25 percent greater capacity than the theoretical quantities given in Table 9-11. The physician and the pharmacist therefore should recommend the use of accurately graduated medicine droppers, teaspoons, and calibrated measuring devices, which may be procured at a small cost (Figure 9-1).

### Approximate Dose Equivalents

For many years the apothecaries' system of weights and measures was used widely by physicians and pharmacists when considering the doses of medicinal substances, and it was customary to translate these apothecary doses into relatively exact amounts when the metric equivalents were mentioned. Today, however, doses are established primarily in the metric system without considering the relation of these metric figures to the corresponding quantities in any other system of weights and measures.

It should be emphasized that exact alternative formulas in the avoirdupois system of weights and measures are not

Figure 9-1. Examples of measuring devices.

obtained by using approximate equivalents but, for the purpose of compounding, should be calculated with the use of practical equivalents.

## WEIGHING AND MEASURING

Having studied the several systems of weights and measures, students may now learn to apply their knowledge to the *weighing* and *measuring* of pharmaceuticals. The former process requires the use of the *balance*, or, for manufacturing purposes, *scales*, and the latter process requires the use of the *measure*, the *graduate*, and the *pipet*. The successful performance of many of the operations in pharmacy depends on a thorough knowledge of the principles of the balance and a correct understanding of its care and use; because weighing is nearly always the preliminary step in any compounding, it will be discussed first.

There is a relativity of accuracy in weighing (or measuring) that must not be overlooked, as illustrated by the following graded list: coal, salt, sugar, epsom salt, penicillin G, morphine, digoxin, vitamin B<sub>12</sub>, and radium. One of the most important things for the pharmacist to learn is the degree of tolerance or error permissible in weighing or measuring any particular ingredient. Obviously, the final item on the list, radium, must be measured with much greater precision and accuracy than coal, the first item.

The empiric weighing and measuring methods of the kitchen, embodied in such concepts as a handful, a pinch, or "sweeten to suit your taste," have no place in pharmacy. Accurate work can be accomplished only by means of suitable apparatus.

### WEIGHING

In pharmacy, weighing usually refers to ascertaining a definite weight of material to be used in compounding a prescription or manufacturing a dosage form.

The *balance* may be defined as an instrument for determining the relative weights of substances. It should be selected correctly for the specific task at hand, used skillfully, protected from damage, and checked periodically, if accurate results are to be obtained. Of even greater importance is its construction. Standards for balances are given by the NIST.<sup>1</sup>

### Construction of the Balance

For systematic consideration pharmaceutical balances may be classified as follows: single-beam (equal-arm or unequal arm), compound lever, torsion, and electronic.

#### SINGLE-BEAM EQUAL-ARM BALANCES

The principle on which single-beam equal-arm balances (or scales) operate is clearly evident in the construction of the

Table 9-11. Approximate Measures Established by Custom

Household Measurement	Apothecary Notation	Metric Volume
1 tumblerful	f ℥ viii	240 mL
1 teacupful	f ℥ iv	120 mL
1 wineglassful	f ℥ ii	60 mL
2 tablespoonfuls	f ℥ i	30 mL
1 tablespoonful	f ℥ iii or ℥ ss	15 mL
1 dessertspoonful	f ℥ ii	8 mL
2 teaspoonful	f ℥ i	5 mL
1/2 teaspoonful	f ℥ ss	2.5 mL

Note: one drop is often considered to be one minim, but this is incorrect, as drops are variable.

classical two-pan analytical balance. This type has a metallic lever or beam, divided into two equal arms at the center by a knife-edge, on which it is supported. At exactly equal distances from this point of support, and situated in the same plane, are placed the end knife-edges; these suspend the pans, which carry the substances to be weighed. A properly constructed balance of this type should meet the following requirements:

- *When the beam is in a horizontal position, the center of gravity should be slightly below the point of support, or central knife-edge, and perpendicular to it.* The relative sensitivity of the balance depends on the fulfillment of this principle, which may be illustrated roughly by forcing a pin through the center of a circular piece of pasteboard. If the edge of the pasteboard is touched slightly, it does not oscillate at all, but rather revolves around the center to a degree corresponding to the impulse given it. In this position it illustrates neutral equilibrium. If the pin is removed and inserted at a very short distance above the center, and the edge of the pasteboard touched as before, it will oscillate slowly, corresponding to a very sensitive beam, the point of support being slightly above the center of gravity as in the balance. If the pin is removed again and inserted far above the center, and the same impulse imparted to the edge, it will oscillate quickly, illustrating stable equilibrium characteristic of a beam that comes to rest quickly and is not particularly sensitive. Unstable equilibrium may be illustrated by balancing the disc so that the point of support is below the center. The slightest touch then causes it to reverse its position completely and finally come to rest with the center of gravity below the point of support.
- *The end knife-edges must be exactly equal distances from the central knife-edge; they all must be in the same plane and the edges absolutely parallel to each other.* It is apparent that the conditions of a good prescription balance cannot be satisfied if there is inequality in the length of the arms of the beam. The distance from the central knife-edge to the one on the left must be exactly the same as the distance from the central knife-edge to the one on the right, otherwise unequal weights would be required to establish equilibrium. If the central knife-edge is placed either above or below a line drawn so that it connects the end knife-edges, the loading of the pans either will cause the beam to cease oscillating or diminish the sensitivity in proportion to the load. If the knife-edges are not parallel, the weight of a body will not be constant upon every part of the pan, but will be greater if placed near the edge on one side, and correspondingly less at a point directly opposite.
- *The beam should be inflexible, but as light in weight as possible, and the knife-edges in fine balances should bear upon agate plates.* The rigidity of the beam is necessary because any serious deflection caused by a loading of the pans would lower the end knife-edges and thus accuracy in weighing would be impossible. The beam should not be heavier than necessary because the sensitivity of the balance thereby would be lessened; to diminish friction, which constantly increases with the age and use of a balance, the bearings of the knife-edges should be agate plates—polished flat pieces of the very hard mineral called agate. A single-beam equal-arm balance with the rider beam graduated to 28 g in increments of 0.2 g, and to 1 oz in increments of 0.01 oz, is shown in Figure 9-2.

#### UNEQUAL-ARM BALANCES

The unequal-arm balance is the type preferred for laboratory work when large amounts are to be weighed (Figure 9-3). The

**Figure 9-2.** Single-beam equal-arm balance. (Courtesy of OHAUS Corporation.)

lever principle on which these scales are constructed is based on the law of physics that at equilibrium the force applied at one end of the lever multiplied by the length of the arm (distance from the fulcrum to the point where the force is applied) must be equal to the product of the force acting at the opposite end of the lever and the length of the other arm. The inequality in the length of the arms of this beam permits the convenient use of movable weights upon the graduated longer arm of the beam, thus dispensing with the use of small weights, which are liable to be lost. This scale is of great advantage in laboratory or manufacturing work because it is particularly adapted for weighing liquids; a sliding tare is set on one beam for the weight of the container, and other sliding weights can be adjusted to the weight of liquid desired. These are available with the beams graduated either in the avoirdupois or metric system.

#### COMPOUND-LEVER BALANCES

The principle of the compound lever was first applied in the construction of balances by Roberval of Paris, in about AD 1660. It was skillfully adapted for both prescription balances and the general counter and platform scales. The principal objection to this type of scale, when compared with single-beam balances, consists in the multiplicity of points of contact and suspension, thus necessarily increasing friction and the liability to disarrangement; however, their general convenience has made them popular.

**Figure 9-3.** Manufacturing laboratory scale and weights. (Courtesy of OHAUS Corporation.)

### TORSION BALANCES

A simple illustration of the principle of torsion is afforded by tying a stout piece of cord to a firm support and inserting a lead pencil in the middle of the cord between the strands, at right angles to it. If the free end of the cord is stretched tightly, resistance is offered to any effort to turn the lead pencil over; if the pencil is released, it at once flies back to its original position. *Torsion* is the term applied to this method of twisting. The principle of supporting the beam of a balance on a tightly stretched wire, with the view of doing away with knife-edges and diminishing friction, occupied the attention of inventors for years.

In 1882 Professor Roeder and Dr. Springer contrived an ingenious torsion balance that gave promise of valuable results. Two illustrations of this original balance were shown on page 54 of the first edition of *Remington's Practice of Pharmacy* in 1885. Improvements have increased its efficiency greatly. The most important difficulty in applying the principle of torsion resistance was overcome by placing a weight just above the center of gravity. Torsional resistance tends to keep the beam in a horizontal position, while the elevation of a weight above the center of gravity, by its tendency to produce unstable equilibrium, exercises an opposite effect—the beam is inclined to be top heavy and, therefore, to tip on either side. If now the weight is made adjustable by mounting it upon a perpendicular screw so that it can be raised or lowered, it is possible to arrange these opposite forces so that one exactly neutralizes the other. In this manner sensitivity is obtained.

The torsion principle has been applied to prescription balances, as well as analytical balances and scales designed to carry heavier loads. In the torsion prescription balance two beams are used, supported on three frames, each of the latter having a flattened metallic band stretched tightly over its edge.

The torsion balance, which has a rider beam graduated upon the upper edge from 1/8 to 15 gr and on its lower edge from 0.01 to 1.0 g, furnishes a very convenient means of weighing small quantities without having to use small weights. Most modern balances have a direct-reading dial instead of a rider beam, with the metric scale on the upper scale and the apothecary scale on the lower.

The prescription balance may be placed upon a base containing a drawer that can be used for holding weights or powder papers.

### ELECTRONIC BALANCES

Electronic balances are single-pan balances with digital or direct-reading features (Figure 9-4). Taring a weighing paper,

**Figure 9-4.** Electronic single-pan balance. (Courtesy of OHAUS Corporation.)

weigh boat, or beakers is done automatically with the push of a button or lever without the need of external balancing weights. These balances are much more sensitive than the traditional prescription balance, are easier and quicker to use, but are usually more expensive than a torsion balance.

### Prescription Balances

The most common type of prescription balance uses the taut-wire frame or torsion principle. Such balances, manufactured to meet the requirements of the NIST Class III balances, have a maximum maintenance sensitivity of 6 mg with no load and with full load (i.e., addition of the 6 mg weight to one pan causes the indicator or the rest point to be shifted not less than one division on the index plate). The Class III balance is used to weigh quantities up to 60 g, depending on the stated capacity and subject to the physical limit of the amount of the material that can be placed on the pan. Electronic balances typically have a sensitivity less than 10 mg (easily meeting standards for a Class III balance) and can weigh small quantities of drug more accurately than a torsion balance. All prescription departments must have a Class III balance.

### REQUIREMENTS

A prescription balance should meet the following general requirements:

- It should be constructed so as to support its full capacity without developing undue stresses, and should not be thrown out of adjustment by repeated weighings of the capacity load. (The capacity of the balance will be seen on the metal plate attached to it.) If the capacity is not stated, it is assumed to be at least 15 g (½ oz). The Class III balances usually have a capacity of 60 g (2 oz).
- The removable pans of a torsion prescription balance should be of equal weight. If the pans show any difference in weight, they should be adjusted by leveling the balance or using small pieces of paper. Pans with any appreciable corrosion or wear should be refinished or replaced.
- A prescription balance should have a leveling device, usually leveling feet or screws, so that the balance can be adjusted to a level position. A balance that does not have these is not entitled to be designated as a prescription balance.
- The balance that has a rider or graduated dial should have, at the end of the graduation, a stop that halts the rider or dial at the zero reading. The reading edge of the rider should be parallel to the graduations on the beam.
- The indicator points, when there are two on the balance, should be sharp, and their ends should not be separated by more than 1 mm (0.04 inch) when the scale is in balance. The distance from the face of the index plate to the indicator pointer or pointers should be small (1 mm or less) to protect the operator against making errors resulting from parallax, because it is unlikely that the eye of the operator will be exactly in line with the indicator and the division on the index plate. The indicating elements as well as the lever system of the balance should be protected against drafts. The balance should have a lid that allows a weighing to be made when the lid is closed.
- A torsion prescription balance must have a mechanical means for arresting the oscillation of the mechanism.

### TESTING

Certain tests may be used to satisfy the user regarding the construction and character of a torsion balance when its origin, history, or condition is in doubt. Additional tests are carried

out by the NIST, manufacturers, and local and state testing agencies.

A Class III torsion prescription balance meets the following basic tests. Use a set of *test weights* and keep the rider or graduated dial at zero unless directed to change its position.

- Sensitivity requirement: Level the balance, determine the rest point, place a 10 mg weight on one of the empty pans, and again determine the rest point. Repeat the operation with a 10 mg weight in the center of each pan. The rest point is shifted not less than one division of the index plate each time the 10 mg weight is added. The sensitivity requirement for an electronic balance is supplied by the manufacturer.
- Arm ratio test: This test is designed to check the equality of length of both arms of the balance. Determine the rest point of the balance with no weight on the pans. Place 30 g of test weights in the center of each pan and determine the rest point. If the second rest point is not the same as the first, place a 20 mg weight on the lighter side; the rest point should move back to the original place on the index plate scale or farther.
- Shift tests: These tests are designed to check the arm and lever components of the balance.
  - a. Determine the rest point of the indicator without any weights on the pans.
  - b. Place one of the 10 g weights in the center of the left pan, and place the other 10 g weight successively toward the right, left, front, and back side of the right pan, noting the rest point in each case. If in any case the rest point differs from the rest point determined in (a), add the 10 mg weight to the lighter side; this should cause the rest point to shift back to the rest point determined in (a) or farther.
  - c. Place a 10 g weight in the center of the right pan, and place a 10 g weight successively toward the right, left, front, and back sides of the left pan, noting the rest point in each case. If in any case the rest point is different from that obtained with no weights on the pans, this difference should be overcome by addition of the 10 mg weight to the lighter side.

A balance that does not measure up to these tests *must* be corrected.

- Rider- and graduated-dial tests: Determine the rest point for the balance with no weight on the pans. Now place on the left pan the 500 mg test weight and move the rider to the 500 mg point on the beam. Now determine the rest point. If it is different from the zero rest point, add a 10 mg weight to the lighter side. This should bring the rest point back to its original position or farther. Repeat this test, using the 1 g test weight and moving the rider or graduated dial to the 1 g division. If the rest point is different it should be brought back at least to the zero rest point position by the addition of 10 mg to the lighter pan. If the balance does not meet this test, the graduated beam or the rider must be corrected. For balances equipped with a dial scale, the dial must be corrected.

### PROTECTION

The necessity for protecting the delicate mechanism of a balance is overlooked frequently, notwithstanding the possibility of having a precision apparatus irretrievably ruined by lack of care in using or cleaning it or in protecting it while at rest. The position chosen for the balance or scales should be on a level and firm counter, desk, or table, where it will be subjected to little risk of damage from dampness, dust, or corrosive vapors and where the knife-edges will not be liable to become dulled by jarring or other vibrations.

In the analytical class of balances, protection is afforded by enclosing them in glass cases having sash doors in the front, sides, or back. They are protected against damage from vibration by a lever for elevating or locking the beam, so that the knife-edges are not in contact with any surface when not in use. To prevent damage from jarring while the balance is in use, from a weight falling on the pan, or other accident, the finest balances are provided with pan supports, which break the fall and serve the additional purpose of quickly arresting the beam, thus saving time while weighing.

In using a prescription balance, neither the weights nor the substance that is to be weighed should be placed on the balance pans while the beam is free to oscillate. The desired weight should be placed upon one pan (usually the one on the right-hand side) and an amount of the substance to be weighed, approximately the desired weight, upon the opposite pan. The beam should be released by means of the lever, and if the substance is in excess, the beam should be locked and a small portion removed and the beam again released and the oscillations observed. This procedure should be repeated until the correct amount is obtained. In case of a deficiency of the substance to be weighed, the reverse procedure is followed until the correct amount is obtained. With practice this can be done very deftly and very quickly and the sensitivity of the balance retained for years.

Substances that react with metals, such as iodine, and those that are adhesive, such as the extracts, should not be weighed directly upon the pans, but rather upon counterpoised watch crystals, or upon glazed paper, care being taken to balance the papers before weighing the substance. In cleaning the balances, great care should be exercised; polishing powders should be used sparingly, as a portion is very apt to find its way into crevices and elude detection until an attempt is made to adjust the balances, when the increased weight of one of the sides of the beam leads to its discovery. Frequent cleaning with soft leather generally is sufficient to keep a balance in good order, but once neglect makes it necessary to use more active measures, some simple polishing powder for the metal work, soap-suds for the nickel plate, and simple brushing for the lacquered brass are all that is necessary.

As the pans are subjected to more wear and tear than any other part of the balance, it is economical to use *solid* rather than *plated* pans because constant friction wears off the plating and the additional cost for replating soon absorbs the difference in price. Equipped in this way, and with agate bearings, a prescription balance is durable and really inexpensive because it will remain fully equal to the most exacting demands for a long time.

### Weights Used in Pharmacy

The weights used by the pharmacist are very important, and care in their selection and examination is necessary. False economy must be avoided, as the use of cheap, inaccurate weights ultimately leads to serious consequences. Official inspectors have found pharmacies using prescription weights that were so worn that the characters on their faces had disappeared; also, weights have been found with bits of hardened extract and dirt almost entirely obscuring their characters. An unused set of standard weights should be kept on hand so that at least once a year the weights in daily use can be tested and adjusted or rejected if necessary. The standard weights should be used also when the balance is tested. The set should contain the following weights in a well-fitted box with forceps: one 50 g, two 20 g, one 10 g, one 5 g, two 2 g, one 1 g, one 500 mg, two 200 mg, one 100 mg, one 50 mg, two 20 mg, and one 10 mg, all adjusted to NIST tolerances for analytical or Class P weights.

### METRIC WEIGHTS

For weighing larger quantities, japped iron metric weights are available. They are preferably hexagonal, to distinguish them from the round avoirdupois weights. Sets of brass weights,

usually in the range of 10 g to 1000 g, fitted into holes of appropriate size in a block of plastic (*block weights*), are especially convenient for many weighing operations. For prescription compounding, accurate sets of weights ranging from 10 mg to 50 g are available.

For analytical purposes, metric weights are used exclusively; usually, the highest weight is 100 g, the lowest 1 mg. The weights from 1 g upward are of finely lacquered brass or of non-magnetic stainless steel or rhodium-plated bronze. The smaller weights are made of squares of platinum or aluminum foil, with one edge turned up to permit them to be handled easily with the forceps. Fractions of a milligram are weighed by means of the rider on the graduated beam of the balance.

In analytical work and in using the Class III balance in prescription work, the weights should never be handled with the fingers but always with the forceps which accompany an accurate set of weights. In the more expensive sets of weights the forceps are tipped with bone, ivory, or plastic to prevent the wearing away of the weights during handling. With proper care the accuracy of a fine set of weights may be maintained for years.

### COMMON AVOIRDUPOIS WEIGHTS

Avoirdupois weights are usually made of iron, and are flat and circular and japanned to prevent rusting. These weights form a pyramidal pile, and range from ½ oz to 4 lb; if found to be incorrect, they may be adjusted by adding to or diminishing the amount of lead that is hammered into a depression in the base of each weight. They are sometimes made of brass in this form, and sometimes of zinc (the latter, however, are brittle and unserviceable). For general use in the pharmacy, the cylindrical weights, known technically as block weights, are preferable. The advantages of block weights are that the gaps left by missing weights are readily noticeable, and the greater part of the surface of the weight is protected from the action of corrosive vapors when the weights are not in use.

### APOTHECARY WEIGHTS

Apothecary weights may be obtained either as *block weights* or in the less-desirable *flat* forms. The round, flat, brass *dram* weights, which have the denomination stamped on their faces in raised characters, are still used but should be replaced. With flat weights, the denomination is often only faintly stamped on the face and thus is liable to be obliterated by constant use or by corrosive contact.

Undoubtedly, the best grain weights are the aluminum wire weights. The wire weights are less susceptible to corrosive action than are the brass weights. Also, the wire weights are more easily and quickly distinguished from one another than are other weight forms, so there is less likelihood of dangerous mistakes: the number of sides in the wire weights at once gives the denomination.

Aluminum grain weights, which are cut out of aluminum plates, are also less liable to be corroded. They usually can be more accurately adjusted than brass weights. The corners of the aluminum weights are clipped, and each weight is usually pressed into a curved form so that it may be picked up easily (Figure 9-5).

Figure 9-5. Aluminum wire and aluminum grain weights.

The need for apothecary weights in modern practice is decreasing. Apothecary weights can easily be converted to the corresponding metric weights, which are easier to use and less prone to error. In addition, electronic balances do not use external weights. Typically, an electronic balance can display weights in several systems at the discretion of the operator.

### Minimum Weighable Quantity

All of the balances described must be used within a degree of error that can be tolerated in prescription compounding and in pharmaceutical manufacturing. The USP allows a maximum error of 5 percent in a single weighing operation. Since the sensitivity requirement of a balance represents the absolute error in using that balance, the percent error will depend on the amount of drug weighed and will increase as the amount of drug decreases.

The minimum weighable quantity (MWQ) with no more than 5 percent error can be calculated for any balance knowing the sensitivity requirement (SR) (i.e., the absolute error) from the following:

$$\text{MWQ} = \text{SR} \frac{100\%}{5\%}$$

### EXAMPLES

Calculate the MWQ with no more than a 5 percent error for a balance with a sensitivity requirement of 10 mg.

$$\text{MWQ} = 10 \text{ mg} \frac{100\%}{5\%} = 200 \text{ mg}$$

Calculate the MWQ with no more than a 3 percent error for a balance with a sensitivity requirement of 2.5 mg.

$$\text{MWQ} = 2.5 \text{ mg} \frac{100\%}{3\%} = 83.3 \text{ mg}$$

### MEASURING

In pharmacy, *measuring* usually refers to the exact determination of a definite volume of liquid. Many types of apparatus are used in this operation, depending on the kind and quantity of liquid to be measured and the degree of accuracy required. (The NIST has requirements for graduates.<sup>1</sup>)

### Large Quantities

Glass measures are preferred for measuring liquids. Although glass measures are subject to breakage, they can indicate volume more accurately because of the transparency of glass.

### THE MENISCUS

When an aqueous or alcoholic liquid is poured into a graduate, surface forces cause its surface to become concave—the portion in contact with the vessel is drawn upward. This phenomenon is known as the formation of a *meniscus* (Figure 9-6), and in determining the volume of a liquid *the reading must be made at the bottom of this meniscus*. This regulation has been established by the NIST, and all glass measuring vessels are graduated on this basis. Liquids with large contact angles, such as mercury, form an *inverted meniscus*, and the reading then is made at the top of the curved surface.

### PROCEDURE

Pharmaceutical manufacturers package liquid preparations in glass or plastic containers equipped with a plastic screw-cap. These containers serve as a stock bottle from which liquids may be poured directly into a graduate. The procedure for pouring liquid from screw-capped containers is as follows:

1. Remove the cap and place it on the counter while the transfer of liquid is made.

Figure 9-6. Error of measurement due to parallax.

2. While holding the graduate in the left hand, grasp the original container with the label in such a position that any excess of liquid will not soil the label if it should run down the side of the bottle.
3. Raise the graduate and hold it so that the graduation point to be read is on a level with the eye, and measure the liquid. (The extension of the graduating mark into a circle that passes entirely around the graduate is an improvement that obviates the necessity of placing the graduate upon a level place, as the corresponding mark upon the opposite side may be seen through the glass and the graduate easily leveled even when held in the hand.)
4. Replace the cap, and return the bottle to the counter or shelf.
5. Pour the liquid into the bottle or mortar for dispensing or compounding.

#### METALLIC MEASURES

Metallic measures are nearly cylindrical in shape, but are slightly wider at the bottom. These are generally used for measuring liquids when the quantity is over a pint. A set usually consists of five (gallon, half-gallon, quart, pint, and half-pint) of these measures. Measures made of tinned iron, or of the enameled sheet iron called agateware, are greatly inferior to those made of *tinned copper* or *stainless steel*; tinned-iron measures soon become rusty, and particles of enameling can chip off, leaving the exposed iron to contaminate the measured liquids.

The initial cost of copper or stainless-steel measures is greater than tinned iron, but they are far more durable. Care must be taken to protect them from blows that will cause dents as these may be serious enough to detract from their accuracy. Cylindrical metric measures, usually made of monel metal or stainless steel and having a diameter just half their height, are available in various sizes. Such containers are relatively expensive, but their resistance to corrosion and wear is a tremendous advantage. Copper, of course, should not be used where it is likely to catalyze oxidation.

#### GRADUATED GLASS MEASURES

Graduated glass measures are nearly always used for quantities of 500 mL or 1 pt or less. There are of two forms, *conical* and *cylindrical* (Figures 9-7 and 9-8). The conical graduate is suitable for some measurements because of the greater ease with which it can be handled, but cylindrical measures are more accurate because of their uniform and smaller average diameter. In a graduated cylinder, the error in volume caused by a deviation of  $\pm 1$  mm in reading the meniscus remains constant along the height of the uniform column; the same deviation causes a progressively larger error in a conical graduate because the diameter, and thus the volume of the 1 mm column, increases along its vertical axis. It is safe to assume that practically all good-grade modern graduates comply with the NIST requirements for internal diameters at stated volumes.

Figure 9-7. Class conical graduate. (Courtesy of Kimble Glass.)

A study has indicated that, to improve accuracy, the lower portions of graduates should not be used, and therefore should not be marked.<sup>2</sup> A composite tabulation (Table 9-12) shows the calculated and the assigned blank portions of graduates. The elimination of the lower markings on graduates was suggested, and in 1955 the NIST specifications for graduates used this principle.<sup>1</sup> The NIST *Handbook* states, "A graduate shall have an initial interval that is not subdivided, equal to not less than one-fifth and not more than one-fourth of the capacity of the graduate." For accurate measurement of volumes less than 1.5 mL, a graduated pipet or a graduated dropper could be used.

#### EFFECT OF LIQUID AND CONTAINER

It is difficult to measure accurately when pouring from a completely filled bottle because of the uneven flow of the liquid. After the first portion of the liquid is removed, the shape of the bottle does not influence the ease of pouring to any appreciable extent unless the neck is extremely narrow.

Viscous liquids pour slowly, but their accurate measurement is not difficult. Experiments showed that when glycerin is poured into a graduate without letting the liquid run down the inside surface, the precision of measurement can be very high. Naturally, the chance of hitting the inner surface is greater with smaller than with larger graduates. The increase in possible deviation then is caused by the slow movement of the viscous liquid to the desired mark.

Figure 9-8. Glass cylindrical graduate. (Courtesy of Kimble Glass.)

Table 9-12. Unmarked (Unreliable) Portions of Graduates

Capacity of graduate (mL)	Calculated blanks (1951)		NIST blanks (mL)
	2.5% <sup>a</sup> allowed (mL)	5% <sup>a</sup> allowed (mL)	
5	3.0	1.5	1
10	4.4	2.2	2
25	11.8	5.9	5
50	15.8	7.9	10
100	20.9	10.5	20
250	36.3	18.2	50
500	66.5	33.2	100
1000	—	—	200

<sup>a</sup> Calculations by Goldstein and Mattocks<sup>2</sup> based on deviation of  $\pm 1$  mm from graduation mark and allowable errors of 2.5% and 5%.

Viscous liquids introduce another factor: drainage time. Graduates are calibrated to contain or deliver indicated volumes within specified limits. Aqueous, alcoholic, and hydroalcoholic liquids can be drained from a graduate in 30 seconds so completely that the delivered and contained volumes are fairly close. When 25 mL of glycerin was measured in the same cleaned and dried cylinders, the received volume measured 23.7 mL after the same time period. Silicone-treated glassware, which now is used frequently, drains completely in a few seconds.

The viscosity factor might be altered when another liquid is to be mixed with the glycerin by measuring and mixing both liquids in a suitable graduate.

## Small Quantities

For measuring smaller quantities of liquids, graduated glass tubes of small diameter should be used. The narrower bore permits greater distances between the graduations on the apparatus, thus allowing greater accuracy in making the reading. For example, with a buret the pharmaceutical chemist can estimate volumes to the nearest 1/100 mL.

Pipets and similar apparatus are more accurate and convenient than very small graduates. The graduations on very small graduates are necessarily in the very small, lowest portion of a comparatively tall measure. To measure 1 mL of a volatile oil in a graduate, the surface that the oil must traverse when this measure is inverted is so great that probably 20 percent of the oil will be left adhering to the measure. In liquid preparations in which the smaller liquid is miscible with the larger quantity of diluting liquid, the graduate may be rinsed and this loss recovered, but inconveniences are largely overcome and greater accuracy secured by using a pipet.

In administering small quantities of liquids, the very convenient "drop" is almost always used. It should be emphasized that *one drop is not equivalent to 1 <minim>* and that *60 drops are not equivalent to 1 f℥*. This impression doubtless arose because 60 ordinary drops of water are about equal to 1 f℥, but the volume of a drop of fluid depends on many factors, including density, temperature, viscosity, surface tension, and the size and nature of the orifice from which it is dropped. Thick, viscous liquids, such as the mucilages and the syrups, necessarily produce large drops because the drop adheres to the surface of the glass as long as its weight does not overcome its power of adhesion, whereas chloroform, a mobile liquid that has very little adhesion to the dropping surface, produces very small drops. The greater the surface tension, the larger the drop, and the greater the extent of surface to which the drop adheres, the larger, proportionally, the drop.

A *normal or standard drop measure* was recommended by the Brussels Conference of 1902 for international adoption. This dropper is recognized in the USP.

## MEDICINE DROPPER<sup>3</sup>

The pharmacopeial medicine dropper consists of a tube made of glass or other suitable transparent material that generally is fitted with a collapsible bulb and, while varying in capacity, is constricted at the delivery end to a round opening having an external diameter of about 3 mm. The dropper, when held vertically, delivers water in drops, each of which weighs between 45 mg and 55 mg.

When drops are specified on a prescription, the usual custom has been to employ an *eyedropper*, but now the standard dropper should be supplied. When accuracy is required, it is particularly important to use a specially calibrated dropper for administering potent medicines. The volume error incurred in measuring any liquid by means of a calibrated dropper should not exceed 15 percent under normal conditions.<sup>3</sup>

## TEASPOON

For household purposes, an American Standard Teaspoon has been established by the American National Standards Institute as containing  $4.93 \pm 0.24$  mL. In view of the almost universal practice of employing teaspoons ordinarily available in the household for the administration of medicine, the teaspoon may be regarded as representing 5 mL and is so accepted by the USP.

It must be kept in mind that the actual volume delivered by a teaspoon of any given liquid is related to the latter's viscosity and surface tension, among other influencing factors.

## The Human Factor

The *human factor of carefulness* is of paramount importance in every pharmaceutical operation in which accuracy is essential. Accurate measurement of liquids requires accurate equipment, careful manipulation, good vision, and a steady hand.

## DENSITY AND SPECIFIC GRAVITY

Several terms are used to express the mass (weight) of equal volumes of different substances:

- *Absolute density* is the ratio of the mass of an object, determined in or referred to a vacuum, at a specified temperature, to the volume of the object at the same temperature. This relationship is expressed mathematically as:

$$\text{Absolute density} = \frac{\text{Mass in grams (in a vacuum)}}{\text{Volume in millimeters}}$$

- *Apparent density* differs from absolute density only in that the mass of the object is determined in air; the mass is influenced by the difference in the buoyant effect of air on the object being weighed, and on the standard masses (weights) used for comparison. If the object and masses are made of the same material, or have the same density, there will be no difference in the buoyant effect, and the apparent density will be identical with the absolute density.
- *Relative density* is an expression sometimes employed to indicate the mass of 1 mL (not cc, which is very slightly different) of a standard substance, such as water, at a specified temperature, relative to water at 4°C taken as unity. Thus, at 4°C the relative density of water is 1.0000, whereas its absolute density at the same temperature is 0.999973. Water attains its maximum absolute density of 0.999973 at 3.98°C. To convert a relative density of water to absolute density, the former should be multiplied by 0.999973.
- *Specific gravity* may be defined as the ratio of the mass of a substance to the mass of an equal volume of another substance taken as the standard. For gases, the standard may be hydrogen or air; for liquids and solids, it is water.

From what has been stated, it is obvious that in a determination of specific gravity there will be, in general, a difference in the result if the masses (weights) are determined in air or in vacuum. If the masses are determined in, or referred to, a vacuum, the result is a *true specific gravity* (sometimes called *absolute specific gravity*); if the masses are determined in air, the calculated result is an *apparent specific gravity*. The difference between these specific gravities is, as a rule, very small.

A very important variable in specific gravity determinations is temperature, and this is doubly important because both the temperature of the substance under examination and the temperature of the standard may be different. The temperatures are commonly shown as a ratio, with the temperature of the water always being indicated in the denominator. The common practice with regard to the determination of specific gravity is that defined by the USP: "Unless otherwise stated, the specific gravity basis is 25°/25°, i.e., the ratio of the weight of a substance in air at 25° to that of an equal volume of water at the same temperature."

But it is not always convenient, or desirable, to determine the weight of both the substance and the water at 25°C, or even to determine the weight of the substance at the same temperature as that at which the water is weighed. Thus, the substance may be weighed at 25°C and compared with the weight of an equal volume of water at 4°C, in which case the specific gravity is reported as being on a 25°C/4°C basis. In the case of theobroma oil, which is solid at 25°C, the specific gravity is determined on a 100°C/25°C basis; for alcohol, it is determined on a 15.56°C/15.56°C basis because many years ago the US government adopted 60°F (15.56°C) as the temperature at which alcoholometric measurements are to be made for government control of alcoholic liquids.

It is apparent that a completely informative statement of specific gravity must indicate the temperature of the substance under examination, as well as that of the equal volume of water. Furthermore, it should be stated whether the determinations of mass (weight) were made on an in vacuum or in air basis; in the latter case, the material of construction of the weights also should be indicated (as the buoyant effect of air on weights depends on their volume).

## CALCULATIONS

The principle underlying the determination of the specific gravity of either a liquid or a solid is the same: to find the ratio of the mass (weight) of the substance to that of an equal volume of water. This may be expressed by a simple relationship:

$$\text{Specific gravity} = \frac{W_s}{W_w}$$

where  $W_s$  is the weight of the substance, and  $W_w$  the weight of an equal volume of water.

## DENSITY

*Density* is defined as the mass of a substance per unit volume. It has the units of mass over volume. *Specific gravity* is the ratio of the weight of a substance in air to that of an equal volume of water. In the metric system both density and specific gravity may be numerically equal, although the density figure has units. In the English system, density and specific gravity are not numerically equal; for example, the density of water is 62.4 lb/ft<sup>3</sup> and the specific gravity is 1. This shows the convenience of the metric system. The equations for calculating density, weight, and volume are:

$$\text{Density} = \frac{\text{Weight}}{\text{Volume}}$$

$$\text{Weight} = \text{Density} \times \text{Volume}$$

$$\text{Volume} = \frac{\text{Weight}}{\text{Density}}$$

Given any two variables, the third one can be calculated.

## Examples

1. A pharmacist weighs out 2 kg of glycerin (density 1.25 g/mL). What is the volume of the glycerin?

$$\text{Volume} = \frac{2000 \text{ g}}{1.25 \text{ g/mL}} = 1600 \text{ mL}$$

2. What is the weight of 60 mL of oil whose density is 0.9624 g/mL?

$$\text{Weight} = 60 \text{ mL} \times 0.9624 \text{ g/mL} = 57.7 \text{ g}$$

3. Calculate the weight of 30 mL of sulfuric acid (density 1.8 g/mL).

$$\text{Weight} = 30 \text{ mL} \times 1.8 \text{ g/mL} = 54 \text{ g}$$

4. If a prescription order requires 25 g of concentrated hydrochloric acid (density 1.18 g/mL), what volume should the pharmacist measure?

$$\text{Volume} = \frac{25 \text{ g}}{1.18 \text{ g/mL}} = 21.2 \text{ mL}$$

## PROBLEMS

(Please see answers at the end of the chapter)

1. What is the weight in grams of 1 L of alcohol (density 0.816 g/mL)?
2. What is the volume (mL) of 1 lb (avoir) of glycerin (density 1.25 g/mL)?
3. What is the volume (mL) of 65 g of an acid whose density is 1.2 g/mL?

## PHARMACEUTICAL CALCULATIONS

Pharmaceutical dispensing and compounding calculations use simple arithmetic. The errors that may arise often are due to carelessness, as in improper placing of decimal points, incorrect conversion from one system of measurement to another, or uncertainty over the system of measurement to be used. Before proceeding with any calculation, it is imperative that the problem presented (in a prescription, chart order, formula, etc.) be read carefully, that the information given and required be identified, and that the procedure to be used in the calculation be selected.

Before students read this part of the chapter and attempt to solve the problems, the information in the preceding part of this chapter must be understood thoroughly. Often, several steps are necessary to solve problems. Shortcuts should not be taken unless one is certain they are proper. Many problems can be solved by more than one procedure, such as by ratio and proportion or by dimensional analysis. If students find a procedure that is more logical to them and gives the correct answer, it should be used. Thus, the solutions to sample problems used here generally should be considered suggestions, rather than the only way to solve a given type of problem.

## MATHEMATICAL PRINCIPLES

A few mathematical principles (e.g., common decimal fractions, exponents, powers and roots, significant figures, and logarithms) will be reviewed, as these are areas where students often become careless or have forgotten skills. Following this, various types of practical pharmaceutical problems that the pharmacist may be required to solve are discussed and solutions are given. Where practical, rules for solving these problems are given. No attempt is made to elaborate on any mathematical theory.

The problems generally consist of determining the quantity or quantities of material(s) required to compound prescriptions properly and make products used to aid the compounding of prescriptions. The materials used to compound prescription orders may be pure or mixtures of substances in varying strengths. The strengths of mixtures may be denoted in different ways. Conversions may be necessary between systems of varying strengths or between different measuring systems. At the end of each section, sample problems are given for the student to solve, the answers to which appear at the end of the chapter.

Because of the decreasing importance of the apothecary system, the metric system is emphasized here. Chemicals and preparations most likely will be purchased using the avoirdupois or metric systems. Prescription orders are filled in the system indicated on the order, usually the apothecary or metric systems.

The student should become familiar with the terminology used in writing prescription orders, such as Latin words and abbreviations used in giving directions to the pharmacist and patient. The prescriber occasionally may use Roman numerals instead of Arabic numerals, so students must be familiar with these (even if the practice is declining).

## Significant Figures

Weighing and measuring can be carried out with only a certain maximum degree of accuracy; the result always is approximate due to the many sources of error such as temperature,

limitations of the instruments employed, personal factors, and so on. Pharmacists must achieve the greatest accuracy possible with their equipment, but it would be erroneous to claim that they have weighed 1 mg of a solid on a Class III prescription balance, which has a sensitivity requirement of 10 mg, or that they have measured 76.32 mL of a liquid in a 100 mL graduate, which can be read only to 1 mL. When quantities are written, the numbers should contain only those digits that are *significant* within the precision of the instrument.

*Significant figures* are digits that have practical meaning. In some instances zeros are significant; in other instances they merely indicate the order of magnitude of the other digits by locating the decimal point. For example, in the measurement 473 mL all the digits are significant, but in the measurement 4730 mL the zero may or may not be significant. In the weight 0.0316 g the zeros are not significant but only locate the decimal point. In any result the last significant figure is only approximate, but all preceding figures are accurate.

When 473 mL is recorded, it is understood that the measurement had been made within  $\pm 0.5$  mL or somewhere between 472.5 and 473.5 mL. The student should stop to consider the full implications of this specifically that the measurement is subject to a maximum error of:

$$\frac{0.5}{473} \times 100 = (\text{approx}) 0.1\% \text{ or } 1 \text{ part in } 1000$$

A zero in a quantity such as 473.0 mL is a significant figure and implies that the measurement has been made within the limits 472.95 mL and 473.05 mL or with a possible error of:

$$\frac{0.05}{473} \times 100 = (\text{approx}) 0.01\% \text{ or } 1 \text{ part in } 10,000$$

Thus, 473 is correct to the nearest milliliter, and 473.0 is correct to the nearest 0.1 mL.

## Rules

1. *When adding or subtracting, retain in the sum or remainder no more decimal places than the least number entering into the calculations.* For example,

11.5 g	11.50 g
2.65 g	2.65 g
3.49 g	3.49 g
17.64 g	17.64 g

Answer : 17.6 g    Answer : 17.64 g

In the first column 11.5 g was weighed to 0.1 g or with an accuracy of  $\pm 0.05$  g. Although the other two weighings were made with an accuracy of  $\pm 0.005$  g, the sum can be expressed properly only to one decimal place.

In the second column 11.50 g was weighed to the nearest 0.01 g or with an accuracy of  $\pm 0.005$  g. Since all weighings were made with this degree of accuracy, the sum may be stated as in the example, 17.64 g.

Retain all figures possible until all the calculations are completed and then retain only the significant figures for the answer. Additions or subtractions involving both large and small quantities, each expressed with maximum significance, are often useless. For example, if one were to add 1.2 and 0.041 g, the physical sum would be 1.2 g, regardless of the fact that the two numbers add numerically to 1.241. To express the physical sum as 1.241 g would convey an erroneous degree of accuracy with which the quantity was known.

2. *When multiplying or dividing, retain in the answer no more significant figures than the least number entering*

**Table 9-13. Different Equivalent Values and the Number of Significant Figures to Which the Answer is Correct**

Weight (g)	Equivalent weight (gr/g)	Equivalent weight (gr)	Significant figures
4.522 ×	15.432 =	69.78	4
4.522 ×	15.43 =	69.77	4
4.522 ×	15.4 =	69.6	3
4.522 ×	15 =	68	2

into the calculation. The meaning of this rule may be illustrated by the use of equivalents during conversions from one measuring system to another. Table 9-13 gives different equivalent values and the number of significant figures to which the answer is correct. Always use an equivalent that will give the desired degree of accuracy. Repeated multiplication of an approximation increases the error progressively; therefore, retain all figures during calculations and drop insignificant figures as the final step.

## FRACTIONS

### COMMON FRACTIONS

An example of a common fraction is  $3/8$ . It is read as “three-eighths” and indicates three parts divided by eight parts of the same thing. The units with both numbers must be the same. Pharmacists measure  $3/8$  of a fluid ounce into a graduate, they measure 3 fluidrams, out of 8 fluidrams (a fluid ounce contains 8 fluidrams).

The following principles should be applied when using common fractions:

1. The value of a fraction is not altered by multiplying or dividing both numerator and denominator by the same number.
2. Multiplying the numerator or dividing the denominator by a number multiplies the fraction by that number.
3. Dividing the numerator or multiplying the denominator by a number divides the fraction by that number.
4. To add or subtract fractions, form fractions with the *lowest common denominator*, perform the arithmetical operation, and reduce to the lowest common denominator.
5. To multiply fractions, multiply all numbers above the line to form the new numerator and multiply all numbers below the line to form the new denominator. Cancel if possible to simplify and reduce to the lowest common denominator.
6. To divide by a fraction, multiply by the reciprocal of the fraction.

### DECIMAL FRACTIONS

Fractions with the power of 10 as the denominator are known as *decimal fractions* and are written by omitting the denominator and inserting a decimal point in the numerator as many places from the last number on the right as there are ciphers of 10 in the denominator.

The following principles should be applied when using decimal fractions:

- When adding or subtracting decimals, align the decimal points under each other.
- When multiplying decimals, proceed as with whole numbers, then place the decimal point in the product as many places from the first number on the right as the sum of the decimal places in the multiplier and the multiplicand.

- When dividing by a decimal fraction, move the decimal point to the right, in both divisor and dividend, as many places as it is to the left in the divisor to form a whole number in the divisor; proceed as with whole numbers. The decimal point in the quotient should be placed immediately above the decimal point in the dividend.
- When converting a common fraction into a decimal fraction, divide the numerator by the denominator and place the decimal point in the correct place.
- When converting a decimal fraction into a common fraction, place the entire number, as the numerator, over the power of 10 containing the same number of ciphers of 10 as there are decimal places. Cancel, if possible, to simplify.

## EXPONENTS, POWERS, AND ROOTS

In the expression  $2^4 = 16$ , the following names are given to the terms: 16 is called the *power* of the *base* 2 and 4 is the *exponent* of the power. If the exponent is 1, it usually is omitted. The following laws should be recalled:

- The product of two or more powers of the same base is equal to that base with an exponent equal to the sum of the exponents of the powers; e.g.,  $2^5 \times 2^3 = 2^8$ .
- The quotient of two powers of the same base is equal to that base with an exponent equal to the exponent of the dividend minus the exponent of the divisor; e.g.,  $2^8 \div 2^3 = 2^5$ .
- The power of a power is found by multiplying the exponents; e.g.,  $(2^8)^3 = 2^{24}$ .
- The power of a product equals the product of the powers of the factors; e.g.,  $(2 \times 3 \times 4)^2 = 2^2 \times 3^2 \times 4^2$ .
- The power of a fraction equals the power of the numerator divided by the power of the denominator; e.g.,

$$\left(\frac{2}{3}\right)^2 = \frac{2^2}{3^2}$$

- The root of a power is found by dividing the exponent of the power by the index of the root; e.g.,

$$\sqrt[3]{3^6} = 3^{\frac{6}{3}} = 3^2$$

- Any number other than 0 with an exponent 0 equals 1; e.g.,  $2^0 = 1$ . A number with a negative exponent equals 1 divided by the number with a positive exponent equal in numerical value to the negative exponent; e.g.,

$$2^{-4} = \frac{1}{2^4}$$

## LOGARITHMS

*Logarithms (logs)* were invented to facilitate the solution of involved and lengthy problems. Many calculations that are difficult by ordinary arithmetical processes are performed rapidly and easily with the aid of logs; the advent of modern calculators and computer spreadsheet programs has made this use of logs obsolete. Logs still appear, however, in many chemical and pharmacokinetic equations.

The log of a number is the exponent of the power to which a given base must be raised in order to equal that number.

$$Y = a^x$$

$$\log_a Y = x$$

John Napier, of Scotland, who discovered logs over three centuries ago, used the natural log number, 2.71828+, as the base. Henry Briggs, using Napier's discovery a few years later, introduced 10 as the base, which is the most convenient for practical purposes. Napier's system is called *natural logs*, and Briggs' system is called *common logs*. In this latter system the natural numbers are regarded as powers of the base 10 and the corresponding exponents are the logs; e.g.,

$$6 = 10^{0.7782}$$

$$\log_{10} 6 = 0.7782$$

For natural logs,

$$6 = e^{1.792}$$

$$\ln_e 6 = 1.792$$

## LAWS AND RULES

The following laws, governing the use of logs, are based on the laws of exponents, and hence hold for any log system.

- The log of a product equals the *sum* of the log of the component numbers; for example, for  $25 \times 2$ :

$$\log(25 \times 2) = \log 25 + \log 2 = 1.3979 + 0.3010 = 1.6989$$

- The log of a quotient equals the log of the numerator minus the log of the denominator; for example, for  $25 \div 2$ :

$$\log(25/2) = \log 25 - \log 2 = \log 10^{1.3979} - \log 10^{0.3010}$$

$$= 1.3979 - 0.3010 = 1.0969$$

- The log of a power of a number equals the log of the number multiplied by the exponent of the power; for example, for  $(25)^{12}$ :

$$\log(25)^{12} = 12 \log 25 = 12 \times 1.3979 = 16.7748$$

- The log of a root of a number equals the log of the number divided by the index of the root; for example, for  $\sqrt{25}$ :

$$\log \sqrt{25} = \log 25^{1/2} = \frac{\log 25}{2} = \frac{1.3979}{2} = 0.6990$$

- The log of a negative power of a number equals the reciprocal of the number multiplied by the exponent of the power; for example,  $(5)^{-2}$ :

$$\log(5)^{-2} = -2 \log 5 = -2 \times 0.6990 = -1.398$$

## The Log of a Number

The logarithm of a number can be easily obtained from a calculator or computer spreadsheet program.

1. Find the logarithm of 273:

$$\log 273 = 2.4362$$

$$\ln 273 = 5.6095$$

2. Find the logarithm of 0.08206:

$$\log 0.08206 = -1.08587$$

$$\ln 0.08206 = -2.5003$$

## The Antilog of a Number

To find the number corresponding to a given log (or antilog), the reverse procedure of that discussed above is employed (i.e., the appropriate numerical base is raised to the exponent expressed by the logarithm).

1. Find the number corresponding to the antilog 3.8357:

$$\log X = 3.8357$$

$$X = 10^{3.8357} = 6850$$

2. Find the number corresponding to the natural log 0.4351:

$$\ln X = 0.4351$$

$$X = e^{0.4351} = 2.71828^{0.4351} = 1.5451$$

3. Using the Henderson–Hasselbalch equation for an acidic substance, find the ratio of ionized to un-ionized drug at a pH of 3.0. The  $pK_a$  of the drug is 7.4.

## PHARMACEUTICAL PROBLEMS

The student who knows algebra, has studied the previous sections of this chapter, and recognizes the Roman numerals and Latin abbreviations used on prescription orders (for directions to the pharmacist and patient by the prescriber) should have sufficient knowledge to solve the routine problems encountered in a pharmacy. The various symbols and abbreviations and their meanings must be well understood. Explanations of some practical problems, representative of those faced in practice, are presented below. Practice problems follow each section, and the answers to these problems are found at the end of this chapter. To solve each problem properly, the following procedure is suggested:

1. Analyze the problem carefully so that all data are clearly fixed in the mind; determine what is given and what is asked.
2. Select the most direct method of solving the problem. Not all problems can be solved properly in one step. Look up doses, equivalents, and abbreviations when you are not sure.
3. Prove or check the result. Many problems encountered in pharmacy still utilize the apothecary and avoirdupois systems; however, solving these problems in contemporary practice is based on converting these systems into metric units prior to solving the problem mathematically. This approach will be followed in this text. Methods for the mathematical manipulation of apothecary and avoirdupois units and direct problem solving in these systems can be found in previous editions of *Remington*.

## ADDITION

Review weighing and measuring systems discussed earlier in this chapter.

## Rules

1. Add like quantities. Using the metric system, if the quantities are not alike, change them to a common unit.
2. When adding decimals, keep the decimal points directly under each other.
3. When adding fractions, reduce to the lowest common denominator (LCD), add the resulting numerators, and reduce the fraction, if possible, by canceling.

## Examples

- Add 3 kg, 33 g, and 433 mg.  
Convert to a common unit. The gram is convenient because it is the unit of weight.

$$3 \text{ kg} \times \frac{1000 \text{ g}}{\text{kg}} = 3000 \text{ g}$$

$$33 \text{ g} = 33 \text{ g}$$

$$433 \text{ mg} \times \frac{1 \text{ g}}{1000 \text{ mg}} = 0.433 \text{ g}$$

Answer: 3033.433 g

**PROBLEMS**

1. Add 25 mg, 25 g, 210 mg, 2 kg, 1.75 g, 215 mg, 454 g, and 30 mg.
2. The following quantities of a drug were removed from a container: 31 g, 225 g, 855.6 g, and 45.4 g. What is the total weight removed from the container?

**SUBTRACTION****RULES**

1. Subtract only like quantities. If the quantities are not alike, change to a common unit.
2. Treat common and decimal fractions as indicated in the section on addition.

**EXAMPLES**

1. Subtract 285 mL from 1 L. Convert to a common unit.

$$\begin{array}{r} 1000 \text{ mL} \\ -285 \text{ mL} \\ \hline 715 \text{ mL} \end{array}$$

Answer: 715 mL

**PROBLEMS**

1. How much is left in a 5 L container after the removal of 895 mL?
2. A pharmacist buys 5 g of a potent drug and at different times dispenses 0.2 g, 0.85 g, 90 mg, and 150 mg on prescription orders. How much of the drug remains?

**MULTIPLICATION****RULES**

1. The product has the same denomination as the multiplicand.
2. If the multiplicand is composed of different denominations in the metric system, form a common unit before multiplying and reduce the product to measurable units.
3. Multiply fractions and decimals as in any arithmetic problem, and reduce fractional quantities to measurable or weighable units.

**EXAMPLES**

1. What will be the total weight of the ingredients in a prescription order for 25 units, each unit containing 0.4 g of Solid F, 0.01 g of Solid G, and 5 mg of Solid H? First, convert to a common unit such as grams.

$$\begin{aligned} 0.4 \text{ g} + 0.01 \text{ g} + 0.005 \text{ g} &= 0.415 \text{ g total weight of one unit} \\ 0.415 \text{ g/unit} \times 25 \text{ units} &= 10.375 \text{ g total weight of all units} \end{aligned}$$

2. Multiply 22.4 mL by 2.65.

$$\begin{array}{r} 22.4 \text{ mL} \\ \times 2.65 \\ \hline 59.36 \text{ mL} \end{array}$$

**PROBLEMS**

1. Multiply 48.5 mL by 3.24.
2. A certain preparation is to contain 0.0325 g of a chemical in each milliliter of solution. How much must be weighed out to make 5 L of the solution?

3. How much cod liver oil is necessary to make 2500 capsules, each containing 0.33 mL?
4. How many milligrams are used to make 1500 units, each of which contains 250 µg of a drug?

**DIVISION****RULES**

1. The quotient always has the same denomination as the dividend.
2. If the dividend is composed of different denominations, form a common unit in the metric system before dividing and reduce the quotient to weighable or measurable quantities.
3. Treat fractions and decimals as explained in the multiplication section.

**EXAMPLE**

1. Divide 3 L by 25.

$$\frac{3 \text{ L}}{25} = 0.120 \text{ L or } 120 \text{ mL}$$

**PROBLEMS**

1. How many 65 mg capsules can be made from 50 g of a drug?
2. The dose of a drug is 0.1 mg. How many doses are contained in 15 mg of the drug?
3. How many 325 mg capsules of a drug can be filled from a 454 g amount?

**CONVERSION**

As long as the student knows the interrelationships of the various units within the different weighing and measuring systems (e.g., 20 gr = 1 ℥, 3 ℥ = 1 ℔; 1000 mg = 1 g), there are only three conversions necessary to memorize in order to convert between the apoth, avoird, and metric systems. These are:

$$\begin{aligned} 1 \text{ gr (avoird)} &= 1 \text{ gr (apoth)} \\ 1 \text{ gr} &= 64.8 \text{ mg} \\ 1 \text{ f}\ddot{z} &= 29.6 \text{ mL} \end{aligned}$$

*Learn them!*

With these three conversions the student is able to derive all other necessary conversions.

**Apothecary Conversions**

Various equalities within the apothecary system may be calculated.

1. The number of grains in a dram, grains in a pound, and so on may be calculated using the following steps.

$$\begin{aligned} \frac{20 \text{ gr}}{\text{℥}} \times \frac{3 \text{ ℥}}{3} &= \frac{60 \text{ gr}}{3} \\ \frac{60 \text{ gr}}{3} \times \frac{8 \text{ ℥}}{3} \times \frac{12 \text{ ℥}}{4 \text{ ℔}} &= \frac{5760 \text{ gr}}{4 \text{ ℔}} \end{aligned}$$

Cancel the units. If they do not cancel properly, something has been omitted.

2. Convert 1 ℥ (apoth) to weighable quantities in the avoird system:

$$1 \text{ gr (apoth)} = 1 \text{ gr (avoird)}$$

Since 1 gr (apoth) = 1 gr (avoir), the number of grains in one system equals the number of grains in the other system; e.g., 480 gr (apoth) = 480 gr (avoir).

$$\frac{20 \text{ gr}}{\text{M}} \times \frac{3 \text{ M}}{3} \times \frac{83}{\text{ʒ}} = \frac{480 \text{ gr}}{\text{ʒ (apoth)}}$$

$$480 \text{ gr (apoth)} = 480 \text{ gr (avoir)}$$

$$437.5 \text{ gr} = 1 \text{ oz avoir}$$

$$\frac{480 \text{ gr}}{-437.5 \text{ gr}} = \frac{42.5 \text{ gr}}{42.5 \text{ gr}}$$

Answer: 1ʒ(apoth) = 1 oz, 42.5 gr (avoir)

3. Conversions in the metric system are made in the same manner. Convert 1 g to mg.

$$1 \text{ g} \frac{1000 \text{ mg}}{\text{g}} = 1000 \text{ mg}$$

Convert 1 g to kg.

$$1 \text{ g} \frac{1 \text{ kg}}{1000 \text{ g}} = 0.001 \text{ kg}$$

The same procedure is valid for volume measurements in the metric system.

4. Conversions between the apothecary and metric weight systems can be based on the conversion factor 15.4 gr = 1 g, which may be restated as 15.4 gr/g or 1 g/15.4 gr.

- a. How many milligrams equal 1 gr?

$$\frac{1 \text{ g}}{15.4 \text{ gr}} = 0.0648 \text{ g/gr} = 64.8 \text{ mg/gr} \text{ or } 64.8 \text{ mg} = 1 \text{ gr}$$

- b. How many grams are in 1ʒ?

$$\frac{1 \text{ g}}{15.4 \text{ gr}} \times \frac{480 \text{ gr}}{\text{ʒ}} = \frac{311 \text{ g}}{\text{ʒ}}$$

- c. How many grams are in 1 oz (avoir)? Remember: 1 gr (apoth) = 1 gr (avoir).

$$\frac{1.000 \text{ g}}{15.4 \text{ gr}} \frac{437.5 \text{ gr}}{\text{oz}} = \frac{28.4 \text{ gr}}{\text{oz}}$$

Other weight conversions are then found in a similar manner.

5. Conversions between the apothecary and metric measuring systems can be based on the conversion factor 1 fʒ = 29.6 mL, which may be restated as 1 fʒ/29.6 mL or 29.6 mL/fʒ. How many minims are in 1 mL?

$$\frac{480 \text{ m}}{\text{fʒ}} \times \frac{1 \text{ fʒ}}{29.6 \text{ mL}} = \frac{16.2 \text{ m}}{\text{mL}}$$

## RULES

- The USP states that for prescription compounding one uses practical equivalents, defined as exact equivalents rounded to three (3) significant figures.
- To calculate quantities required in pharmaceutical formulas, the USP directs the use of practical equivalents.
- In converting doses the USP uses approximate equivalents. Use USP tables wherever possible.

## EXAMPLES

- Convert 1 pt, 4 fʒ into milliliters. First, convert into fluid ounces.

$$\frac{16 \text{ fʒ}}{\text{pint}} \times 1 \text{ pint} + 4 \text{ fʒ} = 20 \text{ fʒ}$$

Second, convert fluid ounces to milliliters.

$$20 \text{ fʒ} \times \frac{29.6 \text{ ml}}{\text{fʒ}} = 592 \text{ mL}$$

Answer: 1 pt, 4 fʒ = 592 mL.

- What is the weight of 1200 g in the apothecary system?

$$1200 \text{ g} \frac{15.4 \text{ gr}}{\text{g}} = 18,480 \text{ gr}$$

Or:

$$1200 \text{ g} \frac{1 \text{ lb}}{373 \text{ g}} = 3.22 \text{ lb}$$

- Convert 1 pound (apoth) into grams.

$$\frac{1 \text{ g}}{15.4 \text{ gr}} \times \frac{480 \text{ gr}}{\text{ʒ}} \times \frac{12 \text{ ʒ}}{\text{lb}} \times 1 \text{ lb} = 374 \text{ g}$$

- Convert 25 gr to grams.

$$25 \text{ gr} \frac{1 \text{ g}}{15.4 \text{ gr}} = 1.62 \text{ g}$$

- Convert 50 g to grains.

$$50 \text{ g} \frac{15.4 \text{ gr}}{\text{g}} = 770 \text{ gr}$$

## PROBLEMS

- Convert:
  - 6.50 grains into milligrams.
  - 3/10 grain into milligrams.
  - 3½ apoth ounces into grams.
  - 2ʒ into milligrams.
  - 3½ avoirdupois ounces into grams.
  - 1 lb avoirdupois into grams.
- Convert:
  - 550 g into weighable quantities in the avoirdupois system.
  - 450 mg into grains.
  - 550 g into weighable quantities in the apoth system.
  - 100 µg into grains.
  - 1 kg into lb (avoir).
- Convert the following doses into metric weights:
  - 1/100 gr.
  - 1/320 gr.
  - 1/6 gr.
  - 5 gr.
  - 20 gr.
- Convert:
  - 200 minim into mL.
  - 3ʒ into mL.
  - 8ʒ into mL.
  - 1 pt into mL.
  - 5 <minim> into mL.
  - 0.1 mg into gr.
  - 5 mg into gr.
- Answer the following questions.
  - How many gr are in 1ʒ?
  - How many drams are in 1ʒ?

- c. How many grains are in 1 oz (avoir)?
- d. How many gr are in ½ lb (apoth)?
- e. Convert 250 gr to weighable quantities in the apothecary system.

### HOUSEHOLD EQUIVALENTS

Common household equivalents are found in Table 9-11. These are used to interpret the prescriber's instructions to the patient. The teaspoonful usually is indicated by the symbol  $\text{f}\overline{3}$  or 5 mL, although 1  $\text{f}\overline{3}$  does not equal 5 mL. The problem of "the teaspoonful" has been discussed by Morrell and Ordway<sup>4</sup> and by Madlon-Kay and Mosch.<sup>5</sup> For practical purposes, a teaspoonful is equal to 5 mL, and 1  $\text{f}\overline{3}$  in the directions to the patient on the prescription means 1 teaspoonful.

For purposes of solving most compounding and dispensing problems, the exact equivalents rounded to three significant places should be used.

### DOSAGE CALCULATIONS

In the past various rules for calculating infants' and children's dosages have been devised. All of them give only approximate dosages because they erroneously assume that the child is a small adult; some of them are still used because as yet no absolute method of calculating an infant or child's dose has been found. Children are sometimes more susceptible than adults to certain drugs. Doses for infants and children, where they are known, may be found in the USP Drug Information, the *Pediatric Dosage Handbook* published by APhA, and textbooks on pediatrics.<sup>6-8</sup> Doses should not be calculated when it is possible to obtain the actual infant's or child's dose.

#### RULES FOR APPROXIMATE DOSES FOR INFANTS AND CHILDREN

1. *Young's Rule* (for children 2 years old and older)

$$\frac{\text{Age (years)}}{\text{Age (years)} + 12} \text{ Adult dose} = \text{child's dose (approx)}$$

2. *Clark's Rule*

$$\frac{\text{Weight (lb)}}{150} \times \text{Adult dose} = \text{Child's dose (approx)}$$

3. *Fried's Rule* (for infants up to 2 years old)

$$\frac{\text{Age (months)}}{150} \text{ Adult dose} = \text{Child's dose (approx)}$$

4. *The Square Meter Surface Area Method* relates the surface area of individuals to dose. It is thought that this is a more realistic way of relating dosages.

$$\frac{\text{Body surface area of child}}{\text{Body surface area of adult}} \text{ Adult dose} = \text{Child's dose (approx)}$$

The average body surface area for an adult has been given as 1.73 m<sup>2</sup>; hence,

$$\frac{\text{Body surface area of child (m}^2\text{)}}{1.73 \text{ m}^2} \text{ Adult dose} = \text{Child's dose (approx)}$$

#### Calculating Doses for Individuals—of Any Age or Size

Many drugs have doses stated as the amount of *drug/m<sup>2</sup> body surface area* and may be calculated as follows:

$$\frac{\text{Dose of drug}}{\text{m}^2 \text{ body surface area}} \text{ Body surface area (m}^2\text{)} = \text{dose}$$

Many physiological functions are proportional to body surface area, such as metabolic rate and kidney function.

Drug doses are often stated in *mg/kg body weight* and may be calculated as follows:

$$\frac{\text{Dose of drug}}{\text{kg body weight}} \text{ Body weight (kg)} = \text{Dose}$$

This is the most common way of determining children's doses. Drug doses also may be stated in *units*, as with vitamins A and D, penicillin, and hormones. This means that a certain quantity of biological activity of that drug is called 1 unit. When the term unit is used in connection with a drug, the calculations involved are the same as those for more familiar weight or volume notations. The USP often standardizes the unit for such drugs, so the expression "USP Units" is used. This means the units are calculated based on a USP assay procedure and reference standard.

#### EXAMPLES

1. The adult dose of a drug is 325 mg. What is the dose for a 3-year-old child?

Use Young's Rule:

$$\text{Child's dose (approx)} = \frac{3}{3+12} \times 325 \text{ mg} = 65 \text{ mg}$$

2. What is the dose for a 40 lb child if the average adult dose of the medication is 10 mg?

Use Clark's Rule:

$$\text{Child's dose (approx)} = \frac{40}{150} \times 10 \text{ mg} = 2.67 \text{ mg}$$

3. What is the dose for an 8-month-old infant if the average adult dose of a drug is 250 mg?

Use Fried's Rule:

$$\text{Infant's dose (approx)} = \frac{8}{150} \times 250 \text{ mg} = 13.3 \text{ mg}$$

4. If the average adult dose of a drug is 50 mg, what is the dose for a child who has a body surface area equal to 0.57 m<sup>2</sup>?

$$\text{Child's dose (approx)} = \frac{0.57}{1.73} \times 50 \text{ mg} = 16.5 \text{ mg}$$

#### PROBLEMS

1. What is the dose of a drug for a 9-month-old infant if the average adult dose is 25 mg?
2. What is the dose of a drug for a 6-year-old child if the average adult dose is 98 mg?
3. What is the dose of a drug for a child who weighs 28 lb if the average adult dose is 100 mg?
4. What is the dose of a drug for an individual who has a 1.21 m<sup>2</sup> body surface area? The average adult dose is 400 000 units.
5. What is the dose of a medication for a child who weighs 66 lb if the dose is stated as 2.5 mg/kg body weight?
6. What is the dose of a drug for an average adult patient if the dose of the drug is 45 mg/m<sup>2</sup>?

#### PROBLEM-SOLVING METHODOLOGY

The problem-solving method illustrated in solving pharmaceutical problems is *dimensional analysis* (which is based on *ratio*

and proportion). Dimensional analysis is widely used in many scientific disciplines and offers a consistent way to solve problems. Dimensional analysis also overcomes many difficulties students and pharmacy practitioners have in problem interpretation and provides a well-defined, consistent starting point in the solution of pharmaceutical problems.

### Dimensional Analysis

The basis for dimensional analysis is the formation of relationships between quantities, multiplication and canceling units until only the units of the desired answer remain. As an example, if 100 g of a drug cost US\$1.80, how much will 25 g cost? Begin by collecting all of the information in the problem and identify all relationships with units and labels. In this problem, we know the following:

$$\frac{\$1.80}{100 \text{ g drug}}, 25 \text{ g drug}$$

Identify the units you want for the answer (US\$). Identify a relationship from the problem that contains the unit(s) desired for the answer, forming the skeleton of the process.

$$\frac{\$1.80}{100 \text{ g drug}} \quad ? = \$$$

Complete the process by using terms from the problem (or equivalents) necessary to cancel out units until only the unit(s) of the answer remain on the right side.

$$\frac{\$1.80}{100 \text{ g drug}} \quad 25 \text{ g drug} = \$$$

Solve mathematically.

$$\text{Answer} = \$0.45$$

Dimensional analysis can be used to solve most pharmaceutical problems, regardless of complexity, using a consistent procedure:

1. Collect all the information and relationships in the problem complete with units and labels.
2. Identify the unit(s) and label of the answer.
3. Select a starting point corresponding to the unit(s) and label of the answer in the numerator.
4. Complete the process using relationships in the problem and known conversions to cancel units.
5. Solve the problem mathematically.

More complex problems use the same basic procedure: e.g., if 100 g of a drug cost US\$1.80, what would be the cost of the drug to prepare 4 f $\bar{3}$  of a solution containing 5 g of the drug per teaspoonful?

*Step 1:* Collect all information and relationships:

$$\frac{\text{US\$1.80}}{100 \text{ g drug}}, \frac{5 \text{ g drug}}{1 \text{ tsp}}, 4 \text{ f}\bar{3}$$

*Step 2*

$$= \text{US\$}$$

*Step 3*

$$\frac{\text{US\$1.80}}{100 \text{ g drug}} \quad ? = \text{US\$}$$

*Step 4*

$$\frac{\text{US\$1.80}}{100 \text{ g drug}} \times \frac{5 \text{ g drug}}{1 \text{ tsp}} \times \frac{1 \text{ tsp}}{5 \text{ mL}} \times \frac{29.6 \text{ mL}}{1 \text{ f}\bar{3}} \times 4 \text{ f}\bar{3} = \text{US\$}$$

(The 3rd and 4th terms are known definitions and equivalents needed to cancel units.)

*Step 5*

$$\text{Answer} = \text{US\$0.53}$$

With practice, steps 2 through 4 can be written in one operation.

### EXAMPLES

1. Determine the amount of each ingredient contained in one dose of the following prescription.

Solid A	300 mg
Solid B	150 mg
Solid C	200 mg

M ft capsules, D.T.D. No. 12

The directions to the pharmacist are to mix and make 12 capsules each containing the three solids in the amounts indicated. Thus, the dose of each ingredient is as stated in the prescription.

2. How much of each ingredient is contained in one dose of the following prescription?

Solid E	7.2 g
Solid F	0.24 g
Solid G	1.2 g

M div capsules, No. 24

In this prescription the prescriber requests that 24 capsules be made from the three ingredients. The amounts of the ingredients requested are considerable, and drugs usually do not have doses of 7.2 g or 1.2 g, so division of the amounts by the number of doses (24) is required. The pharmacist should check a textbook or compendium to confirm the average adult dose.

$$\text{Drug E: } \frac{7.2 \text{ g}}{24 \text{ capsules}} \times 1 \text{ capsule} = 0.300 \text{ g}$$

$$\text{Drug F: } \frac{0.24 \text{ g}}{24 \text{ capsules}} \times 1 \text{ capsule} = 0.010 \text{ g}$$

$$\text{Drug G: } \frac{1.2 \text{ g}}{24 \text{ capsules}} \times 1 \text{ capsule} = 0.050 \text{ g}$$

3. A prescription calls for 10 units of a drug to be taken 3 times a day. How much will the patient have taken after 7 days?

$$\frac{10 \text{ units}}{\text{dose}} \times \frac{3 \text{ doses}}{\text{day}} \quad 7 \text{ days} = 210 \text{ units}$$

4. If 250 units of an antibiotic weigh 1 mg, how many units are in 15 mg?

$$\frac{250 \text{ units}}{\text{mg}} \quad 15 \text{ mg} = 3750 \text{ units}$$

5. If the dose of a drug is 0.5 mg/kg of body weight/24 h, how many grams will a 33-lb infant receive per 24 h and per week?

$$\frac{1 \text{ g}}{1000 \text{ mg}} \times \frac{0.5 \text{ mg}}{\text{kg} \times 24 \text{ hours}} \times \frac{1 \text{ kg}}{2.2 \text{ lb}} \times 33 \text{ lb} \times 24 \text{ hours} = 0.00750 \text{ g}$$

$$\frac{0.00750 \text{ g}}{\text{day}} \times \frac{7 \text{ days}}{\text{week}} \times 1 \text{ week} = 0.0525 \text{ g}$$

6. A patient is to receive 260  $\mu\text{g}$  of a drug 4 times a day for 14 days. How many 1/250 gr tablets must be dispensed?

$$\frac{1 \text{ tablet}}{\frac{1}{250} \text{ gr}} \times \frac{1 \text{ gr}}{64.8 \text{ mg}} \times \frac{1 \text{ mg}}{1000 \text{ g}} \times \frac{260 \text{ g}}{\text{dose}} \times \frac{4 \text{ doses}}{\text{day}} \times 14 \text{ days} =$$

$$56.2 \text{ tablets} = 57 \text{ tablets}$$

7. An antibiotic is available as an injection containing 10 mg antibiotic/mL. How many milliliters are needed for an infant weighing 8 kg, the dose being 1.4 mg/kg of body weight?

$$\frac{1 \text{ mL}}{10 \text{ mg}} \times \frac{1.4 \text{ mg}}{\text{kg}} \times 8 \text{ kg} = 1.12 \text{ mL}$$

8. A preparation for coughs contains 1.5 g of an expectorant per 100 mL. How many grains of the expectorant are there in a teaspoonful?

$$\frac{15.4 \text{ gr}}{1 \text{ g}} \times \frac{1.5 \text{ g}}{100 \text{ mL}} \times \frac{5 \text{ mL}}{1 \text{ tsp}} \times 1 \text{ tsp} = 1.16 \text{ gr}$$

### PROBLEMS

1. Calculate the dose for each ingredient in the following prescription.

Chemical J	10 mg
Chemical K	50 mg
Chemical L	300 mg

M ft capsules, D.T.D. No. 14

2. Calculate the dose of each ingredient in the following prescription.

Drug Q	10.5 g
Drug R	6.3 g

M div 21 doses

3. An  $\text{f}\overline{3}$  prescription contains 6  $\text{f}\overline{3}$  of a tincture. If 1 teaspoonful 4 times a day is prescribed, how much tincture does the patient take per dose and how much is taken daily?

4. How many 0.3 mL doses are contained in 15 mL of a solution?

5. If 1 mg of a hormone equals 22.5 units, how many milligrams are required to obtain 1 unit?

6. If a bottle contains 80 units of a drug/mL, how many milliliters must the patient take to get a 60 unit dose? If the bottle contains 10 mL total volume of the drug solution, how many days' supply will patients have if they use 60 units a day?

7. A 10 mL ampule contains a 2.5 percent solution of a drug. How many milliliters are needed to give a dose of 150 mg?

8. The dose of an antibiotic is 75 mg for a child. How much of a flavored suspension containing 125 mg antibiotic/5 mL must be given to the child per dose?

9. How many milligrams of a drug are there in each teaspoonful of a syrup that contains 0.5 percent of the drug?

### REDUCING AND ENLARGING FORMULAS

Determine the total weight or volume of ingredients and convert, if necessary, to the system of the quantities desired. The quantities in the original and new formulas will have the same ratio.

### EXAMPLES

1. The formula for a syrup is:

Drug M	140 g
Sucrose	450 g
Purified water qs	1000 mL

- a. Find the quantities required for 100 mL.

$$\text{Drug M: } \frac{140 \text{ g}}{1000 \text{ mL}} \times 100 \text{ mL} = 14.0 \text{ g}$$

$$\text{Sucrose: } \frac{450 \text{ g}}{1000 \text{ mL}} \times 100 \text{ mL} = 45.0 \text{ g}$$

Purified water: to make 100 mL

- b. What quantities are required to compound 60 mL of the syrup?

$$\text{Drug M: } \frac{140 \text{ g}}{1000 \text{ mL}} \times 60 \text{ mL} = 8.40 \text{ g}$$

$$\text{Sucrose: } \frac{450 \text{ g}}{1000 \text{ mL}} \times 60 \text{ mL} = 27.0 \text{ g}$$

Purified water: to make 60 mL

2. Calculate the amounts needed for 100 g of antiseptic powder, as follows:

Solid A 2 g

Solid B 1 g

Solid C 7 g

Solid D 25 g

Solid E  $\frac{115 \text{ g}}{150 \text{ g}}$

$$\text{factor} = \frac{100 \text{ g}}{150 \text{ g}} = 0.667$$

Solid A: 2 g  $\times 0.667 = 1.33 \text{ g}$

Solid B: 1 g  $\times 0.667 = 0.667 \text{ g}$

Solid C: 7 g  $\times 0.667 = 4.67 \text{ g}$

Solid D: 25 g  $\times 0.667 = 16.7 \text{ g}$

Solid E: 115 g  $\times 0.667 = 76.7 \text{ g}$

3. Prescriptions where the instruction to the pharmacist calls for making a certain number of doses of an ingredient or mixture of several ingredients are a type of formula enlargement. The expression usually used is "D.T.D.," which means "let such doses be given." Occasionally the prescriber will not use this expression, but inspection of amounts of the ingredients indicates that this is what is desired. For example,

Solid H 50 mg

Solid K 150 mg

Liquid N 0.2 mL

M ft capsules, D.T.D. No. 24

The pharmacist checked the individual doses of the ingredients and found them to be slightly below the average adult dose, confirming that the prescriber wanted the quantities listed to be multiplied by 24.

$$\text{Solid H: } \frac{50 \text{ mg}}{\text{capsule}} \times 24 \text{ capsule} = 1200 \text{ mg or } 1.2 \text{ g}$$

$$\text{Solid K: } \frac{150 \text{ mg}}{\text{capsule}} \times 24 \text{ capsule} = 3600 \text{ mg or } 3.6 \text{ g}$$

$$\text{Solid N: } \frac{0.2 \text{ mL}}{\text{capsule}} \times 24 \text{ capsule} = 4.8 \text{ mL}$$

### PROBLEMS

1. The formula for a liquid preparation is

Liquid C	35 mL
Solid B	9 g
Liquid R	2.5 mL
Liquid P	20 mL
Purified water, sufficient to make	100 mL

Calculate the quantities of the ingredients to make 2.5 L.

2. The formula for an ointment is:

Solid G	1
Liquid D	30

Solid M	3
Ointment base, sufficient to make	100

Calculate quantities of the ingredients for 2 lb (apoth).

3. How much of each of the three solids and how much purified water are needed to properly compound the following prescription order?

Solid N	0.1 mg
Solid Q	2.5 mg
Solid R	150.0 mg
Purified water, qs	5 mL

M ft solution, D.T.D. No. 48

4. How much of each ingredient is required to compound 90 mL of the following product?

Solid S	7.5 g
Solid T	25 g
Oil C	350 mL
Alcohol	250 mL
Purified water, qs	1000 mL

## PERCENTAGE

Percent means per hundred. Fifteen percent is written 15% and means 15/100, 0.15, or 15 parts in a total of 100 parts. Percent is a type of ratio and has units of parts per 100 parts. Thus, 10% of 1500 tablets is  $10/100 \times 1500$  tablets = 150 tablets.

To change percent to a fraction, the percent number becomes the numerator and 100 is the denominator. To change a fraction to percent, put the fraction in a form having 100 as its denominator; multiply by 100 so that the numerator becomes the percent.

$$\frac{1}{2} = \frac{50}{100}; \frac{50}{100} \times 100 = 50\%$$

$$\frac{1}{8} = \frac{12.5}{100}; \frac{12.5}{100} \times 100 = 12.5\%$$

Calculations involving percentages are encountered continually by pharmacists. They must be familiar not only with the making a certain number of doses of an ingredient or mixture of arithmetical principles, but also with certain compendial interpretations of the different type percentages involving solutions and mixtures. The USP states:

Percentage concentrations of solutions are expressed as follows:

- *Percent weight in weight (w/w)* expresses the number of g of a constituent in 100 g of product.
- *Percent weight in volume (w/v)* expresses the number of g of a constituent in 100 mL of product, and is used regardless of whether water or another liquid is the solvent.
- *Percent volume in volume (v/v)* expresses the number of mL of a constituent in 100 mL of product.

The term *percent* used without qualification means, for mixtures of solids, percent weight in weight; for solutions or suspensions of solids in liquids, percent weight in volume; for solutions of liquids in liquids, percent volume in volume; and for solutions of gases in liquids, percent weight in volume. For example, a one percent solution is prepared by dissolving 1 g of a solid or 1 mL of a liquid in sufficient of the solvent to make 100 mL of the solution.

## Ratio Strength

Ratio strength is another manner of expressing concentration. Such phrases as “1 in 10” are understood to mean that one part of a substance is to be diluted with a diluent to make 10 parts

of the finished product. For example, a 1 : 10 solution means 1 mL of a liquid or 1 g of a solid dissolved in sufficient solvent to make 10 mL of solution. Ratio strength can be converted to percent by:

$$\frac{1 \text{ g substance}}{10 \text{ mL solution}} \times 100 \text{ mL solution} = 10 \text{ g substance}$$

$$\frac{10 \text{ g substance}}{100 \text{ mL solution}} = 10\%$$

The expression “parts per thousand” (e.g., 1 : 5000) always means parts weight in volume when dealing with solutions of solids in liquids and is similar to the above expression. A 1 : 5000 solution means 1 g of solute in sufficient solvent to make 5000 mL of solution. This can be converted to percent by:

$$\frac{1 \text{ g substance}}{500 \text{ mL solution}} \times 100 \text{ mL solution} = 0.02 \text{ g substance}$$

$$\frac{0.02 \text{ g substance}}{100 \text{ mL solution}} = 0.02\%$$

The expression “trituration” has two different meanings in pharmacy. One refers to the process of particle-size reduction, commonly by grinding or rubbing in a mortar with the aid of a pestle. The other meaning refers to a dilution of a potent powdered drug with a suitable powdered diluent in a definite proportion by weight. It is the second meaning that is used in this chapter.

When pharmacists refer to a “1 in 10 trituration” they mean a mixture of solids composed of 1 g of drug plus sufficient diluent (another solid) to make 10 g of mixture or *dilution*. In this case the “1 in 10 trituration” is actually a solid dilution of a drug with an inert solid. The strength of a trituration may also be stated as percent *w/w*. Thus, the term trituration has come to mean a solid dilution of a potent drug with a chemically and physiologically inert solid.

The meanings implied by the USP statements in the section on percentage are illustrated below with a few examples of the three types of percentages.

## Weight-in-Volume Percentages

This is the type of percent problem most often encountered on prescriptions. The volume occupied by the solute and the volume of the solvent are *not* known because sufficient solvent is added to make a given or known final volume.

### EXAMPLES

1. Prepare 1 f $\mathcal{J}$  of a 10% solution. Since this is a solution of a solid in a liquid, this is a *w/v* solution.

$$\frac{10 \text{ g drug}}{100 \text{ mL soln}} \times \frac{29.6 \text{ mL}}{1 \text{ f}\mathcal{J}} \times 1 \text{ f}\mathcal{J} = 2.96 \text{ g drug}$$

2.96 g is dissolved in sufficient purified water to make 29.6 mL of solution.

2. How much of a drug is required to compound 4 f $\mathcal{J}$  of a 3% solution in alcohol?

$$\frac{3 \text{ g drug}}{100 \text{ mL soln}} \times \frac{29.6 \text{ mL}}{1 \text{ f}\mathcal{J}} \times 4 \text{ f}\mathcal{J} = 3.55 \text{ g drug}$$

3. How much 0.9% solution of sodium chloride can be made from  $\frac{1}{2}$   $\mathcal{J}$  of NaCl?

$$\frac{100 \text{ mL soln}}{0.9 \text{ NaCl}} \times \frac{31.1 \text{ g}}{1 \mathcal{J}} \times 0.5 \mathcal{J} = 1730 \text{ mL soln}$$

4. How many grams of a drug are required to make 120 mL of a 25% solution?

$$\frac{25 \text{ g drug}}{100 \text{ mL soln}} \quad 120 \text{ mL} = 30 \text{ g drug}$$

5. How would you prepare 480 mL of a 1 in 750 solution of an antiseptic? *Remember:* Percent w/v is indicated. One in 750 means 1 g of the antiseptic dissolved in sufficient solvent to make 750 mL solution.

$$\frac{1 \text{ g drug}}{750 \text{ mL soln}} \quad 480 \text{ mL} = 0.64 \text{ g drug}$$

Dissolve 0.64 g of antiseptic in sufficient solvent to make 480 mL solution.

6. How much of a substance is needed to prepare 1 L of a 1 : 10 000 solution? The ratio 1 : 10 000 means 1 g of a substance in 10 000 mL of solution.

$$\frac{1 \text{ g substance}}{10,000 \text{ mL soln}} \quad \frac{1000 \text{ mL}}{1 \text{ L}} \quad 1 \text{ L} = 0.1 \text{ g substance}$$

7. How would you prepare 120 mL of 0.25% solution of neomycin sulfate? The source of neomycin sulfate is a solution which contains 1 g neomycin sulfate/10 mL.

$$\frac{10 \text{ mL stock soln}}{1 \text{ g drug}} \quad \frac{0.25 \text{ g drug}}{100 \text{ mL soln}} \quad 120 \text{ mL soln} = 3 \text{ mL stock soln}$$

Add sufficient purified water to 3 mL of stock solution to make 120 mL.

### PROBLEMS

- How would you make 3 f $\bar{z}$  of a 12.5% solution?
- How many liters of a 4% solution can be made from 4 $\bar{z}$  of a solid?
- How many liters of an 8% solution can be made from 500 g of a solid?
- How many grams of a drug are needed to make 4 L of a 1 in 500 solution?

### Weight-in-Weight Percentages

Density must be considered in some of these problems. If a weight-in-weight solution is requested on a prescription, both the solute and solvent must be weighed, or the solute and the solvent may be measured if their densities are taken into consideration in determining the volumes. Since the solutions are made to a given weight, a given volume is not always obtainable.

### EXAMPLES

1. What weights of solute and solvent are required to make 2 $\bar{z}$  of a 3% w/w solution of a drug in 90% alcohol?

$$\frac{3 \text{ g solute}}{100 \text{ g soln}} \times \frac{31.1 \text{ g soln}}{1 \bar{z} \text{ soln}} \times 2 \bar{z} \text{ soln} = 1.87 \text{ g solute}$$

$$\frac{31.1 \text{ g soln}}{1 \bar{z} \text{ soln}} \times 2 \bar{z} \text{ soln} = 62.2 \text{ g soln}$$

$$62.2 \text{ g soln} - 1.87 \text{ g solute} = 60.3 \text{ g solvent}$$

2. The solubility of boric acid is 1 g in 18 mL of water at 25°C. What is the percentage strength, w/w, of a saturated solution? One gram of boric acid in 18 mL of water makes a saturated solution, and 18 mL of water weighs 18 g, hence the weight of solution is 19 g. The amount of boric acid present is 1 g in 19 g of solution; therefore, the following relationship can be set up:

$$\frac{1 \text{ g drug}}{19 \text{ g soln}} \times 100 \text{ g soln} = 5.26 \text{ g drug}$$

$$\frac{5.26 \text{ g drug}}{100 \text{ g soln}} = 5.26\%$$

3. How many grams of a chemical are needed to prepare 200 g of a 10% w/w solution? Ten percent w/w means 10 g of solute in 100 g total solution. The following relationship may be set up:

$$\frac{10 \text{ g solute}}{100 \text{ g soln}} \quad 200 \text{ g soln} = 20 \text{ g solute}$$

4. How would one make a 2% w/w solution of a drug in 240 mL of alcohol? The density of alcohol is 0.816 g/mL.

- a. First, convert 240 mL to weight. *Remember:* alcohol is the solvent and it has a density different from that of water.

$$\frac{0.816 \text{ g alcohol}}{1 \text{ mL alcohol}} \quad 240 \text{ mL alcohol} = 195.8 \text{ g (196 g) alcohol}$$

- b. Two percent w/w means 2 g solute in 100 g solution. In this problem the final weight of solution is not known; 240 mL (196 g) of alcohol represents the solvent only. The solvent is 98% w/w of the total solution, so the following relationship may be set up:

$$\frac{2 \text{ g solute}}{98 \text{ g alcohol}} \quad 196 \text{ g alcohol} = 4.00 \text{ g solute}$$

- c. Dissolve 4.00 g of the drug in 240 mL alcohol. The resulting solution will be 2% w/w and have a volume slightly larger than 240 mL because of the volume displacement of the drug.
5. How much of a 5% w/w solution can be made from 28.4 g of a chemical?

$$\frac{100 \text{ g soln}}{5 \text{ g chemical}} \quad 28.4 \text{ g chemical} = 568 \text{ g soln}$$

6. How many milliliters of a 70% w/w solution having a density of 1.2 g/mL will be needed to prepare 600 mL of a 10% w/w solution?

- a. Drug needed:

$$\frac{10 \text{ g drug}}{100 \text{ mL soln (10%)}} \times 600 \text{ mL soln (10%)} = 60 \text{ g drug}$$

- b. Weight of 70% solution needed.

$$\frac{100 \text{ g soln (70%)}}{70 \text{ g drug}} \quad 60 \text{ g drug} = 85.7 \text{ g soln (70%)}$$

- c. Volume of 70% solution needed.

$$\frac{1 \text{ mL soln (70%)}}{1.2 \text{ g soln (70%)}} \quad 85.7 \text{ g soln (70%)} = 71.4 \text{ mL soln (70%)}$$

Compounding problems involving solid preparations (such as mixtures of powder) and semisolid preparations (such as ointments, creams, and suppositories) are also percent w/w. The following is an example of this.

1. How much drug is required to make 2 $\bar{z}$  of a 10% ointment?

$$\frac{10 \text{ g drug}}{100 \text{ g oint}} \times \frac{31.1 \text{ g oint}}{1 \text{ } \frac{3}{4} \text{ oint}} \times 2 \frac{3}{4} \text{ oint} = 6.22 \text{ g drug}$$

The same procedure could be used for such mixtures as powders and suppository masses. Instead of using units in the various measuring systems, quantities can be indicated "by parts." The term "parts" then can mean any unit in any measuring system, as long as the units are kept constant.

2. How many grams of each of the following three ingredients are required to make 30 g of the product?

Solid A	0.5 part
Powder B	3.0 parts
Powder C, qs	30.0 parts

Since the product is a mixture of powders, percent w/w is indicated. In the above prescription order the total product is 30 parts because powder C is used to "qs" or "make up to" 30 parts. Therefore, 0.5 g of solid A and 3.0 g of powder B are needed.

$$\frac{1 \text{ g drug}}{19 \text{ g soln}} \times 100 \text{ g soln} = 52.6 \text{ g drug}$$

$$\frac{52.6 \text{ g drug}}{100 \text{ g soln}} = 52.6\%$$

3. How much of each of the following ingredients is needed to make 60 g of the ointment?

R <sub>x</sub> Solid D	3.0 parts
Solid E	6.0 parts

ointment Base Q	$\frac{30.0 \text{ parts}}{39.0 \text{ parts total}}$
-----------------	---

$$\frac{3.0 \text{ g solid D}}{39.0 \text{ g oint}} \times 60 \text{ g oint} = 4.26 \text{ g solid D}$$

$$\frac{6.0 \text{ g solid E}}{39.0 \text{ g oint}} \times 60 \text{ g oint} = 92.3 \text{ g solid E}$$

$$\frac{30.0 \text{ g base Q}}{39.0 \text{ g oint}} \times 60 \text{ g oint} = 46.2 \text{ g base Q}$$

4. What is the percent strength of a salt solution obtained by diluting 100 g of a 5% solution to 200 g? Assign the 5% solution as soln 1. Assign the final solution as soln 2.

$$\frac{5 \text{ g salt}}{100 \text{ g soln 1}} \times \frac{100 \text{ g soln 1}}{200 \text{ g soln 2}} \times 100 \text{ g soln 2} = 2.5 \text{ salt}$$

$$\frac{2.5 \text{ g salt}}{100 \text{ g soln 2}} = 2.5\% \text{ w/w}$$

### PROBLEMS

1. How much of the drug and solvent are needed to compound the following prescription?

R <sub>x</sub> Compound A	6% w/w
Solvent, qs	4 } oz

2. How many grams of solute are needed to prepare 240 g of a 12% w/w solution?  
 3. How many kilograms of a 20% w/w solution can be made from 1 kg of the solute?  
 4. How would you prepare, using 120 mL of glycerin (density, 1.25 g/mL), a solution that is 3% w/w with respect to a drug?  
 5. How much of each substance is needed to prepare a total of 24 g of the following suppository mass?

Compound K	0.3 g
Solid H	0.15 g
Suppository base, qs	2.0 g

6. How would one prepare 500 mL of a 15% w/w aqueous solution?  
 7. How much of each of the ingredients is required to make 1 kg of the following mixture?

Powder P	1 part
Powder Q	8 part
Powder R	12 part
Powder S	15 part
Total	$\overline{36 \text{ part}}$

8. How much of each ingredient is required to prepare the following ointment?

R <sub>x</sub> Coal Tar Solution	10%
Hydrophilic Ointment, qs	30 g

### Volume-in-Volume Percentages

A direct calculation of percentage from the total volume is made. Volumes, unlike weights, may not be additive. However, this does not present a problem because the final solution is made up to the desired volume with the diluent.

In the case of potent substances, a properly prepared stock solution permits the pharmacist to obtain accurately a quantity of solid that might otherwise be difficult to weigh. In the case of frequently prescribed salt solutions, a stock solution readily provides the required amount of salt without the necessity of weighing and dissolving it every time.

Stock solutions may be of various concentrations depending on the requirements for use. The stock solutions should be labeled properly and fractional parts needed to make various strengths also may be listed as a further convenience.

There is a type of compounding and dispensing problem that involves the concept of stock solutions. This involves the patient diluting a dose from the prescription order to a given volume to obtain a solution of desired concentration.

For example, how many grams of a salt are required to make 90 mL of a stock solution, 5 mL of which makes a 1 : 3000 solution when diluted to 500 mL? Assign the stock solution as soln 1. Assign the final dilution as soln 2.

$$\frac{1 \text{ g salt}}{3000 \text{ mL soln 2}} \times \frac{500 \text{ mL soln 2}}{5 \text{ mL soln 1}} \times 90 \text{ mL soln 1} = 3.0 \text{ g salt}$$

### EXAMPLES

1. How many minims of a liquid are needed to make 6 } of a hand lotion containing 0.5% v/v of the liquid?

$$\frac{16.2 \text{ mL liq}}{1 \text{ mL liq}} \times \frac{0.5 \text{ mL liq}}{100 \text{ mL lotion}} \times \frac{29.6 \text{ mL lotion}}{1 \text{ } \frac{3}{4} \text{ lotion}} \times 6 \frac{3}{4} \text{ lotion} = 14.4 \text{ mL liq}$$

Add sufficient lotion to 14.4 minim of the liquid to make 6 } of the product.

2. How much 90% alcohol is required to compound 500 mL of a 10% alcohol mixture?

$$\frac{100 \text{ mL (90)}}{90 \text{ mL alcohol}} \times \frac{10 \text{ mL alcohol}}{100 \text{ mL (10)}} \times 500 \text{ mL (10)} = 55.5 \text{ mL (90)}$$

### PROBLEMS

1. How many minims of a liquid are needed to make 4 } of a 12.5% v/v solution?  
 2. What volume of 50% v/v alcohol could be prepared from 1 L of 95% v/v alcohol?  
 3. What is the percentage strength, weight in weight, of a liquid made by dissolving 16 g of a salt in 30 mL of water?

- How much drug will be required to prepare 1℥ of a 2.5% solution?
- What is the percentage, weight in weight, of sugar in a syrup made by dissolving 5 kg of sugar in 8 kg of water?
- How many grams of a drug are required to prepare 120 mL of a 12.5% aqueous solution?
- How much drug is needed to compound a liter of a 1 : 2500 aqueous solution?
- A solution contains 37% of active ingredient. How much of this solution is needed to prepare 480 mL of an aqueous solution containing 2.5% of the active ingredient?
- How much of a drug is required to make 2 qt of a 1 : 1200 solution?

## STOCK SOLUTIONS

To facilitate the dispensing of certain soluble substances, the pharmacist frequently prepares or purchases solutions of high concentration. Portions of these concentrated solutions are diluted to give required solutions of lesser strength. These concentrated solutions are known as *stock solutions*. This procedure is satisfactory if the substances are stable in solution or if the solutions are to be used before they decompose.

In the case of potent substances, a properly prepared stock solution permits the pharmacist to obtain accurately a quantity of solid that might otherwise be difficult to weigh. In the case of frequently prescribed salt solutions, a stock solution readily provides the required amount of salt without the necessity of weighing and dissolving it every time.

Stock solutions may be of various concentrations depending on the requirements for use. The stock solutions should be labeled properly and fractional parts needed to make various strengths may also be listed as a further convenience.

There is a type of compounding and dispensing problem that involves the concept of stock solutions. This involves the patient diluting a dose from the prescription order to a given volume to obtain a solution of desired concentration.

For example, how many grams of a salt are required to make 90 mL of a stock solution, 5 mL of which makes a 1 : 3000 solution when diluted to 500 mL? Assign the stock solution as soln 1. Assign the final dilution as soln 2.

$$\frac{1 \text{ g salt}}{3000 \text{ mL soln 2}} \times \frac{500 \text{ mL soln 2}}{5 \text{ mL soln 1}} \times 90 \text{ mL soln 1} = 3.0 \text{ g salt}$$

## PROBLEMS

- How much of a drug is needed to compound 120 mL of a prescription order such that when 1 teaspoonful of the solution is diluted to 1 qt, a 1 : 750 solution results?
- How many grams of a drug are needed to make 240 mL of a solution of such strength that when 5 mL is diluted to 2 qt, a 1 : 2500 solution results?
- An ampule of solution of an anti-inflammatory drug contains 4 mg of drug per mL. What volume of the solution is needed to prepare a liter of solution that contains 2 μg of the drug per mL?

## PARTS PER MILLION

An expression that is occasionally used in compounding prescriptions is *parts per million* (ppm). This is another way of expressing concentration, particularly concentrations of very dilute preparations. A 1 percent solution may be expressed as 1 part/100; a 0.1 percent solution is 0.1 parts/100 or 1 part/1000. A 1 ppm solution contains 1 part of solute/1 million parts of solution; 5 ppm is 5 parts solute/1 million parts solution, and so on. Remember that the two parts must have the same units, except in the metric system where 1 g = 1 mL of water.

Sodium fluoride is a drug that may be prescribed by a dentist as a preventative for tooth decay in children. It is used only in very dilute solutions due to the drug's toxicity and because only minute quantities are needed. For example, how much sodium fluoride would be needed to prepare the following prescription?

R<sub>x</sub> Sod Fluoride, qs  
Purified water, qs 60 mL  
Make soln such that when 1 f℥ is diluted to 1 glassful of water a 2 ppm soln results.  
sig: 1 f℥ in a glassful of water a day.

The mathematics to solve this compounding problem are easy once the steps for calculating the answer are outlined. This problem should be worked "backward."

- The amount of NaF needed is not known.
- One glassful of water has a volume of 240 mL. The concentration of NaF in 240 mL is 2 ppm.
- The NaF solution poured into the glass came from a teaspoonful dose (1 f℥), which is equal to 5 mL.
- The 5 mL dose came from the prescription order bottle containing a NaF solution.

$$\frac{2 \text{ g NaF}}{1,000,000 \text{ mL dilution}} \times \frac{240 \text{ mL dilution}}{5 \text{ mL R}_x} \times 60 \text{ mL R}_x = 0.00576 \text{ g NaF}$$

The pharmacist would weigh out 5.76 mg (actually, one would weigh out a larger quantity and take an aliquot part) and qs to 60 mL.

Another variation of this problem is the prescriber requesting the concentration in terms of fluoride ion (F<sup>-</sup>). In this case the atomic weight of F<sup>-</sup> and molecular weight of NaF are used in the calculation. If the request called for 2 ppm fluoride, the initial calculations would be the same as above, and an additional step would be added at the end. The 5.76 mg would now represent the weight of fluoride ion needed. This must be converted to weight of NaF. The molecular weight of NaF is 42 and the atomic weight of fluorine is 19. The following proportion can be set up.

## PROBLEM

- How many milligrams of NaF are needed in the following prescription?

R<sub>x</sub> Sodium fluoride  
Purified water, qs to 90 mL  
M ft solution such that when 1 f℥ is diluted to 1 glassful of water a 3 ppm NaF soln results.

## DILUTION AND CONCENTRATION

Stock solutions can be diluted to make a product that has a lower concentration; also mixtures of powders or semisolids (e.g., ointments) can be diluted to give a product of lower concentration of the drug(s). The diluent is an inert solid or semisolid or base that does not contain any active ingredients.

Mixtures also may be concentrated by adding pure drug or mixing with a product containing a higher concentration of the drug. For example, how much of a diluent must be added to 50 g of a 10 percent ointment to make it a 5 percent ointment?

- How many grams of active ingredient are in 50 g of 10% ointment?

$$\frac{10 \text{ g drug}}{100 \text{ g oint (10\%)}} \quad 50 \text{ g oint (10\%) = 5 g drug}$$

2. How many grams of a 5% ointment can be made from 5 g of active ingredient?

$$\frac{100 \text{ g oint (5\%)}}{5 \text{ g drug}} \times 5 \text{ g drug} = 100 \text{ g oint (5\%)}$$

3. How many grams of base must be added to the 50 g of the original 10% ointment?

$$100 \text{ g oint (5\%)} - 50 \text{ g oint (10\%)} = 50 \text{ g base}$$

The term *trituration* was used previously to mean a dilute powder mixture of a drug. It is often necessary to dilute this mixture further to obtain the required amount of drug.

1. How much of a 1 in 10 trituration of a potent drug contains 200 mg of the drug? A 1 in 10 trituration means 1 g of drug in 10 g of mixture or 1 g of drug plus 9 g diluent. *Remember:* Mixtures of solids are percent w/w.

$$\frac{10 \text{ g trituration}}{1 \text{ g drug}} \times \frac{1 \text{ g drug}}{1000 \text{ mg drug}} \times 200 \text{ mg drug} = 2 \text{ g trituration}$$

2. How much diluent must be added to 10 g of a 1 : 100 trituration to make a mixture that contains 1 mg of drug in each 10 g of the final mixture?
- a. Determine the amount of drug in 10 g of trituration.

$$\frac{1 \text{ g drug}}{100 \text{ g trituration}} \times 10 \text{ g trituration} = 0.1 \text{ g drug}$$

- b. Determine the amount of mixture that can be made from 0.1 g (100 mg) of drug.

$$\frac{10 \text{ g mixture}}{1 \text{ mg drug}} \times \frac{1000 \text{ mg drug}}{1 \text{ g drug}} \times 0.1 \text{ g drug} = 1000 \text{ g mixture}$$

- c. Determine the amount of diluent needed.

$$1000 \text{ g mixture} - 10 \text{ g trituration} = 990 \text{ g diluent}$$

### PROBLEMS

1. The following prescription order was received in a pharmacy. If the only *R* cream available is a 10% concentration, how much of the 10% cream and how much diluent are required to compound the prescription?

$$\bar{R}_x \quad \bar{R} \text{ Cream } 3\% \dots 30 \text{ g}$$

2. How many grams of a 1 : 100 trituration contain 100 μg of the active ingredient?
3. How many grams of a 1 : 1000 dilution can be made from 1 g of a 1 : 25 trituration?

### MIXING DIFFERENT STRENGTHS

#### RULES

1. The sum of the products obtained by multiplying a series of quantities by their respective concentrations equals the product obtained by multiplying a concentration by the sum of the quantities. For example, the sum of the products—obtained by multiplying the individual weights or volumes of a series of preparations by the concentration of a given ingredient contained in each preparation—is equal to the product obtained by multiplying the total weight of the series of preparations by the percentage of the given ingredient resulting

from a homogeneous mixture of the same series of preparations.

2. When mixing products of varying strengths, the units and type of percent (w/w, w/v, v/v) must be kept constant.

### EXAMPLES

1. What is the percent of alcohol in a mixture made by mixing 5 L of 25%, 1 L of 50%, and 1 L of 95% alcohol?
- a. Determine the total amount of alcohol in the three solutions and the total amount of solution (1 L = 1000 mL). Assume additivity of volumes on mixing.

$$\frac{25 \text{ mL alcohol}}{100 \text{ mL (25\%)}} \times 5000 \text{ mL (25\%)} = 1250 \text{ mL alcohol}$$

$$\frac{50 \text{ mL alcohol}}{100 \text{ mL (50\%)}} \times 1000 \text{ mL (50\%)} = 500 \text{ mL alcohol}$$

$$\frac{95 \text{ mL alcohol}}{100 \text{ mL (95\%)}} \times 1000 \text{ mL (95\%)} = 950 \text{ mL alcohol}$$

- b. Determine the percent of alcohol in the mixture. There is a total of 2700 mL of alcohol in 7000 mL of total solution.

$$\frac{2700 \text{ mL alcohol}}{7000 \text{ mL mixture}} \times 100 \text{ mL mixture} = 38.6 \text{ mL alcohol}$$

$$\frac{38.6 \text{ mL alcohol}}{100 \text{ mL mixture}} = 38.5\%$$

2. What is the strength of a mixture obtained by mixing 50 g of a 5%, 100 g of a 7.5%, and 40 g of a 10% ointment?

$$\frac{5 \text{ g drug}}{100 \text{ g oint (5\%)}} \times 50 \text{ g oint (5\%)} = 2.5 \text{ g drug}$$

$$\frac{7.5 \text{ g drug}}{100 \text{ g oint (7.5\%)}} \times 100 \text{ g oint (7.5\%)} = 7.5 \text{ g drug}$$

$$\frac{10 \text{ g drug}}{100 \text{ g oint (10\%)}} \times 40 \text{ g oint (10\%)} = 4.0 \text{ g drug}$$

There is a total of 14.0 g of active ingredient in 190 g of total mixture.

$$\frac{14.0 \text{ g drug}}{190 \text{ g mixture}} \times 100 \text{ g mixture} = 7.37 \text{ g drug}$$

$$\frac{7.37 \text{ g drug}}{100 \text{ g mixture}} = 7.37\%$$

### PROBLEMS

1. What percent of a drug is contained in a mixture of powder consisting of 0.5 kg, containing 0.038% of a drug, and 10 kg, containing 0.043% of a drug?
2. What is the strength of a mixture produced by combining the following lots of alcohol: 2 L of 95%, 2 L of 50%, and 7 L of 60%?
3. What is the percent of drug content in the following mixture: 2 kg of 3%, 300 g of 2.5%, and 500 g of 4.2% resin?

### ALLIGATION ALTERNATE

*Alligation* is a rapid method of calculation that is useful to the pharmacist. The name is derived from the Latin *alligatio*,

meaning the act of attaching, and it refers to lines drawn during calculation to bind quantities together. This method is used to find the proportions in which substances of different strengths or concentrations must be mixed to yield a mixture of desired strength or concentration. When the proportion is found, a calculation may be performed to find the exact amounts of the substances required.

### RULES

1. Line up the concentrations of all the starting materials in a vertical column in order of concentration, traditionally from high to low. Pure drugs are defined as being 100%; solvents or vehicles are designated as 0%.
2. Place the concentration of the desired product in a second column such that it is bracketed by concentrations of starting materials. With two starting materials, the desired product simply falls between the two.
3. Cross subtract the two columns to give a parts formula that can be used to calculate specific amounts of each starting material.

### EXAMPLES AND PROCEDURE

1. In what proportion must a preparation containing 10% of drug be mixed with one containing 15% of drug to produce a mixture of 12% drug strength? Applying the above rules gives:

The concentrations of the starting material are lined up in the first column in decreasing or increasing order and the desired percent or concentration is placed in the center column. The third column is obtained by cross-subtracting as indicated by the arrows and gives a parts formula for mixing the two starting materials. Thus, mixing 2 parts of 15% drug preparation with 3 parts of 10% drug preparation will produce 5 parts of a drug mixture of the desired 12% strength.

2. In what proportion must 30% alcohol and 95% alcohol be mixed to make 500 mL of 50% alcohol? Set up the problem in the following manner:

In a total of 65 parts, 20 parts of 95% alcohol 45 parts of 30% alcohol are needed. Since the total is proportional to 500 mL, the following can be calculated:

$$\frac{20 \text{ parts(mL)95\%}}{65 \text{ parts(mL)50\%}} \times 500 \text{ (mL)50\%} = 154 \text{ mL 95\%}$$

$$\frac{45 \text{ parts(mL)30\%}}{65 \text{ parts(mL)50\%}} \times 500 \text{ (mL)50\%} = 346 \text{ mL 30\%}$$

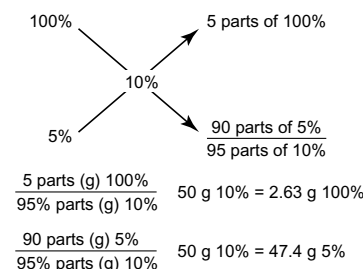

Since volumes are not additive, sufficient water may be needed to make 500 mL.

3. How many grams of an ointment containing 0.18% of active ingredient must be mixed with 50 g of an ointment

containing 0.14% of active ingredient to make a product containing 0.15% of active ingredient?

4. Occasionally it is necessary for a pharmacist to increase the strength of a product. For example, a prescription calls for 50 g of a 10% ointment. The pharmacist only has a 5% ointment and the pure ingredient available. How much of the 5% ointment and the pure ingredient are needed to compound the prescription?

### PROBLEMS

1. How much ointment containing 12% drug and how much ointment containing 16% drug must be used to make 1 kg of a product containing 12.5% drug?
2. In what proportion should 50% alcohol and purified water be mixed to make a 35% alcohol solution? (The purified water is 0% alcohol.) *Note:* This problem may be solved by a method other than alligation as was shown above.
3. How many grams of 28% w/w ammonia water should be added to 500 g of 5% w/w ammonia water to produce a 10% w/w ammonia concentration?
4. How many milliliters of 20% dextrose in water and how many milliliters of 50% dextrose in water are needed to make 1 L of 35% dextrose in water?

### PROOF SPIRIT

For tax purposes, the US government calculates the strength of pure or absolute alcohol (herein referred to as  $C_2H_5OH$ ) by means of *proof degrees*. This means that 100 proof spirit contains 50% (by volume) or 42.49% (by weight) of  $C_2H_5OH$ , and its specific gravity is 0.93426 at 60°F. Thus, 2 proof degrees equals 1% (by volume) of  $C_2H_5OH$ . One proof gallon is one gal of 50% (by volume) of  $C_2H_5OH$  at 15.56°C (60°F). In other words, a proof gallon is a gallon that contains  $\frac{1}{2}$  gal of  $C_2H_5OH$ . A proof gallon is 100 proof.

The term *10 degrees under proof* ( $10^\circ$  up) signifies that 100 volumes of the spirit contains 90 volumes of proof spirit plus 10 volumes of water, and *30 degrees over proof* ( $30^\circ$  op) indicates that 100 volumes diluted with water yields 130 volumes of proof spirit. To prepare proof spirit, 50 volumes of  $C_2H_5OH$  are mixed with 53.71 volumes of water to allow for the contraction that occurs to yield 100 volumes of product.

The terms *proof strength*, *proof gallon*, and *proof spirit* are used so that the tax is levied only on the actual quantity of  $C_2H_5OH$  contained in any mixture. Therefore, it is sometimes necessary for the pharmacist to convert alcohol purchased

to proof strength to compute tax refunds or convert proof strengths to percent for compounding purposes.

A quantity of solution that contains  $\frac{1}{2}$  gal of  $C_2H_5OH$  is said to contain one proof gal. Proof gallons may be calculated by the following two equations:

$$\text{Proof gal} = \frac{\text{gal v/v strength}}{50\% \text{ v/v}}$$

$$\text{Proof gal} = \frac{\text{gal proof strength}}{100 \text{ proof}}$$

The second equation is the same as the first because proof strength is always twice the % v/v strength. With these equations, given any two variables the third can be calculated.

### EXAMPLES

1. What is the taxable alcohol in 1 pt of alcohol USP?

$$1 \text{ pt} = \frac{1}{8} \text{ gal} \quad (8 \text{ pt} = 1 \text{ gal})$$

Alcohol USP is 95% v/v; therefore,

$$\text{proof gal} = \frac{\text{gal \%strength}}{50\%} = \frac{1/8 \text{ gal } 95\%}{50\%} = 0.2375 \text{ proof gal}$$

2. How much Diluted Alcohol USP can be made from 1 qt of alcohol labeled  $\frac{1}{2}$  proof gallon? Diluted alcohol USP is 49% v/v; therefore,

$$\begin{aligned} \text{Proof gal} &= \frac{\text{gal \%strength}}{50\%} \\ \text{gal} &= \frac{0.5 \text{ proof gal } 50\%}{49\%} = 0.510 \text{ gal} \end{aligned}$$

### PROBLEMS

1. How many proof gallons are there in 1 qt of a preparation that is labeled 75% v/v alcohol?
2. How many proof gallons are there in a pint of an elixir that contains 14% alcohol?
3. How much Diluted Alcohol USP can be made from 1 gal of 190 proof alcohol?

### SATURATED SOLUTIONS

Occasionally, it is necessary for a pharmacist to make saturated solutions. Solubility in the USP/NF is expressed as the number of milliliters of a solvent that will dissolve 1 g of a solid; for example, 1 g dissolves in 0.5 mL of water. In other words, if 1 g of a solid is dissolved in 0.5 mL of water, a saturated solution results. An example will illustrate this.

1. How much of a drug is needed to make 120 mL of a saturated solution if 1 g of the drug dissolves in 7.5 mL of water?

Calculate the amount of drug that can be dissolved in 120 mL of water.

$$\frac{1 \text{ g drug}}{7.5 \text{ mL water}} \times 120 \text{ mL water} = 16 \text{ g drug}$$

When 16 g of the drug is dissolved in 120 mL of water, a saturated solution results that has a volume greater than 120 mL because the solid will take up a certain volume. Only 120 mL would be dispensed.

2. What is the % w/w of the above solution?

$$120 \text{ g(mL) water} + 16 \text{ g drug} = 136 \text{ g solution}$$

$$\frac{16 \text{ g drug}}{136 \text{ g solution}} \times 100 \text{ g solution} = 11.8 \text{ g drug}$$

$$\frac{11.8 \text{ g drug}}{100 \text{ g solution}} = 11.8\% \text{ w/w}$$

### PROBLEMS

1. What is the solubility of a chemical if a saturated aqueous solution is 0.5% w/w?
2. How many grams are needed to make 500 mL of a saturated solution if 1 g of the solute is soluble in 14 mL of solvent?

### MILLIEQUIVALENTS

The quantities of electrolytes administered to patients are usually expressed by the term *milliequivalents* (mEq). The reason that weight units (mg, g) are not used is because the electrical activity of the ions, which in this instance is important, may be best expressed as milliequivalents. (See Chapter 15 "Ionic Solutions and Electrolytic Equilibria.")

A milliequivalent is 1/1000 of an *equivalent* (Eq). An equivalent is the weight of a substance that combines with or replaces one gram-atomic weight (g-at wt) of hydrogen. In pharmacy, the terms equivalent and equivalent weight (Eq wt) have been used interchangeably. For problem solving it is convenient to identify the molar weight in terms of mg per mmol and the number of mEq per mmol as follows:

$$\text{Molecular weight} = \frac{\text{g}}{\text{mole}} = \frac{\text{mg}}{\text{mmol}}$$

$$\frac{\text{mEq}}{\text{mol}} = \text{valence}$$

For example, KCl has a molecular weight of 74.5; the above parameters would be 74.5 mg/mmol and 1 mEq/mmol.

Water of hydration contributes to the molecular weight (mol wt) of a compound but *not* to the valence, and the total mol wt is used to calculate mEq.

### EXAMPLES

1. Calcium ( $Ca^{2+}$ ) has a gram-atomic weight of 40.08. Determine the number of mEq/mmol. As the valence of the calcium ion is 2, there are 2 mEq/mmol.
2. A solution (100 mL) that contains 409.5 mg of NaCl/100 mL has how many mEq of  $Na^+$  and  $Cl^-$ ? The molecular weight of NaCl is 58.5.

$$\text{There is } \frac{1 \text{ mEq } Cl^-}{\text{mmol NaCl}} \text{ and } \frac{1 \text{ mEq } Na^+}{\text{mmol NaCl}}$$

$$\frac{1 \text{ mEq } Cl^-}{\text{mmol NaCl}} \times \frac{1 \text{ mmol NaCl}}{58.5 \text{ mg NaCl}} \times \frac{409.5 \text{ mg NaCl}}{100} \text{ mL} \times 100 \text{ mL} = 7.0 \text{ mEq } Cl^-$$

Since NaCl is a 1:1 electrolyte, the solution contains 7.0 mEq of  $Cl^-$  and 7.0 mEq of  $Na^+$ .

3. A prescription order calls for a 500 mL solution of potassium chloride to be made so that it will contain 400 mEq of  $K^+$ . How many grams of KCl (mol wt: 74.5) are needed?

$$\frac{1 \text{ mEq}}{\text{mmol}} \text{ and } \frac{74.5 \text{ mg}}{\text{mmol}}$$

$$\frac{1 \text{ g KCl}}{1000 \text{ mg KCl}} \times \frac{74.5 \text{ mg KCl}}{\text{mmol KCl}} \times \frac{1 \text{ mmol KCl}}{\text{mEq } K^+} \times 400 \text{ mEq } K^+ = 29.8 \text{ g KCl}$$

4. How many mEq of  $K^+$  are in a 250 mg tablet of potassium phenoxymethyl penicillin (mol wt: 388.5; valence: 1)?

$$\frac{1 \text{ mEq } K^+}{\text{mmol Pen}} \text{ and } \frac{388.5 \text{ mg Pen}}{\text{mmol Pen}}$$

$$\frac{1 \text{ mEq } K^+}{\text{mmol Pen}} \times \frac{1 \text{ mmol Pen}}{388.5 \text{ mg Pen}} \times \frac{250 \text{ mg Pen}}{\text{Tab}} \times 1 \text{ Tab} = 0.644 \text{ mEq } K^+$$

5. How many mEq of Mg are there in 10 mL of a 50% magnesium sulfate injection? The mol wt of  $MgSO_4 \cdot 7H_2O$  is 246.

$$\frac{2 \text{ mEq } Mg^{2+}}{\text{mmol drug}} \text{ and } \frac{246 \text{ mg drug}}{\text{mmol drug}}$$

$$\frac{2 \text{ mEq } Mg^{2+}}{\text{mmol drug}} \times \frac{1 \text{ mmol drug}}{246 \text{ mg drug}} \times \frac{1000 \text{ mg drug}}{\text{g drug}} \times \frac{50 \text{ g drug}}{100 \text{ mL}} \times 10 \text{ mL} = 40.7 \text{ mEq } Mg^{2+}$$

6. A vial of sodium chloride injection contains 3 mEq/mL. What is the percentage strength of this solution? The mol wt of NaCl is 58.5.

$$\frac{1 \text{ mEq}}{\text{mmol}} \text{ and } \frac{58.5 \text{ mg}}{\text{mmol}}$$

$$\frac{1 \text{ g}}{1000 \text{ mg}} \times \frac{58.5 \text{ mg}}{\text{mmol}} \times \frac{1 \text{ mmol}}{1 \text{ mEq}} \times \frac{3 \text{ mEq}}{\text{mL}} \times 100 \text{ mL} = 17.6 \text{ g}$$

$$\frac{17.6 \text{ g}}{100 \text{ mL}} = 17.6\%$$

### PROBLEMS

- What is the mEq wt of ferrous ion ( $Fe^{2+}$ ) which has an atomic weight of 55.85 g?
- What is the mEq wt of sodium phosphate ( $Na_2HPO_4 \cdot 7H_2O$ )?
- How many mEq of  $Na^+$  are in 60 mL of a 5% solution of sodium saccharin (mol wt: 241 ; valence: 1)?
- How many mEq of  $Ca^{2+}$  are there in a 600 mg calcium lactate pentahydrate (mol wt: 308.30) tablet?
- How many mEq of sodium are there in a 5 gr sodium bicarbonate tablet? The mol wt of  $NaHCO_3$  is 84 and the valence is 1.
- How many mEq of Na are there in 500 mL of  $\frac{1}{2}$  normal saline solution? Normal saline solution contains 9 g NaCl/L; mol wt NaCl is 58.5.
- How much KCl is needed to make a pint of syrup that contains 10 mEq of  $K^+$  in each tablespoonful? The mol wt of KCl is 74.5.

### TEMPERATURE

#### RULES

The relationship of Celsius (C) and Fahrenheit (F) degrees is:

$$9(^{\circ}C) = 5(^{\circ}F) - 160$$

where  $^{\circ}C$  is the number of degrees Celsius and  $^{\circ}F$  is the number of degrees Fahrenheit.

#### EXAMPLES

- Convert 77°F to  $^{\circ}C$ .

$$9(^{\circ}C) = 5(77) - 160$$

$$^{\circ}C = \frac{385 - 160}{9} = 25^{\circ}C$$

- Convert 10 $^{\circ}C$  to  $^{\circ}F$ .

$$9(10) = 5(^{\circ}F) - 160$$

$$^{\circ}F = \frac{90 + 160}{5} = 50^{\circ}F$$

### PROBLEM

- Convert:
  - 30 $^{\circ}C$  to  $^{\circ}F$
  - 100 $^{\circ}C$  to  $^{\circ}F$
  - 37 $^{\circ}C$  to  $^{\circ}F$
  - 120 $^{\circ}F$  to  $^{\circ}C$

LOCATION PARAMETERS 134

DESIGN OF EXPERIMENTS AND COLLECTION OF DATA 135

DESIGN AND CONDUCT OF CLINICAL TRIALS 137

THE BINOMIAL AND NORMAL PROBABILITY DISTRIBUTIONS 138

ESTIMATION AND STATISTICAL INFERENCE 141

DATA TRANSFORMATIONS 173

### INTRODUCTION

The laws of physics in connection with mathematical models and tools are quite capable to deterministically describe natural phenomena. But the more complex the situation to be described gets, i.e., the more influences need to be considered if we wanted to describe them accurately, the more we find our results to be erroneous. And in a scale where quantum effects also play a role, we have to deal with true uncertainty.

Statistics gives us a means to deal with probabilities or errors in measurements. With the help of statistics, we can (among others) describe data, calculate estimates of its distribution, and decide whether to reject a hypothesis in a rational and reproducible manner.

### DATA

Data may come in discrete steps, as for instance, the number of patients that benefit from a certain therapy, or they may be continuous, meaning that the values can have infinitely many manifestations, even in a finite interval. An example for continuous data are, for instance, the masses of tablets.

In reality, however, all our measuring devices have a limited measuring accuracy, so in principle all experimental data comes in discrete quantities. This is important when statistical methods demand continuous data as a prerequisite, like the Mann-Whitney U test. We have to deal carefully with values that occur multiple times – statisticians call them “ties”. (Ties are not supposed to occur with continuous data because there will always be a difference, however small it may be. But in gathering real data, ties become real, too, because of the limited precision of the measurement.)

### DATA VISUALISATION

In statistics we want to explore data and make inferences from it. An important first step is to visualise the data. The human brain has developed extraordinary capabilities for pattern recognition, and thus we can grasp important statistical parameters like location and spread of the data, or spot correlations, clusters, outliers, and so on, with a single glance.

### Stem-and-Leaf Plot

A simple means to display data is the stem-and-leaf plot. It puts the data in order and provides visual information on the location, spread, and form of the data. It retains a least two significant digits of each data point.

A stem-and-leaf plot is constructed as follows:<sup>1</sup>

1. Split each score or value into two sets of digits. The first or leading set of digits is the stem, and the second, or trailing, set is the leaf.
2. Draw a vertical line, and list all possible stem digits left to the line from lowest to highest.

3. For each data point write the leaf values on the line labeled by the appropriate stem number.

If appropriate, you can list each stem digit twice and put leaves starting with digits 0 to 4 on the first line, and leaves starting with digits 5 to 9 on the second.

### Example 1. Example of a stem-and-leaf plot

For example consider the heights of the students of my statistics class: Their heights in centimetres are as follows: 195, 191, 198, 185, 158, 170, 160, 158, 172, 165, 185, 169, 187, 180, 178, 172, 180, 173, 168, 168, 172, 174, 160, 184, and 171.

The corresponding stem-and-leaf plot is presented in Table 10-1.

Table 10-1. Stem-and-Leaf Plot of Students' Heights

### SAMPLES AND POPULATIONS

Many experiments have as an objective the definition or comparison of two or more groups of data. For example, one may wish to compare the efficacy of two antihypertensive agents or a new antipsychotic drug versus a placebo. Or it may be desired to estimate the average drug content and variability of a batch of tablets. In virtually all such experiments, it is not realistic to observe all possible experimental units. In fact, sometimes the entire population of conceivable observations cannot be identified completely. The potential experimental material for a clinical study comparing an antipsychotic drug to a placebo would include not only patients but also persons with the disease who are not yet diagnosed. All of these people are the population or universe. Clearly, one would not perform an experiment that included the entire population for many reasons:

- All of these people could not be identified.
- The time or money to conduct such a huge experiment is not available.
- To include so many people in such an experiment could be dangerous or unethical.

It is not necessary to run such a large experiment to arrive at a fair conclusion regarding the efficacy of the drug. In fact, in

most cases, the test consists of a relatively small *sample* taken from a relatively large *population*.

Another more concrete example is the process of sampling in quality control. It may be of interest to estimate the proportion of defective tablets or the average drug content and uniformity of tablets in a production batch. Certainly in the latter case every tablet in the batch would not be examined because the test is destructive, i.e., the tablet is destroyed during the analysis for drug content. Rather, a sample of 20 tablets would be chosen to estimate the average drug content of the more than 1 million tablets in the batch.

Thus, in typical experiments in the pharmaceutical sciences, a small sample from the population is examined in order to make inferences about the large population.

## SUMMARY NUMBERS

In the next step we try to reduce the amount of data. We can try to specify a distribution by a mathematical model (e.g., normal distribution) and a finite set of parameters of that distribution. A sentence like, "The data follow a normal distribution with mean  $\mu$  and variance  $\sigma^2$ " contains more information than a thousand or more data points. This is because any normal distribution is completely determined by its mean and its variance (or its standard deviation, the square root of the variance).

## LOCATION PARAMETERS

The single most important parameter for any distribution of data from ordinal or interval scales is its location parameter or central value.

### Mode

For data from nominal scales, we can only name a mode, i.e., the value that occurs most frequently. A data set or distribution may have more than one mode; it is then called bimodal or multimodal.

### Median

The median is a location parameter for data on ordinal or interval scales. At most, one half of the data are lower than the median, and at most, one half of the data is higher. If the data set consists of an odd number of observations ( $n$  say), the median equals the  $(n+1)/2$  observation in the ordered data set. For an even number of observations, the median can be either stated as the average of the  $(n/2)$ th and the  $(n/2 + 1)$ th value (for data from an interval scale) or as the  $(n/2)$ th or  $(n/2 + 1)$ th values themselves, then referred to as "lower median" and "upper median."

For a complete population the median is identical to the 50% quantile.

### Mean

The arithmetic mean can only be stated for data from an interval (or ratio) scale. The population mean is commonly denoted by the Greek letter  $\mu$ , whereas the mean of a sample data set is referred to as  $\bar{x}$ . The sample mean  $\bar{x}$  is an unbiased estimator for the population mean  $\mu$ . The mean is defined as the sum of the observed values divided by the number of measurements:

$$\bar{x} = \left( \sum_{i=1}^n x_i \right) / n$$
 which makes it the average of the observed values.

### Spread Parameters

Other important information about a set of data is the variability or spread of the data.

#### RANGE

The difference between the largest and smallest value in a data set is known as the range.

#### VARIANCE

Another measure for the variability of the data that depends on all values is the standard deviation  $\sigma$  or its square, the variance

$$\sigma^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n-1}$$

For independent random variables  $X$  and  $Y$ , the variances are additive:  $Var(X+Y) = Var(X) + Var(Y)$ . For instance, the content of a drug in the parts of a divisible tablet varies by the variance  $Var_{tbl}$  of the content of the whole tablet, plus the variance  $Var_{div}$  introduced by the breaking:  $Var_{tot} = Var_{tbl} + Var_{div}$ . The additive property of variances is the key to analysis of variance (ANOVA, see below).

## Covariance

When considering data in more than one dimension, we are usually interested in the extend of the relationship of any two dimensions. For example, if we take the masses, compaction forces, hardness, and friability of a set of tablets, we might want to know whether compaction forces increase or decrease with the mass of the granules in the die, or how hardness or friability change with the compaction force. The answers might seem trivial in this example, but the statistical concept of covariance can give a quantitative answer to this question. The covariance is a generalisation of the variance. If we rewrite the formula for the calculation of the variance as:

$$Var(x) = \frac{\sum (x_i - \bar{x})(x_i - \bar{x})}{n-1}$$

we find that the covariance is quite similar:

$$Cov(x, y) = \frac{\sum (x_i - \bar{x})(y_i - \bar{y})}{n-1}$$

We have just replaced the second factor in the numerator by the difference of value and mean in another dimension. (Thus, if we calculate the covariance of one dimension with itself, we get the variance.) From the equation above it is also obvious that  $Cov(x, y) = Cov(y, x)$ .

The covariance  $Cov(x, y)$  tells us whether the two variables  $x$  and  $y$  are correlated or not: If the covariance is positive,  $y$  increases as  $x$  increases; if it is negative,  $y$  gets smaller with increasing  $x$ ; if the covariance is zero,  $x$  and  $y$  are independent of each other.

## FREQUENCY DISTRIBUTIONS

A *frequency distribution* of a data set can be constructed by counting the number of data points falling into a series of intervals (usually of equal size). The frequency distribution and its corresponding graph, a *histogram* or *bar chart*, show the distribution of the data, its central value (e.g., mean or median), and variability (e.g., SD or range). Example 2 shows the weights of 50 weanling rats to be used in an experiment.

### Example 2. The weights in gram of 50 rats at weaning were as follows

30	47	37	29	38
32	42	32	30	34
34	32	33	37	36
39	33	45	40	35
43	41	35	32	41
36	27	28	35	30
38	28	41	37	34
41	36	32	30	37
31	31	35	28	25
26	49	34	34	33

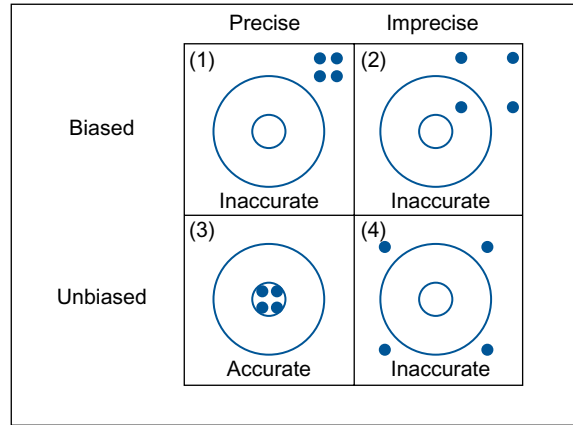

Table 10-2 is a frequency distribution with 13 intervals derived from the data given in Example 2. A rule of thumb is to use 8 to 20 intervals, depending on the quantity and spread of the data. The histogram or bar chart of these data is shown in Figure 10-1.

**BIAS, PRECISION, AND ACCURACY**

*Precision* refers to the reproducibility of a series of measurements. If the values are very close to each other, the measurements are said to be precise. *Accuracy* refers to the closeness of measurements to the true value. For example, if a tablet contains exactly 200 mg of drug, and three analyses show a drug content of 205, 205, and 206 mg, it might be concluded that the analysis is precise, but not accurate. *Bias* refers to a systematic difference from the true value. Figure 10-2 illustrates these concepts.

The three assays observed above seem to be biased on the high side, i.e., errors in the assay procedure result in too-high values. Figure 10-2 shows that “precise” data need not be accurate. In fact, there need not be any relationship or correlation between the qualities of precision and accuracy. Note that biased data cannot be accurate but can be precise.

In addition to the concept of bias in the area of experimental measurements, it appears also in the field of experimental design. Bias can be introduced into an experiment, not because of an error in an experimental measurement, but because of poor judgment. For example, consider an experiment where the efficacy of oral and sublingual nitroglycerin are to be compared by administering both products to 20 patients on two different occasions and measuring the time to incidence of an angina attack in a treadmill test. Each of 20 patients will receive both the oral and buccal forms. If each patient receives the buccal drug on Monday and the oral drug on the following Sunday, a bias may be observed in the experimental results even if the measurements are not biased. This could be due to either the day of the week when the test was given (gloomy Monday versus a holiday weekend day) or an order effect where there is a

**Figure 10-2.** Diagram illustrating bias, precision, and accuracy. The shots on targets 1 and 2 are biased; in both cases the shots cluster away from the bull’s-eye. The clusters on targets 3 and 4 both are unbiased; the center of each cluster is on the bull’s-eye. The shots on targets 1 and 3 are precise; both sets are bunched together. The shots on targets 2 and 4 are scattered widely, hence imprecise. Only the shots on target 3 are accurate—precise and unbiased.

different effect, depending on which drug is given first. For example, there may be psychological factors causing the response to drug taken first to be systematically better (or worse) than that taken second, or the weather may be such as to cause more positive results on the first occasion. In the latter case, differences between the two dosage forms would be exaggerated (biased) in favor of the drug administered first, the buccal drug. To obviate this potential bias, we would give ten of the patients the oral drug first (Monday) and the buccal drug second (Sunday). The other ten patients would receive the products in opposite order. Perhaps, an improvement in this design would be to test the drugs on the same day of the week, e.g., Monday.

**Table 10-2. Frequency Distribution of Rat Weights**

**DESIGN OF EXPERIMENTS AND COLLECTION OF DATA**

The application of statistics in the analysis of data is optimal when the data are collected in a planned or designed manner. If data are analyzed after the fact (retrospective analysis), great care should be taken to examine the data for possible bias. For example, prescription-volume data gathered for the years 1970 to 1980 may be available only from cities with populations greater than 500 000 or from cities in the Western States. Clearly, conclusions from such data should not be applied indiscriminately to the entire country. Also, the information may have been gathered on a voluntary basis; without knowledge of the characteristics of those who did and did not supply the information, the conclusions could be tainted.

The manner in which data are collected is connected to the planning and design of experiments. In the collection of data, a small sample generally is taken from a large population or universe. Sometimes a sample is taken inadvertently when the original intention was to obtain data from the population. For example, when a questionnaire is sent to every pharmacist in the state, there always will be some people who do not respond to the questionnaire, and anything less than 100% response constitutes a sample. A variety of examples of sampling methods is illustrated below.

**SAMPLING BY QUESTIONNAIRE**

Suppose that questionnaires on the sales of certain drugs were sent to all pharmacists in a state and only 50% were returned. In this type of survey, the results tabulated from such a sample

probably would be biased because those who did not return the questionnaire would not be represented in the sample.

It has been shown that persons who respond may have different characteristics from those who do not respond. In this hypothetical example, perhaps unanswered questionnaires were represented largely by pharmacists who had large drug sales and were too busy to answer. In another community a pharmacist may have little or no sales of the drugs, resulting in a nonresponse. The reason for each unanswered questionnaire is unknown. These unreturned questionnaires cause a bias, the direction and magnitude of which is unknown.

Other potential errors in this type of response that may introduce bias include the way in which the question is asked, the order in which questions are asked, and the psychological interaction between the interviewer and respondent. Questionnaire and survey techniques that can be employed to reduce or eliminate bias in the sample of responses have been proposed by mathematical statisticians.<sup>2</sup>

For example, public opinion polls use certain statistical sampling techniques that not only reduce bias but also optimize the information gathered. The Census Bureau has information about the percentages of men, women, and children in the US in various income and nationality groups, in addition to many other detailed categorizations. A sample may be designed to contain the same proportion of particular group(s) as that in the population. Instead of mailing questionnaires, interviewers may be recruited and assigned quotas of the types of people to interview. The interviewers fill out the questionnaires for each respondent during the interview, ensuring a complete response.

It is not possible to elaborate fully on the various methods of sampling here. One should be aware of problems in sampling and aware that a sampling design can be used that will give the limits of error of the resulting compilation for any given cost.<sup>2</sup>

### SAMPLING IN THE CHEMICAL LABORATORY

The procedure for gathering data in the laboratory differs from that of the questionnaire. Different kinds of sampling processes include the sampling of material to be assayed chemically or physically, sampling of analytical reagents and instruments when multiple instruments are available, and sampling of analysts, i.e., the chemists who will perform the assay.

By way of illustration, several samples may be taken from a large lot of digitalis leaves for the chemical determination of acid-insoluble ash, or drug may be analyzed in samples taken from a blend. For the sample to be representative of the lot, the samples should be taken from different parts of the lot to ensure that every part of the lot is represented. Determinations from five samples taken from the same part of a lot (e.g., the top of a container) probably will have values closer together than five samples taken from different parts of the lot (e.g., the top, top-middle, middle, low-middle, and bottom of a container). Despite the good precision, the former five samples may give a biased estimate of the average value for the lot. The more heterogeneous the lot, the more effort should be expended in being sure that every part of the lot is represented by a sample. It might be that the granulation having the most drug is in the bottom of the lot; samples all taken from the top would give an estimate of average drug content that is considerably lower than the true value.

Another aspect of sampling in a chemical determination is the sampling of the chemists who perform the chemical analysis.

If a single chemist makes several determinations on portions taken from the same sample of thoroughly mixed material, one expects the results to be more precise than if several chemists made these determinations. Probably the true reproducibility of a method can be indicated only in terms of how closely an analyst at one laboratory can check an analyst at another laboratory on exactly the same material. Thus, due to slight differences in technique, one chemist always might obtain higher results than another chemist. Thus, the technique of chemists will have an effect on the results and the reproducibility of the method.

### SAMPLING IN BIOLOGICAL AND CLINICAL EXPERIMENTS

A typical animal experiment might involve determining the temperature response of rabbits to pyrogens. The results of such an experiment constitute a sample of all possible results that could be obtained from the population of all possible rabbits, laboratories, and technicians. Using different rabbits, laboratories, and technicians will give different results, all contributing to the variability or error in the experiment. The differences between results from two or more laboratories are usually greater than differences between results obtained by two or more technicians in the same laboratory.

Concurrent conditions – such as season of the year, temperature, and humidity – sometimes can contribute to the experimental variability. In biological experiments differences between animals are relatively large, so experiments repeated in the same laboratory with different animals but under otherwise identical conditions will give different results. The use of statistical procedures gives an estimate of the amount of variation to be expected due to animal differences. The same can be said of clinical studies where more than one clinical site is needed to produce reliable, unbiased results.

Appropriate statistical designs and procedures will eliminate or account for potential bias in experiments. This point may be illustrated by an extreme example, an illustration of what not to do: A technician wishes to compare two drugs as to their effects on the growth of rats. Thirty rats from a single cage are used; the first 15 rats caught are put on Drug 1, and the last 15 caught are put on Drug 2. The first 15 rats caught are less lively than the last 15, and because they are less lively, they very likely differ in size and temperament from the last 15 rats. Thus, the results were biased from the very beginning, and one drug was favored merely because of the method of choosing the animals used for each drug.

Obviously, some method entirely free from subjective influences (unconscious or conscious) should be used. A table of random numbers<sup>3</sup> or computer-generated random numbers commonly is used to assign animals or patients to treatments. Table 10-3 is a short table of random numbers.

In a biological assay, it often is possible to design a dosage schedule that takes advantage of the reduced within-animal variation compared to between-animal variation. Because more than one dose may be given to a single animal, the order of dosing also must be designed to account for possible trends in response to consecutive doses caused by changes in the animal with time or due to site of application.

Note that in a Latin square, each letter occurs only once in each row and each column of the square. A Latin square design was applied to an assay involving two levels of doses of the standard (high and low doses,  $S_H$  and  $S_L$ , respectively), and

**Table 10-3. A Short Table of Random Numbers**

39	61	09	51	68	81	26	30	52	20	61	41	25

37	98	37	56	40	30	70	31	75	03	68	32	15
20	55	68	05	53	73	60	28	96	48	91	81	18

**Example 3. The use of the random number table**

Suppose that 10 patients are to be assigned to two treatment groups, 5 in each group. Table 10-3 can be used to assign patients randomly to groups. Patients first are numbered from 1 to 10. One way of assigning treatments to patients is to read across Table 10-3, and the first five distinct numbers will be assigned to the first treatment. The remaining patients are assigned to the second treatment. A zero will correspond to patient number 10. The first five numbers are 3, 9, 6, 1, and 0. (Note that if a number repeats itself, we skip the number and proceed to the next one.) Therefore, patients numbered 3, 9, 6, 1, and 10 are assigned to the first treatment. If 100 patients are to be assigned to the two treatments, two-digit numbers would be used: reading across, the 50 patients assigned to the first group would be numbered 39, 61, 9, 51, and so on.

There are many ways of using random numbers to ensure randomness in statistical experiments. The number of ways is limited only by the ingenuity of the experimenter. For example, random assignment could be accomplished by assigning patients to Group 1 or 2 as they enter the study, according to the appearance of an odd or even number in the random-number table.

**Example 4. The use of a Latin square design**

This can be illustrated by an epinephrine assay (see *Remington's Practice of Pharmacy*, 14th ed., p 633), where a single dog is given 16 consecutive doses, the order of which is determined by a Latin square design, illustrated by:

A	D	B	C
D	C	A	B
B	A	C	D
C	B	D	A

two levels of doses of the unknown ( $U_H$  and  $U_L$ ), where the four doses correspond to the letters, A, B, C, and D. The dosage schedule is given in Table 10-4. In this type of design, each dose occurs once in each order of administration (e.g., each of the four preparations are represented once in each group). In such an assay equal doses of epinephrine elicit a smaller and smaller rise in blood pressure with each succeeding dose. Therefore, order is important.

In all biological experimentation the design should be planned so that differences in treatment do not coincide with factors that could influence the outcome, such as differences in age, weight, sex, dates of administration, and so forth. This is known as *confounding* in statistical jargon. For example, if males are given a control treatment and females are given a comparative active treatment, the differences between treatments are said to be confounded by sex. That is, it cannot be determined if the outcomes observed are due to treatment, sex, or a combination of these factors.

Animals or patients should be assigned to doses or treatments at random, taking advantage of the availability of optimal experimental designs. Fisher<sup>4</sup> has written an excellent book on planning or designing experiments, which explains fully the various types of designs mentioned here. Cochran and Cox<sup>5</sup> detail useful experimental designs and provide complete directions for

**Table 10-4. Typical Dosage Schedule for an Epinephrine Assay Using a Latin Square Design**

	First Dose	Second Dose	Third Dose	Fourth Dose
First group	$U_L$	$S_H$	$U_H$	$S_L$
Second group	$S_H$	$S_L$	$U_L$	$U_H$
Third group	$U_H$	$U_L$	$S_L$	$S_H$
Fourth group	$S_L$	$U_H$	$S_H$	$U_L$

the analysis of data using these designs. Another book by Cox<sup>6</sup> is less mathematically oriented and comprehended more easily.

**DESIGN AND CONDUCT OF CLINICAL TRIALS**

Proof of the efficacy and safety of new drugs or treatments requires testing in human subjects. This is best achieved by carrying out *controlled clinical trials*. The use of a placebo treatment or an established treatment as a *control*, a basis of comparison, usually is necessary. Thus, the effects of treatment with those of a concurrently tested control or placebo are compared. The trial includes an adequate number of patients to allow a reliable projection of the results to future patients. Theoretically, the results cannot be projected beyond the types of severity of disease or the ages and sex of the patients included in the trial, although in practice this is not always the case.

The distribution of variables such as age, sex, differences in diagnosis, and initial severity of disease among treatments may be controlled by stratification. Usually patients are assigned to treatments at random, and allowances are made for the effects of the variables by using suitable statistical methods. A restricted randomization procedure is useful if it is desired to ensure that about an equal number of patients enter the trial on each treatment. Table 10-5 illustrates a completely randomized design in which 15 patients are allocated at random, five to each of three treatments.

Note that the individual patients in each triad (the groups of three) are assigned randomly to one of the three treatments. Here the randomization is restricted in that each set of three patients, when entered, must be assigned to treatments A, B, and C. The patients are assigned to treatments as they enter the trial. The first patient (#1) gets treatment B. This scheme prevents runs in the randomization wherein a long consecutive number of patients are assigned to the same treatment. Another example is shown in Table 10-6 for a simple crossover design, in which the individual patients take both treatments consecutively and are assigned randomly to one of two treatment order groups.

The latter design may be more efficient than a completely randomized design because each patient acts as his or her own control, thus eliminating patient-to-patient variability in the statistical analysis. However, this advantage may be offset if drug carryover effects are present, or if the severity of the disease wanes in the second period to the point at which treatment differences no longer can be demonstrated.

To be certain that the random allocation is followed strictly, and to remove subjective bias on the part of both the patient

**Table 10-5. Allocation of Patients in Randomized Design**

and the clinical investigator in assessing the effects of the treatments, the clinical trial should be carried out blind. A *double-blind trial* is one in which neither the patient nor the investigator is made aware of the nature of treatment administered.

To ensure that the study remains blinded, all treatments must be packaged as identical-appearing dosage forms. This may require a great deal of ingenuity on the part of the packaging pharmacist, especially with respect to the taste of orally administered liquid products, the color and shape of tablets, and so on. In some cases, the characteristic side-effects of the drugs make it difficult to keep a study blind. In these situations, one must rely more heavily on objective measures of response and less on subjective measures. However, the *placebo effect* may also result in changes in so-called *objective* measure of response.

**THE BINOMIAL AND NORMAL PROBABILITY DISTRIBUTIONS**

Statistical conclusions are based on *probability*. The process of *statistical inference* first considers an assumption about the distribution of the population data. If the observed data from the sample collected do not conform reasonably to the assumed distribution, the results are viewed as *significant*, i.e., the sample data show significant differences from the assumed distribution. For example, it may be assumed or hypothesized that an antibiotic will cure 80% of the patients treated. If three of six patients are cured with the drug, this is the question: What is the probability that three or fewer of six patients treated will be cured if the probability of a single patient being cured is 80%? If this calculated probability is small, the probability of a cure is probably not 80% but rather some lesser value.

To compute these probabilities, the properties of the assumed probability distribution must be known. Two important and often-used distributions in statistical theory are the binomial and normal distributions, which are examples of a discrete and continuous probability distribution, respectively. The experiment discussed in the preceding paragraph, which related to the cure of patients treated with an antibiotic, is an example of one application of the binomial distribution.

**THE BINOMIAL DISTRIBUTION**

The binomial distribution is applicable to data from which one of two mutually exclusive and independent outcomes are possible as a result of a single observation or experimental trial. A patient may be cured or not cured. Only one of these two mutually exclusive events can occur at the time of observation. *Independence*, in this context, means that the probability of a cure for any given patient is 80%, regardless of the experimental outcome of the other patients in the study.

The problem to be solved is to compute the probability that three (or less) of six patients will be cured if the probability of a cure for an individual patient is 0.8, or 80%. The general solution to this problem uses the binomial distribution. If two

independent and mutually exclusive outcomes are possible as the result of an experimental trial, the probability  $p(k)$  of exactly  $k$  outcomes of one kind (arbitrarily called *successes*) in  $n$  binomial trials ( $n$  patients in this example) is:

$$p(k) = \binom{n}{k} p^k (1-p)^{n-k} = \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k}$$

where  $p$  is the probability of success.

**Exercise 1.**

Calculate the probability of exactly three successes (cures) in six trials (patients) if  $p = 0.8$ ; i.e., the probability of a success or cure is 0.8.

Answer :  $p(x) = \binom{6}{3} \cdot 0.8^3 \cdot 0.2^3 = \frac{6 \cdot 5 \cdot 4}{3 \cdot 2 \cdot 1} \cdot 0.512 \cdot 0.008 = 0.082$

Thus, the probability of exactly three cures in six patients is 0.082. This is interpreted to mean that the chance of observing exactly three successes in six binomial trials with  $p = 0.8$  is approximately 8 in 100.

There are seven possible outcomes for the treatment of six patients as shown in Table 10-7, an example of a binomial probability distribution defined by  $n = 6$  and  $p = 0.8$ . It lists all the possible outcomes, with the probability of each outcome. The sum of all the probabilities is equal to 1. This distribution is shown graphically in Figure 10-3. A knowledge of this distribution allows a decision to be made as to whether three or fewer cures in six patients is a probable outcome for patients treated with a drug that has a cure rate of 80%. The probability of observing three or less successes (0, 1, 2, or 3 successes) is  $p(0) + p(1) + p(2) + p(3) = 0.0988$ , or about 1/10. Is this sufficient evidence to say that the true probability of a cure for the drug is less than 0.8? This question will be discussed in more detail in the section on Statistical Inference.

**Table 10-7. Binomial Distribution for  $n = 6$  and  $p = 0.8$**

Number of Successes	Probability of Outcome	Number of Successes	Probability of Outcome
0	0.0000026	4	0.24576
1	0.001536	5	0.39322
2	0.01536	6	0.262144
3	0.08192		

**Figure 10-3.** Binomial distribution for  $n = 6$  and  $p = 0.8$ .

Table 10-8 lists individual probabilities for  $p = 0.2, 0.5,$  and  $0.8,$  for  $n$  equal to 6 to 10, inclusive.

**Exercise 2.**

Calculate the probability of four successes in six trials for  $p = 0.8.$

Answer : 
$$p(4) = \binom{6}{4} \cdot 0.8^4 \cdot 0.2^2 = 0.246$$

The mean of the binomial distribution is  $np.$  Thus, for the binomial distribution with  $p = 0.8$  and  $n = 100,$  the mean is  $np = 80.$  That is, if 100 patients were treated with the antibiotic that has a cure rate of 80%, one could expect to see 80% or 80 patients cured of 100 treated on the average. The standard deviation of a binomial distribution is:  $\sqrt{np(1-p)}.$  The standard deviation of the number of patients cured of 100 treated in the above example is:

$$\sqrt{np(1-p)} = \sqrt{100 \cdot 0.2 \cdot 0.8} = 4$$

This can be interpreted as follows. If 100 patients are treated, it may be expected that 80 are cured on the average, but in any given experiment one probably would not see exactly 80 cured. The number cured will vary around 80, the mean, with a standard deviation equal to 4.

**THE NORMAL DISTRIBUTION**

The normal distribution can be considered as the underlying foundation of statistical theory and its applications. It is a continuous probability distribution ranging from  $-\infty$  to  $\infty.$  A normal

distributions is defined by its mean  $\mu$  and standard deviation  $\sigma.$  The mean can be any positive or negative value, but the standard deviation is always positive. So there are infinitely many normal distributions. The normal distribution with zero mean and unit standard deviation is called the standard normal distribution. Figure 10-4 shows the graphs of two normal probability curves. The normal distribution is characterized by the symmetry about its mean; most of the data cluster around the mean (68 of the data lies in the interval from  $\mu - \sigma$  to  $\mu + \sigma$ ). There are fewer values as the deviation is farther from the mean. The normal distribution is a theoretical probability distribution, not exactly observed in practical situations. However, much data approximate the normal distribution closely enough to make its application useful.

The Central Limit Theorem (CLT) is perhaps the most powerful theorem in statistics. It supports the pervasive use and importance of the normal distribution in statistical analyses. In simple terms, the CLT states that averages or means approach normality as  $n,$  the sample size, increases, no matter what the distribution of the individual variables. For data that are close to normal, means from even a small sample size will be approximately normal. For data that have distributions far from normal, larger sample sizes will be needed for the averages to be close to normal. The concept of the CLT is illustrated by the following example<sup>7</sup>

The outcome  $o$  of a disease after treatment can be (1) death  $o = 1,$  (2) not cured but continue treatment  $o = 2,$  and (3) cured  $o = 3.$  The probabilities of these three outcomes are 0.1, 0.3, and 0.6, respectively. This distribution is shown in Figure 10-5. This is a discrete distribution (three possible outcomes in a single trial), and it clearly is not normal. Figure 10-6 shows the distribution of means of size 20 ( $n = 20$ ). The means are obtained by treating 20 patients, assigning outcomes of 1, 2, or 3, according to the previous definition, and computing the mean. The distribution shown in Figure 10-6 was constructed from a computer simulation representing outcomes that can be expected in

Figure 10-4. Normal probability curves.

Figure 10-5. Probability distribution of outcomes after drug treatments.

realistic situations. Note that the averages cluster almost symmetrically around 2.5 (the mean) and are beginning to look like a normal distribution. One also should note the small variability of the mean results, most values ranging between approximately 2.2 to 2.7. A single outcome varies from 1 to 3.

The CLT allows the use of statistical methods that assume an underlying normal distribution of the data when dealing with averages of data that do not come from a normal distribution.

### COMPUTING PROBABILITIES FROM THE NORMAL DISTRIBUTION

Area represents probability, so the area under the whole normal curve is 1. The probability of observing a single value from a continuous distribution such as the normal is 0. However, one can calculate the probability of observing values in any interval  $[x_1, x_2]$ —designated as  $P(x_1 \leq x \leq x_2)$ —by computing the area under the curve in that interval. Table 10-9 is a short compilation of cumulative probabilities from the standard normal curve (Fig 10-7) that has a mean of  $\mu = 0$  and a standard deviation of  $\sigma = 1$ . Table 10-9 shows the probability of observing a value less than or equal to  $Z$ . For example, the probability of observing a value less than or equal to  $-1$  from the standard normal distribution is 0.16. The symmetry of the normal curve indicates that the probability of a value being greater than or equal to  $+1$  is also 0.16. Since the total area under the normal curve is 1 and area represents probability, the area less than or equal to  $Z = +1$  is  $1 - 0.16 = 0.84$ . This relationship is illustrated in Figure 10-7. In general, to calculate the area in any interval,  $Z_1, Z_2$ , look up the cumulative areas corresponding to  $Z_1$  and  $Z_2$ . The difference of the two areas is the area between  $Z_1$  and  $Z_2$ , or the probability of observing a value in that interval.

#### Exercise 3.

Calculate the probability of a value falling between  $-1.96$  and  $+1.28$  for the standard normal curve.

**Answer:** The area for values less than  $Z = -1.96$  is 0.025. The area corresponding to values less than  $Z = 1.28$  is 0.90. The difference is 0.875. Thus, the probability of observing a value between  $-1.96$  and  $+1.28$  is 0.875.

Figure 10-7. Standard normal distribution.

Since there are an infinite number of normal distributions (defined by their means and standard deviations) a reasonable question is, How would one calculate probabilities from a normal distribution that is different from the standard normal distribution? Fortunately, there is a simple transformation called  $z$ -transformation that converts data from any normal distribution into the standard normal distribution; Table 10-9 can then be used to compute the probabilities.

On order to do the  $Z$  transformation for any  $x$  from a normal distribution with mean  $\mu$  and standard deviation  $\sigma$ , just subtract  $\mu$  from  $x$  and divide the result by  $\sigma$ :

$$z = \frac{x - \mu}{\sigma}$$

The resulting  $z$  value follows the standard normal distribution.

**Example 5.**

What is the probability that a tablet will weigh between 185 and 210 mg if tablet weights have an approximately normal distribution with mean 200 mg and a standard deviation of 10 mg?

Using the Z transformation, we obtain:

$$z_l = \frac{185\text{mg} - 200\text{mg}}{10\text{mg}} = 1.5$$

$$z_u = \frac{210\text{mg} - 200\text{mg}}{10\text{mg}} = 1.0$$

The probabilities of finding values less than  $z_l=1.5$  and  $z_u=1.0$  in the standard normal distribution are found from Table 10-9. They are 0.07 and 0.84, respectively. Therefore, the probability of finding a tablet weighing between 185 and 210 mg is  $0.84 - 0.07 = 0.77$ . Note carefully that the transformation is equivalent to finding a value that is between  $-1.5$  and  $+1.0$  standard deviations from the mean (i.e., 185 mg is  $-15$  mg from the mean, which is equal to  $-1.5$  standard deviation units).

What is the probability that a tablet will weigh less than 180.4 or more than 219.6 mg? The Z transformation results in the values  $-1.96$  and  $+1.96$ . It is an important property of any normal distribution that 95% of the values are found in this interval.

Several Z values appear frequently when testing for statistical significance:

- 68% of the values are within  $\pm 1$  standard deviation of the mean value.
- 80% of the values are within  $\pm 1.28$  standard deviations of the mean value.
- 90% of the values are within  $\pm 1.65$  standard deviations of the mean value.
- 95% of the values are within  $\pm 1.96$  standard deviations of the mean value.
- 99% of the values are within  $\pm 2.58$  standard deviations of the mean value.

**NORMAL APPROXIMATION TO THE BINOMIAL DISTRIBUTION**

The CLT can be applied to the binomial distribution if  $n$ , the number of binomial trials, is sufficiently large. As a general rule, if both  $np_0$  and  $n(1-p_0)$  are equal to or greater than 5 ( $p_0$  being the true probability of success), the normal approximation can be used. For binomial distributions with  $p_0$  close to 0.5, the approximation is good for values of  $np_0$  and  $n(1-p_0)$  smaller than 5. Under these conditions,  $(p - p_0) / \sqrt{p_0(1-p_0)/n}$  is approximately normally distributed with mean 0 and standard deviation 1 (the standard normal distribution). This transformation allows easy calculation of binomial probabilities. The approximation is improved if  $1/(2n)$  is subtracted from the absolute value of the numerator. This is known as the *Yates continuity correction*.

**ESTIMATION AND STATISTICAL INFERENCE**

**ESTIMATION AND CONFIDENCE INTERVALS**

After gathering data from, for example, a survey or an experiment, it is often of interest to estimate the mean value or average of the population. As has been noted, the sample average,  $\bar{x}$ , is

**Example 6.**

When inspecting 100 tablets for quality, what is the probability of observing a proportion of defective tablets equal to or greater than 0.10, if the true proportion defective is 0.07? Using the continuity correction

$$z = \frac{\mu - 2n}{\sigma} = \frac{|0.10 - 0.07| - 1/200}{\sqrt{0.07 \cdot 0.93/100}} = 0.98$$

From Table 10-9, the probability of a value less than  $z=0.98$  is approximately 0.84. The probability of a value greater than  $z=0.98$  is  $1 - 0.84 = 0.16$ . Therefore, the probability of observing a proportion greater than 0.10, when inspecting 100 tablets from this batch, is approximately 0.16.

not exactly equal to the population average,  $\mu$ , but in a well-designed and implemented experiment,  $\bar{x}$  should be an unbiased estimate of the true mean. Thus, the best estimate of the true, but unknown, population average is the sample mean  $\bar{x}$ .

However, the mean of the sample gives no idea of the precision of this average. If the average assay of 10 tablets is 100 mg, it is not known how close this value is to the unknown true value. It would be important to have some estimate of the reliability of the result. *Confidence intervals*, or confidence limits, give an interval that may encompass the mean with a known probability. That is, a 95% confidence interval of 97 to 103 mg means that one would give 19 to 1 odds that the true mean is in this interval. It cannot be said for certain that the true mean is in the interval, but if the experiment were repeated many times and a 95% confidence interval constructed each time, then 19 of 20 such intervals would contain the true mean. For any given experiment, there is no way to tell if the true mean is in the interval, but it is known that the chances are 95% that the true mean is in the interval.

In statistical inference, no statements can be made with assurance. Statistical proofs are not like mathematical proofs. Statistical conclusions are couched in terms of probability. A statement such as “The means are significantly different,” means that it is believed that the means are different but there is a chance, albeit a small one, that the conclusion is incorrect. However, the probability of making the wrong decision is known.

Symmetric confidence limits are computed as:

$$\bar{x} \pm z \cdot \sigma_{\bar{x}}$$

where  $z$  is an appropriate constant, depending on the probability statement (degree of confidence) associated with the confidence interval. For a normally distributed variable with standard deviation known, the value of  $z$  is obtained from Table 10-9. For example, to obtain a 95% confidence interval,  $\pm 1.96$  standard deviations covers 95% of the area. For a 90% confidence interval,  $z = 1.65$ ; for a 99% confidence interval,  $z = 2.58$ . Note that if the standard deviation is unknown but estimated from the sample data, the value of  $z$  for normally distributed variables is replaced by  $t$ , obtained from the  $t$  distribution, which will be introduced in the next section.

On rare occasions, a *one-sided* or an *unsymmetrical* confidence interval may be appropriate. One use of a one-sided interval is described under linear regression as applied to stability prediction.

**STATISTICAL INFERENCE AND THE T DISTRIBUTION**

Statistics are used most often as a decision-making tool. The familiar phrase “the difference is statistically significant” results from the application of statistical inference to experimental data. The procedure allows a probability statement to be made

**Example 7.**

A drug shows an average blood pressure reduction of 9.8 torr when tested on 100 patients. The standard deviation is known to be 8 torr. A 95% confidence interval for the mean blood pressure reduction in torr is:

$$9.8 \pm 1.96 \cdot \frac{8}{\sqrt{100}} = 9.8 \pm 1.57$$

A 99% confidence interval is:

$$9.8 \pm 2.58 \cdot \frac{8}{\sqrt{100}} = 9.8 \pm 2.06$$

Note that if the interval has a higher probability of containing the true mean, the confidence interval is wider.

**Example 8.**

A survey of 1000 pharmacists showed that 30% have more than 15 years of experience and 70% have less than 15 years of experience. A 95% confidence interval on the proportion of pharmacists with more than 15 years of experience is:

$$p \pm 1.96 \cdot \sqrt{p(1-p)/n} = 0.3 + 1.96 \cdot \sqrt{0.3 \cdot 0.7/1000} = 0.3 \pm 0.028$$

This means that the true proportion is between 0.272 and 0.328 with 95% probability.

about comparative data. Statements made using this approach cannot be made with absolute certainty. Because experimental results generally come from sample data, one never can be sure of the exact properties of population data. However, decisions can be made with a known probability of error.

**t Test**

In addition to estimating the mean assay of a batch of 10 tablets, the 10 assay values were obtained to perform a statistical test comparing the average result to that expected based on the labeled potency of 100 mg. If every one of the 3 000 000 tablets in this batch were assayed, the average potency would be known. The random sample of 10 is representative of the entire batch, but it is extremely unlikely that the sample average exactly will equal the batch average. The question to be asked is, in view of the variability of the 10 assays and the average result, can it be ascertained that these 10 tablets came from a population with an average of 100 mg? The solution to this question, an example of statistical inference, is obtained using a simple *t* test. This *t* test consists of the following steps, which can be considered typical in many designed experiments.

**Construct a Null Hypothesis**

A null hypothesis is an assumption about the parameter under investigation, which is the mean value in this example. The null hypothesis is a statement that assumes that the parameter is equal to some value, usually a null value. That is, the hypothetical value is considered to represent a situation of no change. How to construct the null hypothesis is not always obvious, but a few examples should make this concept clearer.

For the tablet assays, no change means that the population average,  $\mu$ , is equal to the labeled potency, 100 mg. The null hypothesis is of the following form:

$$H_0: \mu = 100 \text{ mg}$$

The statistical test allows a decision to be made: the sample of tablets are or are not representative of a population with mean 100 mg.

**Construct an Alternative Hypothesis**

An alternative hypothesis makes an assumption about alternative values of the parameter, usually encompassing complementary values. Thus, if  $H_0$  is  $\mu = 100 \text{ mg}$ , an alternative could include all values greater than or less than 100 mg. This is a two-sided alternative represented as  $H_a: \mu \neq 100 \text{ mg}$ . In some cases, a one-sided alternative may be suitable. This may be expressed as

$$i) H_a: \mu > 100 \text{ mg} \text{ or } H_a: \mu < 100 \text{ mg}$$

The process of statistical inference will result in one of two possible decisions: either accept or reject the null hypothesis. *Rejection* means the alternative is accepted. For a two-sided alternative, it is anticipated in advance that if the null hypothesis is not true, that the true average could be either greater or smaller than the hypothetical or assumed value. A one-sided alternative is viable if the alternative only can take on either a lower or higher value than the hypothetical value or if only higher (or lower) values are of interest.

It is not clear always which alternative (one- or two-sided) is correct or appropriate for any given situation. Usually, two-sided alternatives must be considered because, in most situations, smaller and larger values of the parameter are possible and relevant. Some situations where one-sided alternatives may be best will be discussed.

**Choose the Level of Significance**

The level of significance also is known as the *alpha level* ( $\alpha$ ) or *error of the first kind*. This is the basis of the well-known statement (e.g., the difference is significant at the 5% level). The  $\alpha$  error is set in advance and has the following meaning. The level of significance or  $\alpha$  error is the probability of erroneously stating that the difference between the observed value of the parameter (the mean in this example) and the hypothetical value is real or significant.

The  $\alpha$  error commonly is chosen as 5%, although this is not obligatory. A more conservative approach would be to choose a level of 1%. This would mean that an error of the first kind, i.e., erroneously declaring a difference, is only 1%. It will be seen that a larger difference is needed for significance if the  $\alpha$  error is made smaller. That is, it is more difficult to find a significant difference.

**Beta Error and Power**

Usually, only the  $\alpha$  error is chosen in advance of the experiment. However, it should be understood that there is a second kind of error that should be considered when making statistical decisions. This error, the *beta error* ( $\beta$ ), is the probability of declaring no difference between the observed sample value and hypothesized value of the parameter when, in fact, a difference of size delta ( $\delta$ ) exists. The  $\alpha$  level,  $\beta$  error, and sample size are related. Sample-size determination, an important topic, is discussed in most elementary statistics books.<sup>1,8</sup> When it is declared that differences are (or are not) significant, only the  $\alpha$  level is considered, and not the  $\beta$  error.

**Choose a Sample**

The choice of a proper sample and the size of the sample are very important considerations in statistical experimentation and experimental design. The number of objects to be included in the sample is a consequence of the  $\alpha$  and  $\beta$  errors. The manner in which samples are chosen will dictate the statistical analysis.

**Example 9.**

Consider the estimation of the tablet potency of a batch of tablets based on an assay of 10 individual randomly selected tablets. The assay values in mg are:

98.6	99.3	97.9	100.3	99.6
98.0	100.1	97.5	98.4	99.1

The average is 98.88 mg, and the standard deviation is 0.954 mg. In this example an estimate of the mean and standard deviation is obtained from a sample of size 10.

When the standard deviation is unknown but an estimate is available from a relatively small sample, the *t* distribution is used to describe the distribution of the means. The *t* distribution may be defined as the distribution of:

$$t = \frac{\bar{x} - \mu}{SD/\sqrt{n}}$$

The *t* values show a symmetrical distribution centered at 0; i.e., the mean is 0. The *t* distribution is spread out more than the standard normal distribution. Some commonly used points from the *t* distribution are shown in Table 10-10. The *t* distribution is defined by degrees of freedom (DF), which in Example 9 is *n* - 1. Note that when the DF are large (i.e., *n* is very large), the values in the *t* table approach the corresponding values from the standard normal-curve table (see Table 10-9). For example, the value below which 97.5% of the area is found is 1.96 when the DF are infinite in the *t* table.

When the SD is unknown, values from the *t* table are used to construct confidence intervals in exactly the same manner as was done using Table 10-9. Table 10-10 shows *t* values that cut off areas of the *t* distribution in one tail or symmetrically in both tails of the distribution. For example, the two-tailed 5% points cut off 2.5% of the area in each tail. For *DF*=9, *t* values below -2.262 and greater than +2.262 comprise 5% of the area. Conversely, it can be said that the probability of finding a *t* value between -2.262 and +2.262 is 95% for *DF*=9.

Table 10-10 gives values for one-tailed probabilities for *p*=0.5% and 2.5%. These values correspond to the two-tailed probabilities of 0.01 (1%) and 0.05 (5%). For example, for 9 DF, the probability of finding a *t* value greater than +2.262 (or smaller than -2.262) is 2.5%. In the current example of tablet assays, a 95% confidence interval can be constructed using the *t* distribution. The mean is 98.88 mg and the sample SD is 0.954 mg. The *t* value for 95% of the area for 9 DF is 2.262. The 95% confidence interval in mg is:

$$98.88 \pm 2.262 \cdot \frac{0.954}{\sqrt{10}} = 98.88 \pm 0.68 = 98.20 \text{ to } 99.56$$

This can be interpreted to mean that the probability is 95% that the true mean of the batch lies between 98.20 and 99.56 mg.

Are you surprised by the narrow limits of the interval based on only 10 tablets? The reason for the tight limits is the small standard deviation. Note that this does not guarantee that the true mean, *μ*, lies in this interval; the probability that it does so is just 0.95. As has been emphasized before, statistical statements and conclusions are probabilistic in nature.

**Table 10-10. The Distribution of *t* Giving Both the Two-Sided or Two-Tailed Probability and the One-Sided or One-Tailed Probability According to Degrees of Freedom**

∞	0.253	0.524	0.842	1.282	1.645	1.960	2.326	2.576

In this simple example, the choice of experimental units (tablets to be analyzed) appears to be uncomplicated. However, further thought reveals many alternatives. Ten tablets are to be chosen from 3 000 000. Some possible sampling schemes include (1) take the first 10 tablets from the batch, (2) take the last 10 tablets, (3) take tablets at regular intervals during the run and select 10 of these tablets at random, or (4) take 10 tablets at random from the entire batch. A random sample is one in which each object has an equal probability of being chosen (see under Sampling for more detail). Random samples will assure a valid statistical analysis.

Random sampling can be visualized as a kind of lottery device, in which all of the tablets are mixed and one selected. In many cases, random sampling is not convenient, or the design can be improved by using variations of random sampling schemes. Although the statistical analysis in the present example assumes a random sample, it would not be convenient to implement this procedure for a batch of 3 000 000 tablets. Scheme 3, above, is a more realistic sampling scheme; although it is not truly random, one can proceed as though it were random for this example. In this case, a sample size of 10 tablets is chosen, not for statistical reasons, but because this number has been written into the quality-control procedure. A better procedure would be to base the number of samples on the  $\alpha$  and  $\beta$  levels.<sup>8</sup>

### Determine Whether the Test Should be One- or Two-Sided

In this example, a two-sided test is chosen because the observed average potency could be either lower or higher than the hypothetical value of 100 mg. That is, there is no reason to

believe, based on the manufacturing process, that the observed value should deviate on one side rather than the other of the labeled potency.

### Make Observations and Construct a $t$ Test

Having gathered the tablets and performed the assays, the value of  $t$  is computed. This allows one to make the decision, significant or not significant. For a two-sided test, the  $t$  value is computed as:

$$t_{n-1} = \frac{|\bar{x} - \mu|}{SD/\sqrt{n}}$$

where  $\mu$  is the hypothetical mean defined by the null hypothesis. In this example,  $t$  is:

$$t_{n-1} = \frac{|\bar{x} - \mu|}{SD/\sqrt{n}} = \frac{|98.88 - 100|}{0.954/\sqrt{10}} \gg 3.71$$

The  $t$  value then is compared to the  $t$  values in Table 10-10 at the specified  $\alpha$  level with  $n-1$  DF. For a two-sided test, the absolute value of  $t$  is noted, because either small or large values of the difference ( $\bar{x} - \mu$ ) will lead to significance. If the observed value of  $t$  is equal to or greater than the value in the table, the difference between the observed and hypothetical values of the parameter, the mean in this example, is declared to be statistically significant. The value of  $t$  for a two-sided test at the 5% level for 9 DF is 2.262, the same value used for the 95% confidence interval. This is no coincidence, as will be shown below. Since the observed absolute value of  $t$  (3.71) is larger than the value in Table 10-10 (2.262), significance is declared. The true

potency is apt not to be 100 mg, but rather some lower value, based on the observed value of 98.88 mg.

An examination of the equation for  $t$  reveals that large differences between the observed and hypothetical mean coupled with a small SD of the mean lead to large values of  $t$ . This makes sense, from an intuitive point of view, as large differences with small variability suggest that the difference is real. Also, one should note that had the test showed a non-significant difference, it cannot be said with any assurance that the mean of the batch is 100 mg. In fact, it seems extremely unlikely that this should be true. The data simply do not provide sufficient evidence to show that the mean is different from 100 mg. In this case, the confidence interval would give a region in which the mean probably lies.

If the above test had been performed at the 1% level, it still might have been concluded that the mean of the batch was not 100 mg. The value of  $t$  at the 1% level with 9  $DF$  from Table 10-10 is 3.25. Because 3.71 is greater than 3.25, one would declare significance. A test significant at the 1% level gives greater assurance that the true mean differs from 100 mg, compared to a test significant at the 5% level.

There is a relationship between the two-sided  $t$  test and the confidence interval. For example, if the 95% confidence interval does not cover the hypothetical value defined by  $H_0$ , the test will show significance and vice versa. This suggests that the true mean is different from the hypothetical mean. In the example discussed above, the 95% confidence interval was calculated as 98.2 to 99.56, which does not cover the hypothetical value 100. Therefore, it may be concluded correctly that the  $t$  test will show a significant result at the 5% level. Had the confidence interval in  $t$  cluded 100, the  $t$  test would not be significant.

The example described above is known as a one-sample  $t$  test. In this test, the experimental design consists of determining the mean value of a random sample from a single population and comparing the mean to some hypothetical value. Thus, it may be of interest to compare the mean tail-flick value of an analgesic compound in rats to some value that represents activity based on previous experience, or to compare the average assay result of 10 tablets to the labeled amount or to a previously accumulated average, as may be available from quality-control records.

### TWO INDEPENDENT SAMPLE $T$ TEST

A common design in research involves the comparison of two treatments applied to two independent groups. For example, in a clinical study, a drug is compared to a placebo using 20 patients for the drug treatment and 20 different patients for the placebo treatment. Or the dissolution of tablets prepared by a marketed formulation is compared to the dissolution of tablets prepared from an experimental formulation. Note that this design differs from the one-sample test in that averages are obtained from two groups for purposes of comparison, whereas in the one-sample test, the average of a single group is compared to some hypothetical value.

Three key assumptions are necessary for the two independent sample  $t$  test to be valid: (1) each of the two groups are distributed normally, (2) each of the two groups are distributed with the same variance, and (3) the two samples are independent.

The independence assumption is very important. Independent samples mean that the results for any single individual do not influence the results for any other individual. In the case of a clinical trial, independence would mean that the treatment effect for one patient does not influence the result of a treatment for other patients. If one patient discussed the results of his or her medication with another patient in the study, their results would not be independent. If treatments are applied to more than one rat in a cage, their results would not be independent. In the latter case, competition for food and other animal interactions might favor the stronger animal and influence the treatment effect.

Equality of variance also is an important assumption. If the variances are reasonably close, the test should be conducted as usual. As a general rule, if the variances do not differ by more than a factor of four, no special procedure is needed. If the variances differ widely, a modified procedure should be used (the Behrens-Fisher test<sup>9</sup>). The normality assumption is less critical. The CLT results in approximate normality of means of non-normal variables.

This statistical design consists of randomly dividing  $n$  objects into two groups of size  $n_1$  and  $n_2$ . Treatment 1 is applied to the first group ( $n_1$ ) and treatment 2 is applied to the second group ( $n_2$ ). Optimal treatment allocation in this design is to have an equal number of experimental units ( $n/2$ ) in each group if the primary objective is to compare the means of the two groups. However, if  $n_1$  is not equal to  $n_2$ , the data are analyzed easily, and not much is lost if the two samples are close in size. In animal and human experiments, samples often are lost due to patient dropouts and animal deaths. An experiment that is carried out according to this plan sometimes is called a *parallel design*—two separate groups are treated in parallel.

The test is similar to the one-sample test. In a typical experiment to compare the mean results of the two samples, the null hypothesis is:

$$H_0 : \mu_1 = \mu_2$$

A two-sided alternative has an alternative hypothesis:

$$H_a : \mu_1 \neq \mu_2$$

Once the level (usually 0.05) is specified and data are obtained, a  $t$  test is performed. This allows a decision to be made about the equality of the underlying population averages. As in the one-sample case, a value of  $t$  is computed as:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{s} \sqrt{\frac{n_1 n_2}{n_1 + n_2}}$$

where  $\bar{x}_1$  is the mean of first sample of  $n_1$  observations,  $\bar{x}_2$  is the mean of second sample of  $n_2$  observations, and

$$s^2 = \frac{\sum x_{1i}^2 - (\sum x_{1i})^2 / n_1 + \sum x_{2i}^2 - (\sum x_{2i})^2 / n_2}{n_1 + n_2 - 2}$$

where  $\sum x_{1i}^2$  is the sum of squares of observations in the first sample,  $\sum x_{1i}$  is the sum of observations in the first sample,  $\sum x_{2i}^2$  is the sum of squares of observations in the second sample,  $\sum x_{2i}$  is the sum of observations in the second sample,  $s^2$  is the pooled variance of the two samples.

The examples illustrated so far have used a two-sided test. A one-sided test may be used when the difference can only occur in one direction or when only one direction is relevant.

### PAIRED $T$ TEST

In many situations, the scientist is interested in comparing the means of two experimental treatments using a paired-sample design. This differs from the independent two-sample design in that each of two different treatments may be applied to a single group of experimental units (e.g., patients). In a bioavailability study, a generic drug is compared to a standard drug in each of 20 patients. A new analytical method is compared to a previously used method by comparing assay results on different concentrations of the same material divided into two parts.

The paired design has certain advantages over the two independent sample or parallel groups design. It has been noted that significance is determined by the ratio of the difference of the averages divided by the standard error. This ratio can be increased by reducing the standard error. One way is to increase the sample size. Another way of increasing the value of  $t$  is to reduce the variability.

In a two independent sample test, the variability is a result of the differences among different experimental units (differences

**Example 10.**

Suppose one sample of four and one sample of five are taken, respectively, from each of two lots of amobarbital capsules, and the amount of amobarbital is determined in each capsule. It is desired to determine if there is a significant difference between the two samples.

$$H_0 : \mu_1 = \mu_2$$

where  $\mu_1$  and  $\mu_2$  represent the true averages of the two lots of capsules. This is a two-sided test at the 5% level.

Sample 1	Sample 2
10.1	9.8
13.6	9.6
12.5	11.4
11.4	9.1
	10.1

We have  $\sum x_{1i} = 46.6$ ,  $\sum x_{1i}^2 = 573.18$ ,  $\bar{x}_1 = 11.90$ ,  $n_1 = 4$ , and  $\sum x_{2j} = 50.0$ ,  $\sum x_{2j}^2 = 502.98$ ,  $\bar{x}_2 = 10.00$ ,  $n_2 = 5$ ,

$$s^2 = \frac{573.18 - 47.6^2/4 + 502.98 - 50.0^2/5}{4 + 5 - 2}$$

$$= \frac{573.18 - 566.44 + 502.98 - 500.00}{7} = 1.3886$$

$$s = 1.18$$

$$t = \frac{\bar{x}_1 - \bar{x}_2}{s} \sqrt{\frac{n_1 n_2}{n_1 + n_2}}$$

$$= \frac{11.90 - 10.00}{1.18} \sqrt{\frac{4 \cdot 5}{4 + 5}} = 2.40$$

The degrees of freedom involved in the pooled standard deviation are 7,  $DF = (n_1 - 1) + (n_2 - 1)$ . In the  $t$  table (see Table 10-10), for  $p = 0.05$  and  $DF = 7$  (two tails), the value of  $t$  given is 2.365. The value of  $t$  calculated is greater than this. Therefore, since the probability of these two samples being drawn from the same population is less than 0.05, we conclude that they were drawn from different populations. (This conclusion may be wrong 5 times in 100.) It can be stated that there is a statistically significant difference between the two samples.

among patients' responses to a drug, for example). In the paired test, the variability results from differences within experimental units. The within-individual variability should be less than the between-individual variability. (Theoretically, the measured between-individual variation includes the within-variation; therefore, the between-variation is larger than the within-variation.) Therefore, the paired-sample design has the advantage of reduced variability.

The paired-sample test also needs less experimental material. In a two independent sample design, comparing the response to two drugs, one might use 24 patients in each of two groups. In a paired design, each patient receives both drugs, on two different occasions if necessary. Thus, there is the need to recruit 24 patients rather than 48. For example, when testing a skin preparation, the products could be applied randomly to each arm of the 24 patients.

The paired design can be used only when there is a natural or easy way of pairing the experimental units. When comparing the dissolution of two different formulations, there seems to be

**Example 11.**

A drug is formulated to be dissolved more rapidly by substituting lactose for part of the lipoidal lubricant in the regular-release product. The formulator is convinced that this formulation change only could increase the rate of drug dissolution. A one-sided test at the 5% level is proposed when comparing the drug dissolution from the two products. The time to 50% dissolution for six tablets of each product in minutes is:

Original product:	25	22	29	30	26	24
Modified product:	18	23	24	22	19	16

For this test,  $H_0$  and  $H_a$  are defined as:

$$H_0 : \mu_1 = \mu_2$$

$$H_a : \mu_1 > \mu_2$$

where  $\mu_1$  is the 50% dissolution time for the original product and  $\mu_2$  the respective dissolution time for the modified product.

If the test indicates rejection of the null hypothesis, it must be concluded that the new formulation has a faster dissolution time. If the test shows a nonsignificant difference, it is concluded that the data is insufficient to show that the new formulation reduces the dissolution time. Note that if the data show a longer dissolution time for the new formulation, a test would not be performed, but it would be concluded that the new formulation did not decrease the dissolution time. The average results and standard deviation for the two sets of data are:

$$\bar{x}_1 = 26 \quad \bar{x}_2 = 20.33$$

$$SD_1 = 3.033 \quad SD_2 = 3.141$$

$$t = \frac{26 - 19.17}{3.087/\sqrt{3}} = 3.18$$

Note that the pooled standard deviation is equal to:

$$\sqrt{\frac{SD_1^2 + SD_2^2}{2}}$$

when the sample sizes are equal in the two groups.

For a one-sided test, refer to one tail of the  $t$  distribution. For 10 degrees of freedom ( $6 + 6 - 2$ ), the  $t$  value, leaving 5% of the area in the upper tail, is 1.812 (see Table 10-10). Therefore, it is concluded that the new formulation causes faster dissolution of the drug. Note that it is easier to get significance with a one-sided test. Had the test been two-sided, the  $t$  would have had to exceed 2.228 at the 5% level for significance, according to Table 10-10.

no obvious way of pairing the tablets from the two different formulations, as is the case of applying two treatments to the same individual. In animal experiments, litter mates may be paired. Pairing implies that the paired units are more alike than are two different units. In clinical studies, test units may be paired or matched on the basis of certain characteristics such as sex, age, or severity of disease. Then each subject in the pair is assigned to one of the experimental treatments.

A disadvantage of the paired design is that if treatments cannot be applied concurrently, as may be the case where two drugs administered orally are to be compared, the time to complete the experiment can be extended. In the case of clinical studies, this may be an important detriment because time usually is of the essence. Also, as these studies are prolonged, the chances of patient dropouts increase, and time can influence the progress of the disease.

In the paired design, a missing value means that the single unpaired datum is of no value. In this design, each experimental unit (e.g., each patient) essentially acts as its own control. That is, the comparison is made within each experimental unit. If one of the two paired values is missing, a comparison cannot be made.

Another potential disadvantage is that a *carryover effect* may be present. This means that effects from one treatment may affect the results of the other. For example, in a bioavailability study, if the first drug administered is not eliminated completely before the second drug is given, blood levels of the second drug will be contaminated. Or, in a clinical study, the first drug administered may modify the disease condition so that the effect of the second drug is not comparable directly with that of the first drug.

In any event, there are many situations where the advantages of the paired-sample design strongly suggest its use. For computational purposes, the formula is:

$$t = \frac{\bar{d}}{s/\sqrt{n}}$$

where  $d$  is the mean of the differences  $x_1-x_2$  of the  $n$  pairs of observations,

$$s^2 = \frac{\sum d_i^2 - (\sum d_i)^2/n}{n-1}$$

where  $\sum d_i^2$  is the sum-of-squares of the  $n$  differences,  $\sum d_i$  is the sum of the  $n$  differences, and  $n$  is the number of differences or pairs of observations.

**TESTS FOR PROPORTIONS**

The  $t$  test is applicable for continuous data that is distributed normally. Much of the data that is seen in pharmaceutical experiments is dichotomous. That is, answers to a questionnaire regarding filling a prescription for a specified drug may be yes or no, or a bottle of tablets may be acceptable or not acceptable, or a patient may be cured or not cured. Tests similar to the  $t$  test may be constructed for binomial data. The principle is to compute proportions that are probable, based on the sample proportion. If the probable proportions do not include the hypothetical proportion, the null hypothesis is rejected.

For large sample sizes ( $n$  is large), such computations can be tedious and difficult. Therefore, the normal approximation to the binomial is used whenever possible. Fortunately, in most practical cases, the normal approximation is applicable. When comparing proportions from two independent samples when the normal approximation is clearly not applicable, the Fisher Exact test can be used.<sup>8</sup> (Statistical software programs can compute exact probabilities.) In general, use the rule that  $np$  and  $n(1-p)$  should be equal to or greater than 5 in order to use the normal approximation. In practice, this rule may be relaxed somewhat. When in doubt, a professional statistician should be consulted.

Simple statistical tests for proportions are analogous to the  $t$  tests. For a one-sample test, where the hypothetical value defined by  $H_0$  is  $p_0$ , the ratio:

$$z = \frac{p - p_0}{\sqrt{p_0(1 - p_0)/n}}$$

**Example 12.**

The duration of loss of the righting reflex in minutes was measured in 16 mice, following treatment with a barbiturate. The drug was administered in the morning and the afternoon on two different occasions; the order of giving the morning or the afternoon dose was randomized in each mouse. It was desired to test the null hypothesis that the duration of loss of the righting reflex is the same in the morning and the afternoon (Table 10-11).

$$s^2 = \frac{354 - 40^2/16}{16 - 1} = 16.93$$

$$s = 4.11$$

$$t = \frac{\bar{d}}{s/\sqrt{n}} = 2.43$$

$$DF = n - 1 = 15$$

In the  $t$  table (see Table 10-10), for  $p=0.05$  and  $DF=15$  (two tails), the value of  $t$  is 2.131. The value of  $t$  calculated is greater than this. Therefore, as the probability of the morning and afternoon values being the same is less than 0.05, we conclude that they are different. Apparently, the duration of loss of the righting reflex in mice tested on the barbiturate in the morning was longer than when tested in the afternoon.

Note the similarity of the one-sample  $t$  test and the paired  $t$  test. The test is identical after differences between pairs have been calculated in the paired test. The null hypothesis in the paired test almost always is of the form  $H_0: \delta=0$ , where  $\delta$  is the hypothesized difference of the true means. It is hypothesized that the mean results of the two treatments are identical.

**Table 10-11. Loss of Righting Reflex on 16 Mice**

Mouse No	am $X_1$	pm $x_2$	Difference $D = x_1 - x_2$
1	75	73	2
2	86	89	-3
3	93	89	4
4	87	79	8
5	91	95	-4
6	87	81	6
7	76	77	-1
8	83	89	-6
9	87	82	5
10	95	91	4
11	91	87	4
12	86	86	0
13	83	78	5
14	76	69	7
15	82	78	4
16	93	88	5
			$\sum d_i = 40$ $\sum d_i^2 = 354$ $\bar{d} = 2.5$ $n = 16$

**Example 13.**

A one-sample test for proportions. A questionnaire was sent to pharmacists, asking which of two cold medications the pharmacist would recommend to customers. A statistical test was proposed to decide which product was most recommended. The null hypothesis was that the two products, A and B, were recommended equally:  $H_0: p_a = p_b = 0.50$ . The test is two-sided at the 5% level. Two hundred and fifty (250) pharmacists responded; Product A was recommended 145 times, and Product B was recommended 105 times.

The scientist conducting the experiment had sent out 400 questionnaires and was rightfully concerned about the nonresponders. However, she decided that there was no reason to suspect a bias because of the lack of 100% response and proceeded to analyze the data. The observed proportion of successes (A is a success) is  $145/250 = 0.58$  (or the observed proportion could be 0.42 as well). The absolute value of the numerator of the  $z$  statistic will be the same for  $p = 0.42$  or  $p = 0.58$ .

$$z = \frac{|0.58 - 0.50|}{\sqrt{0.5 \cdot 0.5/250}} = 2.53$$

Since 2.53 exceeds the tabled value for  $\alpha$  of 5% (1.96), it is concluded that Product A is the more recommended product. The normal approximation is improved if  $1/(2n)$  is subtracted from the absolute value of the numerator (*Yates correction*), although the effect of the continuity correction is more evident for small sample sizes. In the present example, the corrected value of  $z$  is 2.47. A 95% confidence interval for the proportion recommending Product A also was reported.

$$0.58 \pm 1.96\sqrt{0.58 \cdot 0.42/250} = 0.519 \text{ to } 0.641$$

**Exercise 4.**

Compute  $z$ , with and without the continuity correction, if 141 of 250 pharmacists recommended Product A. Determine whether the result is significant by using a two-sided test at the 5% level.

Answers:  $z = 2.02$  without continuity correction (significant) and  $z = 1.96$  with continuity (not significant).

may be computed, where  $p$  is the observed proportion and  $n$  is the number of binomial trials, the sample size.

The calculated value of  $z$  is compared to the standard normal distribution rather than to the  $t$  distribution. Refer to Table 10-9 or to the last line in the  $t$  table, Table 10-10. For a two-sided test at the 5% level, the test statistic,  $z$ , must exceed 1.96 for the difference to be considered significant.

**CHI-SQUARE TEST**

To test for differences of two proportions from two independent samples, the chi-square test is used. Chi-square ( $\chi^2$ ) is a probability distribution derived from the sum of squares of normal variables. The chi-square distribution is not symmetrical and can have only positive values. Table 10-12<sup>3</sup> is a short table of chi-square probabilities. This table is used in the same way as the normal and  $t$  tables: first compute a chi-square statistic, and if the value exceeds the tabled value, a significant effect is declared.

**TABLE 10-12. The Chi-Square Table Probability**

DF	P = 0.20	P = 0.10	P = 0.05	P = 0.01
1	1.64	2.71	3.84	6.64
2	3.22	4.61	5.99	9.21
3	4.64	6.25	7.82	11.34
4	5.99	7.78	9.49	13.28
5	7.29	9.24	11.07	15.09
6	8.56	10.64	12.59	16.81
7	9.80	12.02	14.07	18.48
8	11.03	13.36	15.51	20.09
9	12.24	14.68	16.92	21.67
10	13.44	15.99	18.31	23.21
20	25.04	28.41	31.41	37.57
30	36.25	40.26	43.77	50.89

(Data from Fisher RA, Yates F. *Statistical Tables for Biological, Agriculture and Medical Research*. New York: Hafner, 1963.)

**Example 14.**

In tossing a coin, 50% tails and 50% heads are expected. Suppose a coin is tossed 40 times, and 25 heads and 15 tails are obtained, whereas 20 heads and 20 tails are expected. Is the coin biased or weighted in some way?

$$\chi^2 = \frac{(25 - 20)^2}{20} + \frac{(15 - 20)^2}{20} = 2.5$$

The degrees of freedom (DF) associated with  $\chi^2$  are one less than the number of categories. Here  $\chi^2 = 2.5$  with 1 DF. The greater the disagreement between expected and observed, the larger will be  $\chi^2$ . See Table 10-12 for probabilities of getting this value or larger. For 1 DF the probability of getting a value larger than 2.5 is somewhere between  $\alpha = 0.20$  and  $\alpha = 0.10$ . To say that there is a statistically significant departure from the expected values,  $\chi^2$  would have to be larger than 3.84, which is the value for  $\alpha = 0.05$  at 1 DF. A value of  $\chi^2$  larger than 6.64 for 1 DF would indicate a statistically highly significant ( $\alpha < 0.01$ ) departure of the observed from the expected values.

**Example 15.**

Table 10-13 gives the survival rates for drug-treated and control pigs with swine dysentery. The survival rates for the drug-treated and control pigs are  $pD = 25/39 = 64\%$  and  $pC = 21/43 = 49\%$ , respectively. To test the null hypothesis that there is no difference in the survival rates of drug-treated and control pigs,  $\chi^2$  is calculated.

The expected values in each of the four cells can be obtained by multiplying the column total by the row total and dividing this result by the grand total. The expected value for Cell  $a$  is  $46.39/82 = 21.9$ . The expected frequencies for Cells  $b$ ,  $c$ , and  $d$  are 17.1, 24.1, and 18.9, respectively. Note that the sum of the expected frequencies across any row or column equal the totals for the row or column. For example, the expected frequencies for  $b$  and  $d$  are 17.1 and 18.9, which sums to 36, the total number who died. The calculation of  $\chi^2$  is:

$$\frac{(25 - 21.9)^2}{21.9} + \frac{(14 - 17.1)^2}{17.1} + \frac{(21 - 24.1)^2}{24.1} + \frac{(22 - 18.9)^2}{18.9} = 1.91$$

The DF associated with an  $R \times C$  contingency table is  $(R-1)(C-1)$ , so that for a  $2 \times 2$  contingency table, we have 1 DF. Table 10.12 shows that for 1 DF the probability of getting a value of  $\chi^2$  larger than the calculated value 1.91 is greater than  $\alpha=0.10$ . Since  $\alpha$  is not equal to or less than 0.05, we conclude that there is insufficient evidence to indicate that the survival rates for the drug-treated and control pigs are different.

**Table 10-13. Survival Rates in Swine Dysentery**

Treatment	Survived	Died	Total
Drug	$a = 25$	$b = 14$	$a + b = 39$
Controls	$c = 21$	$d = 22$	$c + d = 43$
Totals	$a + c = 46$	$b + d = 36$	$N = 82$

**Example 16.**

Two different types of penicillin (Type I and Type II) were given to each of 22 patients in random order, on successive occasions, and the presence (+) or absence (-) of a detectable blood level was determined (Table 10-14). The percentage of patients with detectable blood levels for the two forms of penicillin are  $pI = 16/22 = 73\%$  and  $pII = 8/22 = 36\%$ . To test the null hypothesis that there is no difference in the percentage of patients with detectable blood levels for the two forms of penicillin, we calculate:

$$\chi^2 = \frac{(b - c - 1)^2}{b + c} = \frac{(|10 - 2| - 1)^2}{10 + 2} = 4.08$$

In Table 10-13 for  $\alpha = 0.05$  and  $DF = 1$ , the value of  $\chi^2$  given is 3.84. The value of  $\chi^2$  calculated is greater than this. Therefore, as the probability of the percentages for type I and type II penicillin being the same is less than 0.05, we conclude that they are different.

Note that this test compares the number of patients who are positive on one test and negative on the other.

**Table 10-14. Data for Example 16**

		Type II		
		+	-	Totals
Type I	+	$a = 6$	$b = 10$	16
	-	$c = 2$	$d = 4$	6
Totals		8	14	22

Chi-square is calculated as:

$$\chi^2 = \frac{(\text{observed frequency} - \text{expected frequency})^2}{\text{expected frequency}}$$

The chi-square test commonly is used for comparing two percentages in a  $2 \times 2$  or fourfold contingency table (Table 10-13).

The chi-square test for comparing two correlated percentages for paired data takes a somewhat different form.

The chi-square distribution is an approximation of the discrete distribution represented by the fourfold table. The

approximation can be improved by applying a *correction factor* for the Observed-Expected values. If the absolute difference is an exact integer (e.g., 4.0), subtract 0.5 from the absolute difference; 4.0 would become 3.5. If the absolute difference has a decimal between 0.5 and 0.99 (e.g., 3.8), change the decimal to

**Exercise 5.**

Calculate the corrected chi-square for Example 15.  
 Answer: 1.79.

0.5; 3.8 would become 3.5. If the decimal is between 0 and 0.5, reduce the absolute difference to its integer value; 4.1 would become 4. In *Example 15*, the absolute difference of Observed-Expected values would be reduced to 3.0.

**THE F DISTRIBUTION AND TESTS OF SIGNIFICANCE**

The  $F$  distribution is suitable for a statistical test comparing two means. The  $F$  distribution is used to compare two variances,  $F$  being defined by the ratio of the variances, with  $n_1 - 1$  DF in the numerator and  $n_2 - 1$  DF in the denominator of the ratio:

$$F_{n_1-1, n_2-1} = \frac{s_1^2}{s_2^2}$$

Similar to the chi-square distribution, the  $F$  distribution consists of only positive values and is a skewed distribution. The ratio of two variances is compared to values in the  $F$  table (Table 10-15<sup>10</sup>) with the appropriate DF in the numerator and denominator to test for statistical significance. If the calculated ratio exceeds the value in the table at a given  $\alpha$  level, the variances differ at the  $\alpha$  level of significance. The following two examples describe the use of the  $F$  test for comparing variances for independent and dependent samples.

Example 17 shows a test to compare the variances of two independent samples using the  $F$  test. Example 18 shows the test for comparing variances in related or paired samples, which uses the  $t$  statistic to determine significance. To compare the variances of samples from two independent populations, the calculation is:

$$F = \frac{s_1^2}{s_2^2} \quad \text{with } s_1^2 > s_2^2$$

where,

$$s_1^2 = \frac{\sum x_{1i}^2 - (\sum x_{1i})^2 / n_1}{n_1 - 1}$$

$$s_2^2 = \frac{\sum x_{2i}^2 - (\sum x_{2i})^2 / n_2}{n_2 - 1}$$

**Example 17.**

Two treatments showed the results in Table 10-16. Entering Table 10-15 with  $f_1 = 6$  and  $f_2 = 5$  DF, we find that the tabulated values of  $F$  are 4.95 and 6.98 for  $\alpha = 2 \cdot 0.05 = 0.10$  and  $\alpha = 2 \cdot 0.05 = 0.05$ , respectively. Thus, the probability of getting a value of  $F$  larger than the calculated value 5.75 is between  $\alpha = 0.05$  and  $\alpha = 0.10$ . Since  $P$  is not equal to or less than 0.05, we conclude that there is insufficient evidence to indicate that the two variances are different.

$$f_1 = n_1 - 1 = 7 - 1 = 6$$

$$f_2 = n_2 - 1 = 6 - 1 = 5$$

$$F = s_1^2 / s_2^2 = 13.81 / 2.40 = 5.75$$

(Data from Snedecor GW, Cochran WG. *Statistical Methods*. 7th edn, Ames: Iowa State University Press, 1980.)

**Table 10-16. Data for Example 17**

	A	B
	6	15
	4	4
	3	10
	7	10
	6	5
	4	11
		9
$\Sigma X_1$	30	64
$\Sigma x_1^2$	162	668
$n_1$	6	7
$S_1^2$	2.40	13.81
$f_1$	5	6

**Example 18.**

A characteristic was measured before and after aging for each of 10 items (Table 10-17). Has the variability changed with aging?

$$\begin{aligned} \Sigma x_B^2 &= 2393.81 \\ \Sigma x_A^2 &= 2252.72 \\ \Sigma x_B x_A &= 2298.92 \\ &= 2393.81 - 148.5^2/10 = 188.59 \\ &= 2252.72 - 147.2^2/10 = 85.94 \\ &= 2298.92 - 148.5 \cdot 147.2/10 = 113.00 \\ t &= \frac{([x_B^2] - [x_A^2])\sqrt{n-2}}{2\sqrt{[x_B][x_A] - [x_B x_A]^2}} = \frac{(188.59 - 85.94)\sqrt{8}}{2\sqrt{188.59 \cdot 85.94 - 113.00^2}} = 2.476 \\ DF &= n - 2 = 8 \end{aligned}$$

In the  $t$  table (see Table 10-10), for  $\alpha=0.05$  and  $DF=8$  (two tails), the value of  $t$  given is 2.306. The value of  $t$  calculated is greater than this. Therefore, because the probability of the variance before and after aging being the same is less than 0.05, it is concluded that they are different. Apparently, the variability decreased after aging.

**Table 10-17. Measurement Before and After Acting**

Item No	Before Aging	After Aging
1	8.3	9.3
2	8.4	10.9
2	14.9	13.2
4	12.2	12.8
5	12.5	16.0
6	15.0	15.2
7	17.1	16.8
8	19.2	16.2
9	22.0	17.9
10	18.9	18.9
	$\Sigma x_B = 148.5$	$\Sigma x_A = 147.2$

To test for significance, the  $F$  ratio is referred to in the  $F$  table (see Table 10-15) with  $f_1=n_1-1$  and  $f_2=n_2-1$  DF. If the calculated value is greater than the value of the table, the null hypothesis that the two variances are the same is rejected (at the  $2P$  level of significance).

If it is desired to compare the variances from paired data, the  $F$  test described above would be inappropriate. Instead, proceed as exemplified below.

The  $F$  distribution is used most often for the comparison of more than two means through the analysis of variance and is equivalent to the  $t$  test if used to compare two means.

**ANALYSIS OF VARIANCE (ANOVA) AND EXPERIMENTAL DESIGN**

There is almost always more than one way to conduct an experiment to achieve a given objective. It was seen that when comparing the means of two treatment groups, two independent groups or a paired design could be used. For example, in a clinical study two treatments could be applied to two separate and independent groups of patients, or each patient could take both treatments.

In the paired experiment, a further refinement could be added with regard to treatment order. For example, if drugs cannot be administered concurrently, the order of drug administration can be balanced. Half of the patients receive Drug A at the first administration, and the other half receive A on the second administration. The patients who receive A on the first occasion will receive B on the second occasion and vice versa. This is known as a *crossover design*.

An alternative design is to assign each patient an order of administration randomly. In the latter case, it is likely that a balanced allocation would not be achieved, as in the crossover design. In fact, there is always a possibility, albeit a small one, that all patients will receive one and the same treatment first and the other treatment second, a situation that intentionally is avoided in the crossover design.

When more than two treatments are to be used in an experiment, a variety of designs are possible. In these cases, one design usually will be optimal, depending on the nature of the experiment, the treatments, and the experimental units or subjects. A common feature of most good designs is *symmetry*. That is not to say that all good designs are symmetrical. In some special cases, an asymmetrical design may be optimal, but this is not the usual circumstance.

The most simple analysis of variance design is known as a *one-way analysis of variance* (one-way ANOVA) or completely randomized design. This is the ANOVA analogy of the two independent sample  $t$  test. In the ANOVA design, there is interest in comparing the means of two or more treatment groups. As has been noted before, in the jargon of clinical trials, this design often is one of a class known as parallel-groups designs.

In the following description, an example from clinical trials will be used. However, one should understand that tablets, bottles, or consumers could be substituted for patients and the process is the same:  $n$  patients are available for the experiment with  $t$  treatments. For example, 150 patients are to be assigned to three treatment groups, one placebo and two active. The  $n$  patients are assigned randomly to the three groups (see the discussion on random assignment). The optimal assignment in the examples discussed in this chapter will result in equal numbers in each group,  $n/t$  units per group. Note that  $n$  is chosen to be divisible by  $t$ . If there are three treatments and  $n=150$ , we randomly would assign 50 units per treatment. A loss of observations will not invalidate the analysis, as is also true in the two independent groups  $t$  test. Observations are made, and the null hypothesis that all  $t$ -means are equal is tested by an ANOVA procedure.

The ANOVA separates the total sum-of-squares,  $\Sigma(x_i - \bar{x})^2$  into parts determined by the experimental structure. For the one-way ANOVA, the sum-of-squares consists of the between (among) and within sum-of-squares. The between sum-of-squares (BSS) represents differences among treatments, large values indicating large treatment differences (e.g., if the

**Example 19.**

Groups of three subjects each were given one of ten food regimens and showed the weight gains (lb) in Table 10-19. These are unpaired data, and this type of study is referred to as a completely randomized experiment. There are only two sources of variation; the variation between regimens and the variation within regimens, as indicated in Table 10-18. The sums-of-squares are obtained as:

$$\begin{aligned} \text{Total SS} &= \sum x^2 - \frac{(\sum x)^2}{n} = 934 - \frac{148^2}{30} = 203.87 \\ \text{Between regimens SS} &= \frac{(\sum x_1)^2}{n_1} + \frac{(\sum x_2)^2}{n_2} + \dots + \frac{(\sum x_{10})^2}{n_{10}} - \frac{(\sum x)^2}{n} \\ &= \frac{7^2}{3} + \frac{3^2}{3} + \dots + \frac{16^2}{3} - \frac{148^2}{30} \\ &= 160.54 \\ \text{Within regimens SS} &= 203.87 - 160.54 = 43.33 \end{aligned}$$

The mean squares are obtained by dividing the sums-of-squares by their corresponding DF. The mean square within regimens,  $s^2$ , is the pooled variance for the ten samples. Since this is the only variance that can be identified as random sampling error (the mean square between regimens has in addition a component due to the variability among regimens), it becomes the denominator in the  $F$  ratio, so that:

$$F = \frac{\text{mean square between regimens}}{\text{mean square within regimens}} = \frac{17.81}{2.17} = 8.22$$

To test for significance, the  $F$  ratio is referred to in the  $F$  table (see Table 10-15) with  $f_1 = t - 1 = 9$  and  $f_2 = \sum(n_i - 1) = 20 = 2 \text{ DF}$ . We find that the calculated value 8.22 is larger than the tabulated value 3.45 for  $P=0.01$ . Therefore, as the probability of these ten samples being drawn from the same population is less than 0.05 (actually, it is less than 0.01), it is concluded that they are not all the same (i.e., not all the means are equal).

treatment means are identical, the BSS will be 0 on the average). The within sum-of-squares (WSS) represents differences within treatments, or error; i.e., the differences among objects (subjects in clinical studies) within a treatment is a measure of the variability of the observations.

An ANOVA table is prepared consisting of source of variation, degrees of freedom, sums-of-squares, and mean square. In the one-way ANOVA, the sources consist of the between, within, and total terms. The sum-of-squares divided by the DF is known as the mean square, *between mean square* (BMS), and *within mean square* (WMS) in the one-way ANOVA (Table 10-18).

For a one-way ANOVA, the DF for treatments is  $t-1$ . The DF for error (within treatments) is  $n-t$ , where  $n$  is the total number of observations. The total sum-of-squares (SS) is exactly the sum of the between and within sums of squares. The error mean square (WMS) corresponds to the variance for the test, and in the case of two treatments, corresponds to the pooled variance in the  $t$  test.

The ratio BMS/WMS has an  $F$  distribution under the null hypothesis, with  $(t-1)$  DF in the numerator and  $(n-t)$  DF in the denominator. If the ratio exceeds the appropriate  $F$  value found in the table, then at least two of the treatments tested are significantly different. The computations consist of simple

**Table 10-18. ANOVA for Example 19**

arithmetic, summing individual values, and their squares. The following numerical example illustrates the computations and should clarify these concepts. Although it always is useful to practice some calculations, computer programs are available that should be used for most practical situations.

**MULTIPLE COMPARISONS IN ANOVA**

If the *F* test is significant and more than two treatments are included in the experiment (*t*>2), it may not be obvious immediately which treatments are different. Some or all of the treatments may be different. Various multiple-comparison procedures have been proposed to solve this problem. It is not always apparent when a particular procedure is best, given the variety of procedures available:

- Least Significant Difference Procedure
- Studentized Range Procedure
- Duncan’s New Multiple Range Procedure
- Dunnett’s Procedure

Several of these tests are described here, with discussion of their application. The general procedure is to list the ranked means from lowest to highest and underline the means that are not statistically significantly different from each other. Sometimes brackets or parentheses are used instead of an underline. The procedure is carried out by calculating a 5% allowance, which is defined as the critical difference between means which allows one to reject the null hypothesis ( $\mu_i = \mu_j$ ) and accept the alternative hypothesis ( $\mu_i \neq \mu_j$ ) for any two sample means  $\bar{x}_i$  and  $\bar{x}_j$  at  $\alpha = 0.05$ . To calculate the 5% allowance, the following data is required:

<i>s</i> <sup>2</sup> :	pooled variance from the analysis of variance
<i>DF</i> :	degrees of freedom for the pooled variance from the analysis of variance
<i>n<sub>i</sub>, n<sub>j</sub></i> :	the number of observations from which the means <i>x<sub>i</sub></i> and <i>x<sub>j</sub></i> were determined, respectively
<i>t</i>	a critical value at $\alpha = 0.05$ , which depends upon the <i>DF</i> and the degree of conservatism desired, as exemplified by the multiple comparison procedures described below

- *Least Significant Difference Procedure*—For this procedure:

$$5\% \text{ allowance} = t \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)}$$

where *t* is the value of *t* from Table 10-10 (two tails). This is the least conservative procedure and assures that the probability that any one comparison is judged to be significant by chance alone is 5%. However, the probability of one or more comparisons being judged significant would be greater than 5%. Applied to the results of Example 19,

$$x^2 = 2.17$$

$$n_i = n_j = 3$$

$$DF = 20$$

and *t* = 2.086 from Table 10-10 for 20 *DF* and  $\alpha = 0.05$  (two tails).

$$5\% \text{ allowance} = t \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)} = 2.086 \sqrt{2.17 \cdot (1/3 + 1/3)} = 2.51$$

Thus, any two means differing by 2.51 or more are judged to be different.

Ranked Means						
B	A,C	I	J	F,G	D,H	E
1.0	2.3	5.0	5.3	5.7	6.3	9.3

or, (BAC)(IJFGDH)(E).

Any two means underscored by the same line (or included in the same parentheses) do not differ statistically at  $\alpha = 0.05$ .

Any two means not underscored by the same line (or not included in the same parentheses) are statistically significantly different at  $\alpha \leq 0.05$ .

- *Studentized Range Procedure* For this method:

$$5\% \text{ allowance} = \frac{Q}{\sqrt{2}} \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)}$$

where *Q* is the studentized range value for *k* treatments from Table 10-20.<sup>11</sup> This is one of the more conservative procedures, and it ensures that the probability of one or more comparisons being judged significant by chance alone is 5%. Applied to the results of Example 19,

$$Q = 5.01 \text{ from table 10-20}$$

for *k* = 10 treatments, 20 *DF* and  $\alpha = 0.05$ .

$$5\% \text{ allowance} = \frac{2}{\sqrt{2}} \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)} = \frac{5.01}{\sqrt{2}} \sqrt{2.17 \cdot (1/3 + 1/3)} = 4.26$$

Thus, any two means differing by 4.26 or more are judged to be different.

Ranked Means						
B	A,C	I	J	F,G	D,H	E
1.0	2.3	5.0	5.3	5.7	6.3	9.3

or, (BACI)(ACIJFGDH)(JFGDHE).

- *Duncan’s New Multiple Range Procedure* For this method:

$$5\% \text{ allowance} = \frac{t_k}{\sqrt{2}} \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)}$$

where *t<sub>k</sub>* are values for 2, 3, ..., *k* treatments obtained from Table 10-21.<sup>12</sup> The critical values will be *A<sub>2</sub>*, *A<sub>3</sub>*, ..., *A<sub>k</sub>*, depending upon how many means are included in the range of ranked means being compared. This is next to the least conservative procedure. Applied to the results of Example 19,

$$5\% \text{ allowance} = \frac{t_k}{\sqrt{2}} \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)} = \frac{t_k}{\sqrt{2}} \sqrt{2.17 \cdot (1/3 + 1/3)}$$

Values of *t<sub>k</sub>* from Table 10-21 for *k* = 2 to 10 treatments, 20 *DF*, and  $\alpha = 0.05$  give the allowances in Table 10-22. Thus, the critical difference between *E* and *B* is 2.89 because the range includes 10 means, the critical difference between *E* and *H* is 2.64 because the range includes three means, and so on.

6	3.30	2.81			

- **Dunnett's Procedure** The three procedures previously described are appropriate when it is desired to compare all possible pairs of means. Dunnett<sup>13</sup> considered the problem when the objective of the study is to compare several treatments with a standard or control. In his method

$$5 \text{ allowance} = t_d \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)}$$

where  $t_d$  is Dunnett's  $tD$  value for  $k$  treatments (excluding the standard or control), obtained from Table 10-23.

Like the studentized range procedure, this is one of the most conservative procedures, and it ensures that the probability of one or more comparisons between treatments and a standard or control being judged significant by chance alone is 5%. The one-tail values (listed in tables for  $\alpha=0.10$ ) are used when the objective of the study is to select only those treatments that have higher (or lower) means than the standard or control. The two-tail values (listed in the table for  $\alpha=0.05$ ) are used when the objective of the study is to select those treatments that are either higher or lower than the standard or control. Of course, the decision to carry out a one-tailed or a two-tailed test must be made before the study begins.

In Example 19, suppose  $J$  is a standard regimen, and it is desired to determine which regimens show different weight gains from  $J$ . Here,  $tD = 2.95$  from Table 10-23 for  $k = 9$  treatments, 20 DF, and  $\alpha = 0.05$  (two-tails).

$$5\% \text{ allowance} = t_d \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)} = 2.95 \sqrt{2.17 \cdot (1/3 + 1/3)} = 3.55.$$

Thus, any regimen mean that differs from the mean for regimen  $J$  by 3.55 or more is judged to be different from  $J$ .

**Ranked Means**

B	A,C	I	J	F,G	D,H	E
1.0	2.3	5.0	5.3	5.7	6.3	9.3

or, (B)(ACIJFGDH)(E).

It would be concluded that  $B$  showed a statistically significant smaller weight gain than  $J$ ,  $E$  showed a statistically significantly larger weight gain than  $J$ , and there was insufficient evidence to indicate that the other regimens were different from  $J$ .

In the same example, if regimen  $A$  is a control group and we knew beforehand that all of the other regimens had to be at least as good as the control or better, it may be desired to select those regimens that are statistically, significantly better. We would proceed as follows:

$$t_d = 2.60 \quad \text{from table 12.23 for } k = 9 \text{ treatments } 20 \text{ DF,}$$

$$\alpha = 0.10 \quad (\text{this corresponds to a one-tail } P = 0.05)$$

$$5\% \text{ allowance} = t_d \sqrt{s^2 \left( \frac{1}{n_i} + \frac{1}{n_j} \right)} = 2.60 \sqrt{2.17 \cdot (1/3 + 1/3)} = 3.12$$

Thus, any regimen mean that is larger than the mean for regimen  $A$  by 3.12 or more is judged to be better than  $A$ .

It can be concluded that  $F$ ,  $G$ ,  $D$ ,  $H$ , and  $E$  showed a statistically significantly better weight gain than  $A$ , and that there is insufficient evidence to indicate that  $B$ ,  $C$ ,  $I$ , and  $J$  were any better than  $A$ .

### OTHER ANOVA DESIGNS COMMON TO PHARMACEUTICAL PROBLEMS

A somewhat more complex design is the *two-way ANOVA*. This design is analogous to the paired  $t$  test but consists of more than two treatments; i.e., more than one treatment is applied to the same experimental unit (e.g., patient) or related units (e.g., litter mates, males between 50 and 60 years, etc.). This design has the same advantages and disadvantages as the paired  $t$  test described earlier in this chapter. The ANOVA table is similar to the one-way table but includes some new terms. The between-treatments term has the same interpretation as that in the one-way analysis, representing differences between treatments. A new term, between rows, represents the variability of the units to which the treatments have been applied (e.g., patients). Finally, the table contains an error term, sometimes referred to as rowx-treatment interaction (patientxdrug in a clinical trial).

**Table 10-23. The  $t_p$  Table Values of  $t_p$  for Dunnett's Procedure for Comparing Several Treatments With a Control at the 5% Level of Significance (Use  $P = 0.10$  Values for a One-Tailed Test and  $P = 0.05$  Values for a Two-Tailed Test.)**

		<b>k (Number Treatments, Excluding the Control)</b>

(Data from Dunnett CW. A multiple comparisons procedure for comparing several treatments with a control. *Am Stat Assoc J* 1955; 50: 1096-1121.)

The treatment mean square is divided by the error mean square (EMS) to form an  $F$  ratio, for purposes of performing a statistical test. Some complications can exist in the interpretation of this table and the  $F$  ratios. The examples here consider treatments as including all treatments of interest, and rows as a random selection of experimental units taken from a large population of such units.

For example, to compare a placebo, a generic drug, and a standard drug (three treatments), use a random selection of patients as the experimental units, with each patient to take each of the three treatments. Another example is the comparison of five analytical methods (five treatments), in which ten analysts, selected at random, each perform assays with each method.

### CROSSOVER DESIGN

A design that is popular in experimental research is the crossover design. This is in the class of paired-sample or two-way designs in that all treatments are applied to each experimental unit. For example, in practically all human bioequivalence studies, each subject takes all of the treatments. That is, if a

control marketed drug is to be compared to two new formulations, each subject takes all three products.

The difference between the crossover and the two-way design (also known as a randomized block design) is that in the two-way design, the order or placement of treatments are assigned randomly to each patient. In the crossover design, an additional constraint, *order* or *balance*, is imposed on the experiment. For example, in a bioequivalence study of three products, these are taken sequentially during three periods. In the crossover design, each product appears an equal number of times in each period.

Table 10-26 shows how three products,  $A$ ,  $B$ , and  $C$ , may be assigned to nine subjects in a bioavailability study. Note that treatments  $A$ ,  $B$ , and  $C$  appear exactly three times in each period and that each subject takes all three products. The balancing of order of administration compensates for period effects. If any extraneous variables affect the outcome differently in one period compared to another, all treatments may be affected equally. This would result in a fair comparison of the different treatments. In a purely random assignment of treatments, it would be unlikely that treatments would be assigned in such a balanced

**Example 20.**

Three variations of an acne preparation and a control are to be tested for skin irritation. The four products, **A**, **B**, **C**, and the control, each are applied to sites on the backs of eight patients. The assignment of the four products to the four sites on the patient is random; i.e., a random assignment of treatments to the four sites on each patient is done for each patient, using a random-number table. The products are applied, and after 24 hours, the degree of irritation is determined by assessing irritation subjectively on a scale of one to ten. A value of one means no irritation, and a value of ten means extreme irritation. The results are shown in Table 10-24.

**Table 10-24. Skin Irritation Test**

Patients	Treatment				Σx	Σx <sup>2</sup>
	A	B	C	Control		
1	7	5	5	4	21	115
2	4	3	5	2	14	54
3	8	9	7	6	30	230
4	8	6	4	5	23	141
5	7	7	4	2	20	118
6	6	7	5	4	22	126
7	5	6	4	5	20	102
8	4	7	5	4	20	106
Totals	49	50	39	32	170	992

The computations are similar to those for the one-way ANOVA. The sum-of-squares for treatments is obtained as before. The sum-of-squares for patients is determined exactly as for treatments except the operation is across rows. This is the same as rotating the table by 90 and treating the rows as columns in the table matrix. The EMS (expected sum of squares) is obtained by subtracting the row and column sum-of-squares from the total sum-of-squares.

$$\begin{aligned} \text{Total SS} &= \sum x_i^2 - \frac{(\sum x_i)^2}{n}, \text{ where } (\sum x_i)^2/n = CT \\ &= 992 - 170^2/32 = 88.875 \end{aligned}$$

$$\begin{aligned} \text{Between treatments SS} &= \frac{49^2 + 50^2 + 39^2 + 32^2}{8} - \frac{170^2}{32} \\ &= 27.625 \end{aligned}$$

$$\begin{aligned} \text{Between patients SS} &= \frac{21^2 + 14^2 + \dots + 20^2}{4} - CT \frac{3705}{4} - CT \\ &= 23.125 \end{aligned}$$

$$\begin{aligned} \text{Error} &= \text{Total SS} - \text{Between treatments SS} - \text{Between subjects SS} \\ &= 88.875 - 27.625 - 23.125 = 38.125 \end{aligned}$$

Table 10-25 shows the ANOVA. Since the *F* ratio for treatments (5.07) exceeds the tabled *F* value with 3 and 21 DF at the 5% level, it can be concluded that at least two of the treatments differ. Although one may apply one of the a posteriori tests discussed under one-way ANOVA, inspection of the results suggests that results for treatments *A* and *B* are similar and both are greater in magnitude than treatments *C* and the control.

**Table 10-25. ANOVA for Data of Table 10-24**

Source of Variation	Analysis of Variance			
	DF	Sums-of-Squares	Mean Square	<i>F</i> Ratio
Between Treatments	3	27.625	9.203	5.07
Between patients	7	23.125	3.304

9	A	C	B

**Example 21.**

Three drug formulations were administered to nine subjects in a bioavailability study, according to the crossover design illustrated in Table 10-26. The area under the blood level curves were computed for each dosing, and the results are shown in Table 10-27.

**Table 10-27. Results of Bioavailability Study**

Subject	Period 1	Period 2	Period 3	Sum
1	B = 107	C = 102	A = 99	308
2	A = 100	C = 106	B = 89	295
3	B = 98	A = 90	C = 128	316
4	C = 71	B = 54	A = 63	188
5	A = 92	B = 111	C = 107	310
6	C = 113	A = 115	B = 91	319
7	B = 169	A = 187	C = 195	551
8	C = 88	B = 95	A = 77	260
9	A = 122	C = 168	B = 155	445
Period sum	I:960	II: 1028	III: 1004	2992
Treatment sum	A: 945	B:969	C: 1078	
Treatment average	105	107.7	119.8	

The ANOVA (Table 10-28) separates the total variance into four parts: subjects, period (order of administration), treatments, and error.

**Table 10-28. ANOVA for Bioavailability Study**

Analysis of Variance				
Source of Variation	DF	Sums-of-Squares	Mean Square	F Ratio
Between subjects	8	29834.1	3729.3	
Between treatments	2	1116.5	558.3	3.15
Order	2	264.3	132.1	0.75
Error	14	1947.2	177.0	
Total	26	33162.1		

$$\sum x_i = 2992 \quad \sum x_i^2 = 364,720$$

$$\text{Total SS} = \sum x_i^2 - \frac{(\sum x_i)^2}{n} = 33,162.1$$

$$\text{Subject SS} = \frac{\sum \text{row}^2}{3} - \frac{(\sum x_i)^2}{n} = 29,834.1$$

$$\text{treatment SS} = \frac{\sum \text{treat.sum}^2}{9} - \frac{(\sum x_i)^2}{n} = 1116.5$$

$$\text{Order SS} = \frac{\sum I^2 + \sum II^2 + \sum III^2}{9} - \frac{(\sum x_i)^2}{n} = 264.3$$

$$\text{Error SS} = \text{Total SS} - \text{Subject SS} - \text{treatment SS} - \text{Order SS} = 1947.2$$

Neither treatments nor order are significant (see Table 10-15). For 2 and 14 DF, an *F* value of 3.70 is needed for significance. Treatment C has a higher average result but fails to reach significance in this study. In the early days of bioequivalence testing, bioequivalence studies were designed to have a power of 0.8 to detect a difference of 20% between treatments. This means that a sufficient number of subjects should be included in the study so that if a true difference of 20% or more exists between two treatments, there will be at least an 80% chance of finding a significant difference. This method of evaluating equivalence has been replaced by a more meaningful confidence interval approach.<sup>8</sup>

order. In an unbalanced design, differences due to periods would not affect treatments equally, resulting in a potential bias and a larger experimental error – the experimental error would include the usual causes of variability and also variability due to period effects. Thus, the crossover design can be considered an improvement over the two-way design in that the error has been reduced and the experiment made more efficient.

Many such designs are available, but care should be exercised to apply the correct design to each experimental situation. The crossover design is related to the Latin square design. Several very good references are available on principles of experimental design. In particular, the book by Cox<sup>6</sup> is recommended because it is not overly technical and can be understood without resorting to too much mathematics.

**Example 22.**

A pilot study to compare the effects of an antihypertensive drug versus placebo was designed with four patients on drug and four on placebo. Blood pressure changes from baseline were measured for six weeks at biweekly intervals. The results are shown in Table 10-29.

**Table 10-29. Reduction in Diastolic Blood Pressure from Baseline**

Patient	Drug Week			Placebo Week			
	2	4	6	2	4	6	
1	10	8	12	2	10	8	12
3	8	6	14	5	6	2	10
4	12	14	8	6	4	0	2
7	10	10	14	8	0	4	10
Average	10.0	9.5	12.0		5.0	3.3	8.5

The ANOVA is shown in Table 10-30. The terms of interest are *treatments* and *treatment × times*. The former term measures differences of the overall average results of the two treatments. The error term for treatments is the mean square for patients. The *treatment × times* term compares the time trends for the two treatments. The error term for the *treatment × times* is patient × times (treatments). If the trends are parallel, this term will not be significant. Significance for this term indicates a lack of parallelism, suggesting that differences between treatments depend on the time of observation.

**Table 10-30. ANOVA for Example 22**

Source	DF	SS	MS	F
Patients	6	109	18.2	
Treatments	1	140.2	140.2	7.7
Times	2	60.3	30.2	3.5
Treatment × times	2	6.3	3.2	0.4
Patient × times (treatments)	12	104	8.7	
Total	23	419.8		

As with most experimental data, a graphic display is recommended. Figure 10-8 is a plot of the average results versus time. The significant difference between treatments ( $\alpha=0.05$ ) is apparent from the plot and the ANOVA. The time trends of both treatments are similar and can be explained by the experimental variability (treatment × times is not significant).

**Figure 10-8.** Plot of average results for Example 22.

If the crossover design becomes unbalanced, due to drop-outs or other conditions, a computer analysis can be used (e.g., SAS).

Another experimental design common in clinical trials is the repeated-measures design, often called a *split-plot design*. For example, two treatments are compared by making observations in two independent groups of patients over time. Although an equal number of patients in each group is desirable, it is not necessary for the data analysis. The observations are made at the same time periods in both groups. The example shows the basic design and ANOVA table. The details of the calculations are not shown. Usually, a software program is used to analyze and summarize the data. The details of the analysis are given in Bolton<sup>8</sup> and Winer<sup>14</sup>.

**NONPARAMETRIC TESTS OF SIGNIFICANCE**

The validity of the *t* test for comparing two means depends to some extent (especially for small samples) on the assumptions that the two populations sampled are distributed approximately normally and have essentially equal variances. A procedure for testing the equality of variances has been discussed previously. Statistical procedures that do not depend on the assumption of normality or any other distribution are called nonparametric tests. Three commonly used procedures are the rank sum test for unpaired data (Rank Sum Test of Significance), the *Signed-Rank Sum Test of Significance*, and the *Sign Test* for paired data.

• *Rank Sum Test of Significance* The rank sum test of significance is the nonparametric analog of the two-independent sample *t* test. The  $n_1$  and  $n_2$  observations are taken from two independent groups. After the  $n_1$  and  $n_2$  observations are arranged in order of size, the combined values are ranked from 1, for the lowest, to  $(n_1+n_2)$  for the highest, and the sum of the ranks *T* of the  $n_1$

**Example 23.**

Data were available on the duration of loss of the righting reflex (minutes) for 10 mice given a standard barbiturate and for 11 mice given a test barbiturate (Table 10-32). Adding the respective ranks for standard drug and test drug we find  $T = 150$  and  $T' = n_1(n_1 + n_2 + 1) - T = 10(10 + 11 + 1) - 150.5 = 69.5$ . Entering Table 10-31 with  $n_1=10$  and  $n_2=11$ , we find that the calculated  $T'$  value 69.5 is less than the tabulated value 73 for  $\alpha=0.01$ . Therefore, because the probability of the standard drug and test drug values being the same is less than 0.05 (actually, it is less than 0.01), it is concluded that they are different. This test compares the medians of the two-populations sampled. The median of an ordered set of observations is defined as the middlemost value for an odd number of observations, and as the average of the two middlemost values for an even number of observations. Thus, the median for the standard drug is,  $(130+148)/2=139$  and the median for the test drug is 103.

**Example 24.**

The procedure is illustrated for data given in Example 12 (Table 10-34). Entering Table 10-33 with  $n = 15$  and  $T = 22.5$ , we find that the calculated  $T$  value 22.5 is less than the tabulated value 25 for  $\alpha=0.05$ . Therefore, because the probability of the morning and afternoon values being the same is less than 0.05, it is concluded that they are different.

observations in the smaller sample is computed. Values that are tied are given average ranks. Also calculate  $T' = n_1(n_1+n_2+1) - T$ , and enter Table 10-31<sup>15</sup> with  $n_1, n_2$ , and  $T$  or  $T'$ , whichever is smaller. If the calculated  $T$  (or  $T'$ ) is equal to or less than the tabled value, the null hypothesis is rejected at the significance level *P*.

• *Signed-Rank Sum Test of Significance* The signed-rank sum test of significance is the nonparametric analog of the paired *t* test. The differences between the *n* paired values are ranked in order of absolute size from 1, for the lowest, to *n*, for the highest, ignoring zero differences. Tied values are assigned

**Example 25.**

The procedure is illustrated for the data given in Examples 12 and 24.

$b = \text{number of positive differences} = 11$

$c = \text{number of negative differences} = 4$

$$\chi^2 = \frac{(b - c - 1)^2}{b + c} = \frac{(11 - 4 - 1)^2}{11 + 4} = \frac{36}{15} = 2.40$$

Table 10-12 shows that for 1 DF the probability of getting a value of  $\chi^2$  larger than the calculated value 2.40 is between  $\alpha=0.10$  and  $\alpha=0.20$ . Since *P* is not equal to or less than 0.05, it is concluded that there is insufficient evidence to indicate that the morning and afternoon values are different. This conclusion is not in agreement with that of the *t* test and the signed-rank test. The reason for this is that the statistical sign test considers only the sign of the difference and not the magnitude and, thus, is a less-sensitive test in borderline situations such as this one.

**Table 10-31. The Rank Sum Table Values of T or T', Whichever is Smaller, Significant at the 10%, 5%, and 1% Levels**

16	35	29	19	29	141	126	100
17	41	34	23	30	152	136	109

an average rank. After the differences are ranked, the signs of the differences are attached to the ranks, and the sum of the positive ranks and of the negative ranks are obtained. Enter Table 10-33, with  $n$  being the number of non-zero differences and the sum  $T$  of positive or negative ranks, whichever is smaller. When the calculated  $T$  is equal to or less than the tabulated  $T$ , the null hypothesis is rejected at the significance level  $P$ .

- **Sign Test** The sign test is also used for paired data, but it is not as powerful as the signed-rank test; it is more difficult to find significant differences when they exist with the sign test. Count the number of positive differences ( $b$ ) and the number of negative differences ( $c$ ), ignoring zero differences, and calculate:

$$\chi^2 = \frac{(b - c - 1)^2}{b + c}$$

This is referred to the chi-square table (see Table 10-12) with  $DF = 1$ , the test being essentially the same as the chi-square test illustrated in Example 16.

**EXACT TESTS**

Statistical distribution functions enable us to calculate the probability of certain events under the null hypothesis -- but only if their prerequisites hold. And even then they are sometimes only approximations to the real distribution of the test

**Table 10-34. Signed Ranks from Example 24**

statistic. For example, in a Mann-Whitney  $U$  test, the tabulated critical values cannot be used if the number of samples is too small or there are too many ties (i.e., a group of subjects for which the experiment results in the same value). In certain models of diseases, however, (e.g., experimental autoimmune encephalomyelitis, see below) only a few different outcomes are defined, and most of the animals will show results of moderate severity. So in this kind of experiment, many ties will occur, and the prerequisites for the Mann-Whitney are not met. Figure shows the theoretical distribution of the test statistic  $U$  of the Mann-Whitney test under the null hypothesis (which is listed in statistic books or calculated by statistic software), compared with the real distribution if ties are present.

However, the computing power of modern computers allows us even to find the exact distributions of events under the null hypothesis. The kind of statistical tests that are based on these exact distribution data are called *permutation tests*. Their working principle is as follows:

Let us suppose that the null hypothesis holds -- so for each subject the result of an experiment is not due to any treatment effects. In other words: Any subject from the control group would have shown the same result as if it had been assigned to the treatment group and vice versa. Thus, the exact null distribution can be found by consideration of all possible assignments of the subjects to the respective treatment groups.

As an example, we take the data from table. It shows severity scores of experimental autoimmune encephalomyelitis in mice. The animals in group 2 were treated with a drug candidate, while group 1 is a control group without medication. We see that the median in group 2 is lower than in group 1, but is this difference statistically significant?

It is common practice in pharmaceutical development to look for positive or negative impacts of the treatment. Therefore, we are going to perform a two-tailed test. So we state the null hypothesis  $H_0$ :

*The treatment has no influence on the severity of the EAE symptoms. (Differences in the severity scores are just caused by chance.)*

The alternative hypothesis  $H_0$  for the two-tailed test is:

*The treatment leads to either an amelioration or aggravation of the symptoms.*

We will reject the null hypothesis, if the chance to find results that are at least as extreme as the actual result of the experiment

Table 10-35.

Score	Group 1	Group 2	Total
0			2
0.5			0
1			9
1.5			0
2			9
2.5			0
3			4

is less than  $\alpha = 5\%$  (significance level). If the chances that the difference in the two groups is merely due to chance is greater than  $\alpha$ , we do not reject to the null hypothesis. However, we must bear in mind that the null hypothesis may actually be wrong and that the experiment (and the statistical evaluation) is just too weak to show the significance of the differences (type II error).

If we add up the ranks for the observations in group 1 to the sum  $R_1$  and the ranks for group 2 to  $R_2$  we find the test characteristic  $U$  of the Mann-Whitney test, with  $n_1$  and  $n_2$  denoting the number of observations in both groups as the smaller of the two values:

$$U_1 = R_1 - \frac{n_1(n_1 + 1)}{2} \quad \text{and} \quad U_2 = R_2 - \frac{n_2(n_2 + 1)}{2}.$$

In the absence of ties, precalculated tables can be used to obtain critical values of the  $U$  distribution for a given level of significance. For large samples,  $U$  is approximately normally distributed with mean  $mn/2$  and variance  $mn(m+n+1)/12$ .

However, if we look at the counts of the scores of this example we find a lot of ties (Table 10-35).

In fact, we observed only four different ranks:

The rank sums for each treatment group are  $R_1 = 191$  and  $R_2 = 109$ , so  $U = 109 - 78 = 31$ .

Since the tabulated  $U$  distribution is not applicable in the presence of so many ties, we need to compute our  $p$ -value from the *exact distribution* of the  $U$  values.

The general idea is that with the null hypothesis being valid, it does not matter which of the 24 animals were assigned to the control group. If there is no effect from therapy, every animal from control and treatment group would have shown the same severity score regardless of which group it was assigned to. Thus every possible combination of 12 animals out of the 24 animals that participate in the test leads to an  $U$ -value that would have occurred if only the random assignment to the control and treatment group had lead to a different partitioning. These  $U$ -values form the null distribution from which we can judge the significance of our result.<sup>16</sup>

In total there are  $\binom{24}{12} = 2704156$  different possibilities (combinations) to arrange 24 animals in two groups of twelve. Though this number is fairly high, modern computers calculate the  $U$ -values for each of them in an instant. (However, computing time rises exponentially with the number of subjects, so there are still limits for the use of permutations tests.)

The exact null distribution is shown in figure together with the conventional  $U$  distribution. We find that the ranks in group 2 are significantly lower than those in group 1 ( $p = 0.016$ ).

## REJECTION OF ABERRANT OBSERVATIONS

It is common practice among chemists and others working in the physical sciences to make observations in duplicate or triplicate. This is usually done for the purpose both of obtaining a more accurate result and detecting mistakes in dilution, weighing, and so on. It is quite a common practice to reject the most extreme of the three results if it appears to disagree with the others.

Youden,<sup>17,18</sup> a chemist as well as a statistician, made a study of the problem of rejection of observations in an attempt to answer three questions:

1. If the extreme observation of triplicates is always rejected when only normal variation is present, how accurate is the result?
2. Is the average of the two closest observations as good an estimate as the average of all three?
3. By how much should the outlying observation of triplicates differ from the other two in order to be reasonably assured that this difference is due to a blunder rather than normal variation?

He found that rejection of the outlying observation resulted not only in the variation being greatly underestimated but in the mean being biased.

If one wished to follow a simple rule of rejection<sup>17,18</sup> of observations in samples of three, so as to reject not more than 5% of the extreme observations arising from normal variation, a rejection ratio of  $D/d$  greater than 20 would be required.

$D/d > 20$  where  $D$  is the difference between the most extreme observations and its closest neighbor and  $d$  is the difference between two closest observations

In the USP there is an excellent chapter on the design and analysis of biological assays, in which are included some tests for rejection of outlying observations. These and other tests can be applied to chemical as well as biological assays.<sup>19</sup> Two criteria are presented here, one for rejecting single suspect observations in one group and the other for rejecting a whole group of observations.

To use the first criterion, arrange the observations in the group in order of their magnitude, and number them from 1 to  $n$ , beginning with the supposedly erratic or outlying observation, thus:

$$y_1, y_2, y_3, \dots, y_n$$

where  $y_1$  is the suspect observation. If there are 3 to 7 observations in the group, calculate:

$$G_1 = \frac{y_2 - y_1}{y_n - y_1}$$

If there are 8 to 10 observations in the group, and the smallest value seems suspect, again arrange them in order from lowest to highest, and calculate:

$$G_2 = \frac{y_2 - y_1}{y_{n-1} - y_1}$$

If there are 11 to 13 observations, follow the same procedure, but use the statistic:

Table 10-36.

**Example 26.**

Suppose among the gains in weight of six rats after a feeding experiment, one weight was found to be much less than the other five. Can that observation be discarded? The six gains in weight are 36, 40, 38, 42, 20, and 39.

Rearrange these in order from smallest to largest and label  $y_1, \dots, y_6$ , where  $n=6$ .

$$y_1 = 20, y_2 = 36, y_3 = 38, y_4 = 39, y_5 = 40, y_6 = 42$$

$$G_1 = \frac{y_2 - y_1}{y_6 - y_1} = \frac{36 - 20}{42 - 20} = \frac{16}{22} = 0.727$$

Referring to the value of  $G_1$  for  $n=6$  in the table,  $G_1=0.698$  for  $\alpha=0.01$ . Since the calculated value of  $G_1$  is larger than this value, reject the value of 20 and work with the remaining five values.

$$G_3 = \frac{y_3 - y_1}{y_{n-1} - y_1}$$

If there are 14-25 observations, follow the same procedure, but use the statistic:

$$G_4 = \frac{y_3 - y_1}{y_{n-2} - y_1}$$

If the largest value is open to suspicion as possibly being aberrant, arrange the observations in order from highest to lowest and number them, always labeling the suspect observation  $y_1$ .

If the calculated value of  $G_1, G_2, G_3$ , or  $G_4$  is larger than the tabled value (which gives the probability of a value being so extreme as that observed), it can be assumed that the observation truly does not belong to the group, and the observation is rejected. The values of  $G$  for a probability  $\alpha=0.01$ , that an outlier could occur at either end are shown in Table 10-35. This same criterion could be used for testing whether the largest or smallest average in a group of averages differs significantly from the remainder of the averages (Table 10-37).

The second criterion for an aberrant observation, as given in the USP, compares the variation or range between various groups. It is a test for the homogeneity of the ranges (the range is again the highest value in a group minus the lowest value) and is for the purpose of locating outliers within one group of values. This method and its accompanying table are presented in considerable detail in the USP. The rejection of outliers, using only statistical criteria, is controversial. A knowledge of the characteristics or properties of the chemical or biological systems being studied should be used when making decisions to reject outlying data.

**QUALITY CONTROL METHODS**

A very short explanation is given here regarding the quality control methods that were developed primarily by Dr Walter Shewhart of the Bell Telephone Laboratories. A more complete explanation can be found in two short publications of the American Standards Association<sup>20,21</sup> and many texts, including Dixon and Massey.<sup>22</sup>

The quality control method for variables involves plotting the data as dots on a graph, with the variable measured on the vertical axis, and time (hours, days, etc.) on the horizontal axis. The control is maintained by inserting, on the chart, the grand average and control limits that have been calculated from accumulated experience and drawn on the chart as parallel horizontal lines, as shown in Figure 10-9. When all the dots fall within the limits, the results are said to be in a state of statistical control. When a dot falls outside the limits, a potential problem is indicated.

In a control chart, usually each dot is an average for a sample consisting of, say, four observations. The standard error of the average then is calculated for each group of four observations, and an average value for the standard error of the average is obtained. This is designated by  $\sigma_{\bar{x}}$ . The grand average of all the averages plotted also is calculated and is labeled  $\bar{x}$ . The 3-sigma control limits used on the control chart can be obtained from:

$$\text{Upper limit} = \bar{\bar{x}} + 3\sigma_{\bar{x}}$$

$$\text{Lower limit} = \bar{\bar{x}} - 3\sigma_{\bar{x}}$$

Thus, it can be seen that the control-chart technique is a graphic means of investigating whether the variation exhibited over a very short period of time is the same as the variation that

**Figure 10-9.** A typical quality control chart.

**Table 10-38. Calculation of Standard Deviation from Range**

Size of Sample (n)	Average Number of Standard Deviations in T-1E Average Range (d)	Size of Sample (n)	Average Number of Standard Deviations in the Average Range (d)
2	1.128	7	2.704
3	1.693	8	2.847
4	2.059	9	2.970
5	2.326	10	3.078
6	2.534		

**Table 10-39. Factors for 3-Sigma Limits<sup>a</sup>**

5	0	2.11	0.577
6	0	2.00	0.483
7	0.08	1.92	0.419
8	0.14	1.86	0.373
9	0.18	1.82	0.337
10	0.22	1.78	0.308

<sup>a</sup> This table contains data from the tables in Appendix 1 of Z1.3—1958.<sup>20</sup>

occurs over a long period of time. If the two variations are identical and all of the plotted dots fall within the control limits, the experiments or processes that produced the data are said to be in a state of *statistical control*.

For many pharmaceutical processes, particularly heterogeneous processes, typical Shewhart control charts do not describe the process adequately. The process seems to not be in control. In these cases, alternative methods should be considered.<sup>23</sup> Control charts are a valuable tool for process validation.

It is possible to calculate the control limits by using the range in each group of four instead of calculating the standard deviation. This is because, on the average, for samples of less than ten, the range and the standard deviation are related very closely. Given the number of observations in the sample, the standard deviation can be calculated by dividing the range by the appropriate figure given in Table 10-38 for the size of the sample, *n*. The factors for calculating 3-sigma limits from the range are given as column  $A_2$  in Table 10-39.

**Example 27.**

A drug manufacturer keeps a record of the uniformity of the machine that is filling a given weight of a drug into ampuls. Samples of the finished product are taken at definite time intervals. The data are accumulated and arranged into groups of four ampuls according to the order in which they were taken from a filling machine. The average and the range are computed for each group of four, as given in Table 10-40, according to the time the samples are taken. The resulting quality-control charts are shown in Figure 10-10.

**Table 10-40. Calculations for a Quality-Control Chart On Averages and Ranges for Samples of 4 from a Filling Machine**

Time	Average (G)	Range (G)	Time	Average (G)	Range (G)
Jan 6			Jan 7		
8 AM	38.1	1.5	8 AM	37.6	2.1
9 AM	37.6	2.1	9 AM	39.1	1.4
10 AM	38.3	1.1	10 AM	38.5	1.1
11 AM	36.5	2.4	11 AM	37.7	1.9
12 M	38.9	3.1	12 M	38.1	2.3
1 PM	37.8	2.8	1 PM	38.5	2.4
2 PM	38.5	1.7	2 PM	37.6	1.6
3 PM	39.4	1.6	3 PM	37.9	1.8
4 PM	36.4	2.5	4 PM	38.6	1.0

Grand average =  $\bar{X} = 38.1$   
 Average range =  $\bar{R} = 1.9$   
 Control limits<sup>a</sup> for average =  $\bar{X} \pm A_2R = 38.1 \pm 0.729(1.9)$   
 Upper limit = 39.49  
 Lower limit = 36.71  
 Control limits<sup>b</sup> for range, are  $D_3 \bar{R}$  or 0(1.9) and  $2.28(1.9)$  which equal 0 and 4.33, respectively.

<sup>a</sup>  $A_2$  is the factor for using the range to calculate 3-sigma limits for the average (i.e., 3 times the standard error of the average). See Table 10-37 for  $N=4$ .

<sup>b</sup>  $D_3$  and  $D_4$  are the factors for using the range to calculate 3-sigma limits for the range (i.e., 3 times the standard error of the range). These values are taken from Table 10-39. In two instances the point plottings fell below the lower control limit, indicating a lower average fill than one might expect, i.e., there is a lack of statistical control.

**Figure 10-10.** Quality control charts for data from Table 10-40.

Control charts using 3-sigma limits can be obtained by the use of figures given in Table 10-37. With  $R$  being the average range, the formulas are:

$$\text{Upper limit for average} = \bar{\bar{x}} + A_2 \bar{R}$$

$$\text{Lower limit for average} = \bar{\bar{x}} - A_2 \bar{R}$$

$$\text{Upper limit for ranges} = D_4 \bar{R}$$

**Example 28.**

A department head in the capsule department of a pharmaceutical company keeps a record of the number of defective capsules found in sections of large lots of capsules (Table 10-41). Each section consists of approximately 19000 capsules. In Table 10-39 and Figure 10-11, where points fall above the upper control limit, a greater number of defects are present than may be expected – there is a lack of statistical control. These sections are reinspected carefully, and action is taken at the machine to correct the causes of bad quality.

$$\bar{p} = \frac{\text{Total number of defectives}}{\text{Total number inspected}} = \frac{131}{31 \times 300} = \frac{131}{9300} = 0.01408$$

$$\begin{aligned} \text{Control limits for } \bar{p} &= \bar{p} \pm 3 \sqrt{\frac{\bar{p}(1-\bar{p})}{n}} \\ &= 0.01408 \pm 3 \sqrt{\frac{0.01408(1-0.01408)}{300}} \end{aligned}$$

Upper limit = 0.0349  
Lower limit = 0

The sample size,  $n$ , from each section is 300 capsules, and typical data are shown in Table 10-41, plotted in Figure 10-11. Note that Sections 21 and 29 appear to be out of control. These sections were subjected to 100% reinspection. Approximately 4.5% of the capsules were defective and were removed.

**Table 10-41. Data Collected from the Process in Example 28**

Section Number	Number Defectives	Fraction Defective	Section Number	Number Defectives	Fraction Defectives
1	3	0.01	17	2	0.0067
2	2	0.0067	18	3	0.01
3	3	0.01	19	4	0.0133

16	3	0.01			

**Figure 10-11.** Control chart for fraction defective.

$$\text{Lower limit for ranges} = D_3 \bar{R}$$

These calculated limits are drawn on the charts as described above.

**CONTROL CHART FOR FRACTION DEFECTIVE**

The control chart for fraction defective may be applied to results of an inspection that accepts or rejects individual items of a product. It is designed with the same objectives in mind as the  $\bar{x}$  and  $s$ ,  $\bar{x}$  and  $\sigma$  charts. Its most effective use is in the improvement of quality, although it also discloses the presence of assignable causes of variation. It provides management with an effective quality history. Fraction defective,  $P$ , may be defined as the ratio of the number of defective articles found in any inspection, or series of inspections, to the total number of articles actually inspected. This is expressed nearly always as a decimal fraction (Fig 10-11). The formula for the control limits on a fraction defective chart is:

$$\bar{p} \pm 3 \sqrt{\frac{\bar{p}(1-\bar{p})}{n}}$$

**ACCEPTANCE SAMPLING**

Acceptance sampling has become one of the major fields of statistical quality control. It is used in many phases of manufacturing, such as inspection of incoming materials, process inspection at various points in the manufacturing operations, and final inspection of the finished product. Sampling inspection usually is used in lieu of 100% inspection for several reasons:

1. The cost of 100% inspection is prohibitive.
2. 100% inspection is fatiguing and may result in the inspectors making errors.
3. The inspection operation may involve destructive testing.

In sampling, one must consider the laws of probability. The risk of rejecting good-quality material and the risk of accepting bad merchandise should be appraised. Sampling plans can be designed and applied in such a manner as to reduce these risks to a minimum and, over a period of time, give assurance of quality products.

The graph illustrating the performance of a sampling plan (i.e., ability to discriminate between acceptable and unacceptable lots) is called an *operating characteristic curve* (OC curve). For any given quality of submitted material, it is possible to determine the probability of acceptance.

Figure 10-12 is an example of an OC curve for the sampling plan described in Example 29. The government publication MIL-STD-105E<sup>24</sup> gives many different sampling plans with their corresponding OC curves. A plan that is appropriate for a product is chosen depending on lot size and seriousness of the defect.

**Figure 10-12.** Operating characteristic curve. (From Military Sampling Procedures and Tables for Inspection by Attributes. MIL-STD-105E. Washington DC: USGPO, 1989.)

### Example 29.

Example of a **statistical sampling plan**. A pharmaceutical manufacturer receives empty bottles of a particular size from a supplier in lots of 20 000 bottles each. The drug firm would like the producer to submit material that is not more than 1.0% defective most of the time, or specifically 95% of the time. See point **A**, Figure 10-12. However, the pharmaceutical firm has agreed to take one chance in 10 of accepting a lot that is 2.6% defective. See point **B**, Figure 10-12.

The acceptance sampling plan that complies with these specifications is as follows. Take a random sample of 540 bottles. Inspect the bottles for defectives. If zero to nine bottles are found defective, accept the lot; if ten or more defectives are found, reject the lot. The operating characteristic curve for this plan is illustrated in Figure 10-12.<sup>24</sup>

One also can see that, using this sampling plan, submitted lots having 0.5% defective will be accepted about 99 times in 100 (probability of acceptance = 0.99) and thus rejected about one time in 100. Submitted lots having 1.75% defective will be accepted 50 times in 100 (probability of acceptance = 0.50) and rejected half the time.

## STATISTICS OF THE STRAIGHT LINE

The use of straight lines to illustrate and define relationships or to help interpret data is common in research investigations. In pharmaceutical research, straight lines may be used for predictive purposes in stability studies or to estimate future events, such as sales figures in market research studies. Straight lines are found in many theoretical relationships in physical and biological chemistry. First-order and zero-order kinetics can be expressed in a linear fashion. Michaelis-Menten kinetics and the Arrhenius relationship can be transformed to a linear

form. Dose-response curves often are linearized if the response is plotted versus log dose. In fact, it is almost always desirable to express a relationship in the form of a straight line, if at all possible.

Reasons for the desirability of straight-line relationships include the ease of interpolation – and in well justified cases, extrapolation – as well as the simplification of the determination of the parameters of the line, the slope, and the intercept. The straight line is defined by these two parameters, and these often have biological and/or physical significance. Consider the example of a first-order kinetic relationship:

$$C = C_0 \cdot e^{-kt}$$

where  $C$  is the concentration at time  $t$ ,  $C_0$  is the concentration at time 0, and  $k$  is the first-order rate constant.

This equation is not linear—a plot of  $C$  versus  $t$  will not result in a straight line. If the experimental data are gathered for  $C$  as a function of time, one usually is interested in defining the first-order relationship, in particular to evaluate the parameters  $k$  and  $C_0$ . This is done most easily by linearizing the equation, using a logarithmic (log) relationship. Using log to the natural base  $e$ , the following linear relationship is obtained.

$$\log C = \log C_0 - k \cdot t$$

This has the form of a straight line. The general equation of a straight line can be expressed as:

$$y = a + bx$$

with the dependent variable  $y$ , the independent variable  $x$ , the slope of the line  $b$ , and the intercept at the  $y$ -axis  $a$ .

Figure 10-13 shows this linear relationship and calculation of the parameters.

The linearized first-order kinetic equation will show a straight line when  $\log C$  is plotted versus time, with intercept  $\log C_0$  and slope  $-k$ . The linearized form makes it easy to obtain the values of  $C_0$  and  $k$ .  $C_0$  is the antilog of the intercept  $a$ , and  $k$  is the negative of the slope  $b$ :

$$C_0 = e^a, \quad k = -b.$$

One of the problems in estimating these values from real data is the variability; a plot does not clearly define a straight line. If variability is large, it may be very difficult to decide how to draw the line. Figure 10-14 shows real data from a pharmacokinetic study, in which plasma drug concentrations are measured following an intravenous bolus injection of drug (a one-compartment model).

When confronted with a relationship that should be linear from a theoretical viewpoint but where the  $x, y$  values do not lie exactly on a single line, the lack of an exact fit will be considered to be due to variability (error) in  $y$  (the dependent variable). In most cases that are encountered, the  $x$  variable (the independent variable) tends to have little error relative to the

**Figure 10-13.** Plot of  $\log C$  versus time.

**Figure 10-14.** Drug plasma levels following an intravenous bolus dose of a drug.

$y$  variable. For example, in a dose-response relationship, the drug is carefully prepared so that an almost unerring dose is administered. However, the response is unpredictable due to the biological variability of the natural material (e.g., animals or bacteria). In a kinetic study, the  $x$  variable, time, can be measured with great accuracy. The dependent variable, concentration, is variable due to analytical error, for example. The best line for such variable data is called the least-squares (LS) line. This line is such that the sum of the squared deviations of each point from the line is minimized. That is, if the vertical distance from each point to the LS line is calculated, and the squares of these distances are summed, the LS line would minimize the sum-of-squares. Deriving the sum of squares with respect to  $a$  and  $b$  leads to the equations:

$$a \cdot \sum x_i + b \cdot \sum x_i^2 = \sum x_i y_i, \quad a \cdot n + b \cdot \sum x_i = \sum y_i$$

and thus

$$a = \frac{\sum x_i^2 \cdot \sum y_i - \sum x_i \sum x_i y_i}{n \cdot \sum x_i^2 - (\sum x_i)^2}, \quad b = \frac{n \cdot \sum x_i y_i - \sum x_i \sum y_i}{n \cdot \sum x_i^2 - (\sum x_i)^2}$$

**Example 30.**

Consider the data from Figure 10-14. See Table 10-42. The equation of the LS line is  $\log C = 1.345 - 0.0886 \cdot t$ , thus:

$$b = \frac{16.036 - 27(4.334)/5}{229 - 27^2/5} = -0.0886$$

$$a = 0.8669 + 0.0886(5.4) = 1.34534$$

$$C \approx 22.14 \cdot e^{-0.0886 \cdot t}$$

**Table 10-42. Concentration vs Time for Example 30**

Time ( $x$ )	1 hr	2 hr	4 hr	8hr	12 hr
Concentration ( $\mu\text{g/mL}$ )	18	15	10	4	2
Log concentration	1.255	1.176	1.000	0.602	0.301

**Example 31.**

In analytical procedures for drugs, a calibration curve often is constructed using known concentrations of the material to be analyzed. The relationship of drug concentration and the analytical measurement usually is linear. In spectrometric methods, absorption usually is proportional to concentration. The data in Table 10-43 were obtained for the construction of such a calibration curve. These data and the LS line are plotted in Figure 10-15. The LS intercept,  $a$ , and slope,  $b$ , are:

$$a = \frac{3000 \cdot 2.4210 - 100 \cdot 72.67}{4 \cdot 3000 - 100^2} \approx -0.0020,$$

$$b = \frac{4 \cdot 2.67 - 100 \cdot 2.4210}{4 \cdot 3000 - 100^2} \approx -0.0243$$

The estimate of the variance of  $y$ ,  $S_{y,x}^2$  is

$$S_{y,x} = \frac{\sum y_i^2 - (\sum y_i)^2/n - b^2 (\sum x_i^2 - (\sum x_i)^2/n)}{n - 2}$$

$$= \frac{1.7607 - 2.421^2/4 - 0.0249^2 (3000 - 100^2/4)}{2}$$

$$= 0.000208$$

The value of the numerator is the sum-of-squares of the difference between the actual values of  $y$  and the value of  $y$  on the LS line, for each  $y$ . The divisor,  $n - 2$ , is the number of data pairs minus 2, the DF. Thus, the estimate of the variance of  $y$  in this example has 2 DF. The reason that 2 is subtracted from the number of data points to obtain the DF is that two parameters are being estimated in the case of a straight line. In previous examples, such as the  $t$  test, only the mean is estimated for a treatment group, and  $DF = n - 1$ .

**Table 10-43. Absorbance vs Concentration**

Concentration	10 mg/L	20 mg/L	30 mg/L	40 mg/L
Absorbance	0.241	0.492	0.710	0.978

**Figure 10-15.** Beer's law plot.

Please note that the denominators in both expressions are equal and need only to be computed once.

It must be noted that, using the formulas for linear regression on transformed data, as in this example, the result does not minimize the sum of squares between measured and estimated concentrations but rather the sum of squares between the logarithms. In order to find the real least squares parameters  $C_0$  and  $k$ , we would need to apply *nonlinear regression techniques*.

This procedure can be used to fit a line for any two variables. If statistical inference procedures are to be applied to the line, certain assumptions about the data are necessary.

1. The  $x$  variable is measured without error. In practical situations, the error in  $x$  should be small, compared to the error in the  $y$  variable.
2. The  $y$  variable is distributed normally with a true mean equal to  $A+Bx$  ( $A$  and  $B$  are the true values of the intercept and slope) and with the same variance,  $\sigma^2$ , at all values of  $x$ .

With these assumptions, the confidence intervals for the line can be computed and statistical tests performed on the parameter estimates,  $a$  and  $b$ .

With an estimate of the variance, statistical procedures can be applied to these data if the assumptions stated above hold. Concentration is measured with little error, whereas the spectrometric readings,  $y$ , have error due to instrumental variability, sample processing, and handling (diluting, pipetting, etc.), among other sources of variability. If it is assumed that the variance is the same at each concentration value and that the concentration values are distributed normally, the following statistical procedures can be used.

### CONFIDENCE LIMITS AND TEST OF THE SLOPE

As in the statistical-hypothesis testing procedures described previously in this chapter, a test of the slope versus a hypothetical value can be performed. Also, confidence limits can be placed on the slope.

### CONFIDENCE LIMITS AND TEST OF THE INTERCEPT

Tests for the intercept and confidence limits are analogous to those presented immediately above for the slope. The variance estimate of the intercept is:

$$S_a^2 = S_{y,x}^2 \left( \frac{1}{n} + \frac{\bar{x}^2}{\sum (x_i - \bar{x})^2} \right)$$

In Example 32, the calibration curve, a reasonable test would be to compare the intercept to zero. That is, one discovers whether zero concentration could correspond to a reading of zero. This would be a reasonable assumption if no interfering substances are present and if the optical density versus concentration relationship is a straight line from 0 to the highest concentration tested.

$$t = \frac{|-0.002 - 0|}{\sqrt{0.00028 \cdot (1/4 + 625/500)}} = 0.1132$$

Since 0.1132 is less than the tabled value at the 5% level (see Table 10-10) with 2 DF, it is concluded that the intercept is not significantly different from zero.

A 95% confidence interval for the intercept is:

$$-0.002 \pm 4.3 \sqrt{0.00028 \cdot (1/4 + 625/500)} = -0.002 \pm 0.082$$

These ideas as applied to analytical data are discussed in some detail by Youden.<sup>25</sup>

### Example 32.

Suppose that a value of 0.025 for the slope of the line is reported in an authoritative publication on this assay procedure. It is desired to determine if the slope in the experiment of Example 31 is different from 0.025 (ie,  $H_0: B = 0.025$ ). The estimate of the variance of a slope is:

$$s_b^2 = \frac{s_{y,x}^2}{\sum (x_i - \bar{x})^2}$$

The test is a two-sided  $t$  test with  $n - 2$  DF of the following form:

$$t = \frac{|b - B|}{\sqrt{s_b^2}} = \frac{|0.02429 - 0.025|}{\sqrt{0.000208/500}} = 1.10$$

Since  $t$  is less than the  $t$  value in the tables with 2 DF at the 5% level (see Table 10-10), it is concluded that the observed slope is not significantly different from 0.025. Note that a relatively large difference from 0.025 would be necessary to obtain significance because of the few DF in this test (the test is not very powerful). To increase the DF, more observations would be needed.

A confidence interval for the slope can be constructed in a manner similar to that described for means. A 95% confidence interval is:

$$\begin{aligned} b \pm t \sqrt{s_b^2} &= 0.02429 \pm 4.30 \sqrt{0.000208/500} \\ &= 0.0243 \pm 0.0028 = [0.0215, 0.0271] \end{aligned}$$

### FITTING A LINE WITH AN INTERCEPT OF ZERO

In some situations, it is desirable to force the LS line to have a  $y$  intercept equal to zero.

### CONFIDENCE INTERVAL FOR Y AND X

Many situations arise where a confidence interval for  $y$  at some specified  $x$  is of interest.

Figure 10-17 shows 95% confidence intervals (confidence band) for the line calculated from the data of Figure 10-16. Note the hyperbolic shape, the interval being smallest at  $\bar{x}$  and wider as  $x$  deviates more from its mean value. Using the lower line of the confidence interval to compute the time to 90%

### Example 33.

In the Beer's Law line in Example 32, if it is known that there are no interfering substances and that the relationship is linear throughout the region of concentration being tested, the assumption that the line must pass through the origin is valid. The slope of this line is calculated as:

$$b = \frac{\sum x_i y_i}{\sum x_i^2} = \frac{72.67}{3000} = 0.02422$$

The slope of the line with 0 intercept is very close to that obtained above where the intercept was computed with no constraints on the value of the intercept.

**Example 34.**

The data from Figure 10-16 show the results of a kinetic stability study, in which drug content in tablets is measured as a function of time. The labeled content is 100 mg. The LS line was calculated as  $p = 103.3 \text{ mg} - 0.483 \text{ mg/month } x$ , where  $p$  is tablet potency and  $x$  is time. Note that the intercept is greater than 100 mg because a slight overage is built into the manufacturing process.

**Figure 10-16.** Tablet stability study.

The variance estimate,  $S^2_{y,x}$ , with 3 DF is equal to 0.367. In such stability studies, it often is of interest to predict the time for drug potency to reach 90% of the labeled amount in order to estimate shelf life or an expiration period. Substituting 90 mg for  $p$  (potency) and solving for time  $x$  yields,

$$x = \frac{103.3 \text{ mg} - 90 \text{ mg}}{0.483 \text{ mg/month}} = 27.54 \text{ month}$$

Therefore, the best estimate of the time to 90% potency is 27.54 months.

When establishing an expiration date, a conservative approach would take into account the error in the estimated values. A two-sided confidence interval can be constructed for the true value of  $y$  at a given  $x$ , using:

$$y \pm t \sqrt{S^2_{y,x} \left( \frac{1}{n} + \frac{(x - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right)}$$

where  $y$  is a point on the LS line. The value of  $t$  (3 DF) for a two-sided 95% interval is 3.182. The width of the confidence interval depends on the value of  $x$ , being minimal when  $x = \bar{x}$ . The value of  $y$  when  $x = \bar{x}$  is

$$y = 103.3 \text{ mg} - 0.483 \text{ mg/month} \cdot 12 \text{ month} = 97.5 \text{ mg}$$

The 95% confidence interval when  $x = \bar{x} = 12$  is:

$$97.5 \pm 3.18 \sqrt{0.367 \left( \frac{1}{5} + \frac{0}{360} \right)} = [96.64, 98.36]$$

**Exercise 6.**

Calculate the 95% confidence interval for potency when  $x = 24$  months.

Answer: 90.21 to 93.19.

potency yields a conservative estimate. In the example in Figure 10-17, a reasonable estimate of the expiration date would be 24 months. A one-sided interval (below the line) has been proposed as being more appropriate for stability data, for one usually is concerned with the loss of potency. For a 95% one-sided confidence interval, for 3 DF, the value of  $t$  from Table 10-10 is 2.353. Using this value of  $t$  to calculate the one-sided confidence interval, the one-sided confidence band shown in Figure 10-18 is obtained. For example, when  $x = 12$  (months), the lower limit has the value 96.86 mg.

With this approach, the expiration date would be set at 25.1 months (see Fig 10-18).

A confidence interval can be computed for  $x$  at a given value of  $y$ . This is sometimes known as inverse estimation. In the stability example, interest would be in computing a confidence interval for the time at which 90% of the potency remains. This time was estimated as 27.5 months. The formula for the confidence interval for  $x$  is more complex than that for  $y$ :

**Figure 10-17.** Two-sided confidence interval for stability data.

**Figure 10-18.** One-sided confidence interval for stability study.

**Exercise 7.**

Use the above formula to show that a one-sided lower interval for  $x$  (time) at a 90% potency is 25.1.

Answer: This answer corresponds to the value of time taken from Figure 10-18.

**Example 35.**

The line for the stability data depicted in Figure 10-16 has a slope of  $-0.483$ , with a variance estimate of  $0.367$  with 3 DF.

The value of  $\sum (x_i - \bar{x})^2$  is 360. Another formulation was prepared and tested for stability. Ten sampling times were used for the stability study, and the slope was determined to be  $-0.533$ . The variance estimate (8 DF) was  $0.289$ , and  $\sum (x_i - \bar{x})^2$  was equal to 2565. The test for equality of the slopes (rate of decomposition) is:

$$t = \frac{10.533 - 0.483}{\sqrt{0.310(1/2565 + 1/500)}} = 1.84$$

Since 1.84 is less than the tabled  $t$  value 2.20 for the 5% significance level with 11 DF, 2.20 (3 from one line and 8 from the other), it can be concluded that the slopes of the two lines are not significantly different.

$$\frac{(x - c^2\bar{x}) \pm t [s_{y,x}/b] \sqrt{(1 - c^2)/n + (x - \bar{x})^2 / \sum (x_i - \bar{x})^2}}{1 - c^2}$$

where

$$c^2 = \frac{(t \cdot s)^2}{b^2 \sum (x_i - \bar{x})^2}$$

**COMPARISON OF THE SLOPES OF TWO LINES**

A statistical test may be performed to compare the slopes of two lines, using a  $t$  test. The null hypothesis is:

$$H_0 : B_1 = B_2 \quad \text{or} \quad B_1 - B_2 = 0$$

The  $t$  test compares the difference of the two slopes to the standard error of the difference. The variances of  $y$  for the two lines are assumed to be equal, and the estimates are pooled as in the two-sample  $t$  test:

$$s_{\text{pooled}}^2 = \frac{s_{y,x}^2(n_1 - 2) + s_{y,x}^2(n_2 - 2)}{n_1 + n_2 - 4}$$

A two-sided  $t$  test with  $(n_1 + n_2 - 4)$  DF results in:

$$t = \frac{|b_2 - b_1|}{\sqrt{s_{\text{pooled}}^2 \left( \frac{1}{x_1^2} + \frac{1}{x_2^2} \right)}}$$

where,  $x_1^2$  and  $x_2^2$  are  $\sum (x_i - \bar{x})_1^2$  and  $\sum (x_i - \bar{x})_2^2$ , respectively.

In a biological assay, a common procedure is to determine the relative potency of two or more substances using the *parallel line assay*. In this procedure, the lines from a plot of response versus log dose are forced to be parallel, and the distance between the lines is a measure of the relative potency. Before performing this procedure, a test is made to ensure that the lines are parallel. Nonparallel lines will cross, suggesting that at low doses one product gives a greater response, whereas at higher doses the other product gives the greater response. Figure 10-19<sup>23</sup> illustrates the principle of this assay. The computations are tedious, and the book by Finney<sup>26</sup> should be consulted for those who wish more detail on the statistical treatment of this and other biological assay methods.

**CORRELATION**

*Correlation* is related to, but should not be confused with, linear regression. It is a measure of the linear relationship between two variables but does not prove linearity. In fact, the

**Figure 10-19.** Relative potency estimate using a parallel line assay. Doses shown for  $\log x_1$  and  $\log x_2$  give the same response for Products A and B, respectively. (From Bolton S. *Pharmaceutical Statistics*. New York: Marcel Dekker, 1984; 416, 463.)

**Exercise 8.**

Compute the correlation between  $x$  and  $y$  for  $x = -2, -1, 0, +1, +2$ , for the relationship  $y = x^2$ .  
Answer:  $r = 0$ .

usual formulas for determining the significance of the correlation assume that the variables already are related linearly. The question that is usually posed indirectly when testing the correlation is, can the value of one of the variables be used to predict the value of the second variable? This amounts to testing the slope of the line relating the variables versus 0. If the slope is significantly different from 0, then the variables have a *significant correlation*. Correlation is used when both variables are subject to error. If one variable is not subject to error (fixed), the linear regression approach to establish the relationship of the variables is more appropriate.

**Figure 10-20.** Correlation diagrams (scatter plots).

**Example 36.**

An experiment was performed to examine the relationship of tablet hardness to tablet dissolution. Dissolution was measured as the time (minutes) for 50% of the drug to dissolve in the USP Dissolution Test. Hardness was measured in kilograms. The following results were obtained for 12 tablets:

Hardness/ kg	6.8	5.3	5.8	7.2	6.9	6.0	6.8	8.1	7.5	6.3
Dissolution/ min	18	17	21	26	28	20	25	29	31	18

These data are plotted in Figure 10-21, known as a *scatter plot*. This plot suggests a trend toward slower dissolution as hardness increases.

**Figure 10-21.** Scatter plot of hardness versus dissolution data (Example 36).

In this example,  $r$  is equal to:

$$r = \frac{1585.5 - 233 \cdot 66.7/10}{\sqrt{236.1 \cdot 6.321}} = 0.81$$

The test of the significance of the correlation coefficient shows  $t = 3.94$  with 8 DF. It is concluded that  $r$  is significantly different from 0, and hardness and dissolution are correlated ( $\alpha < 0.05$ ; see Table 10-10;  $t = 2.228$  for significance at  $\alpha = 0.05$ ).

The measure of association is the correlation coefficient,  $r$ .

$$r = \frac{\sum x_i y_i - \sum x_i \sum y_i / n}{\sqrt{\sum (x_i - \bar{x})^2 \cdot \sum (y_i - \bar{y})^2}}$$

The correlation coefficient can vary between +1 and -1. A correlation coefficient of +1 would result if all points fall exactly on a single line with positive slope; this is a perfect positive correlation. Similarly, if all points fall on a line with negative slope,  $r = -1$ , a perfect negative correlation is observed. If  $r = 0$ , the variables are not correlated. These three cases are shown in Figure 10-20.

In real situations, these extreme results are seen rarely, but rather some intermediate value of  $r$  is observed. The statistical question of interest usually is concerned with the significance of the correlation---a test of  $r$  versus 0. One should appreciate, however, that the meaning of the correlation should be considered carefully. For example, if  $n$ , the number of data pairs, is large, correlation coefficients that are very small (practically insignificant) will be deemed statistically significant. Also, data that is not linear but clearly related may show small correlation coefficients.

The test of the correlation coefficient versus 0 is:

$$t = \frac{r\sqrt{n-2}}{\sqrt{1-r^2}}, \quad (\text{DF} = n - 2)$$

**PRINCIPAL COMPONENT ANALYSIS (PCA)**

**Introduction**

PCA is not a statistical method to infer parameters or to test hypotheses. Instead it provides a means to “reduce a complex data set to a lower dimension to reveal the sometimes hidden, simplified structure that often underlie it.”<sup>27</sup> Imagine a data set that forms a cloud in a very high dimensional system e.g., in spectroscopy: each wavelength channel may be regarded as an axis in a coordinate system of many dimensions (about 600). Every spectrum can now be represented as a point in this coordinate system. Spectra of different batches of a given substance or formulation form a cluster in this system. The question we ask to PCA is now whether there is a way to modify the coordinate system (in rotation and stretching) so that as much information as possible can be found along one of the new axes. This new axis is the principal components of the data. The axis orthogonal to the principal component, along which the second most information is located, forms the second axis, and so on.

But what is the direction with most information? In PCA it is the direction along which most of the variance is spread.

**Figure 10-22.** The original data set for the principal component analysis.

**Figure 10-23.** The principal component is found in the centered data.

As an example we will consider the following simple data set, consisting of 15 measurements in a two dimensional space (see Figures 10-22, 10-23, 10-24):

(1.03, -1.12)	(0.99, -1.65)	(0.2, 0.87)	(-0.18, -0.14)	(1.17, -0.74)
(-0.85, 1.35)	(-0.46, 1.52)	(-0.82, 2.82)	(1.81, -1.82)	(1.22, -1.09)
(0.58, -1.57)	(0.41, 0.7)	(-1.73, 3.13)	(-1.61, 2.32)	(1.6, -1.35)

Figure 10-24. The coordinate system is rotated so that the principal-components lie on the axes.

### Conduct of a PCA

Suppose you had a set of  $n$  measurements (15 in our example), each of which consists of  $m$  dimensions (2 in our example). The data is represented in a  $m \times n$  matrix  $A$ : each column of the matrix consists of the  $m$  elements of one measurement. Our sample data looks like this in the matrix representation:

$$A' = \begin{pmatrix} 1.03 & 0.99 & 0.2 & -0.18 & 1.17 & -0.85 & -0.46 & -0.82 \\ -1.12 & -1.65 & 0.87 & -0.14 & -0.74 & 1.35 & 1.52 & 2.82 \\ 1.81 & 1.22 & 0.58 & 0.41 & -1.73 & -1.61 & 1.6 & 1.6 \\ -1.82 & -1.09 & -1.57 & 0.7 & 3.13 & 2.32 & -1.35 & -1.35 \end{pmatrix}$$

The problem is now to rotate the matrix  $A$  in such a way that the covariances between the rotated dimensions vanish. This can be done by means of centralization and normalization.

### Centralization and Normalization

The first step of performing a PCA is centralization of the data: For each dimension of the original data set, the mean in this dimension is subtracted from all data points. We achieve a new data set in which the mean in all dimensions is zero. It is generally a good idea, though by no means mandatory, to normalize the data, too: for each measurement each of its dimensions is divided by the standard deviation of that dimension. This makes the results independent of the units in which the data were measured; after normalization a data set measured in inches will result in the same normalized data as measurements that were taken in millimeters.

In the sample data the mean of the first dimension  $x_1$  in row 1 has a mean of  $\bar{x}_1=0.224$ , the mean of the second row is  $\bar{x}_2=0.215$ . Subtracting these values from our data and dividing by the respective standard deviation results in:

$$A = \begin{pmatrix} 0.72 & 0.68 & -0.02 & -0.36 & 0.84 & -0.95 & -0.61 & -0.93 \\ -0.78 & -1.09 & 0.38 & -0.21 & -0.56 & 0.66 & 0.76 & 1.52 \end{pmatrix}$$

$$\begin{pmatrix} 1.41 & 0.88 & 0.32 & 0.17 & -1.74 & -1.63 & 1.22 \\ -1.19 & -0.76 & -1.04 & 0.28 & 1.70 & 1.23 & -0.91 \end{pmatrix}$$

Now the sum of each row is zero, and the respective standard deviations are equal to 1.

### Calculation of the Covariance Matrix

In the next step we have to calculate the so called covariance matrix of the data. For all the  $m$  dimensions, we calculate all possible covariances between any two dimensions  $d_i, d_j, i \in \{1, \dots, m\}, j \in \{1, \dots, m\}$  (c.f. page). The covariances are arranged in a square  $m \times m$  matrix. Since  $Cov(x, y) = Cov(y, x)$  the covariance matrix is symmetrical. Since  $Cov(x, x) = Var(x)$  the values along the main diagonal are the variances of the data along the respective dimensions.

The covariance matrix of the data in our example is:

$$C = \begin{pmatrix} 1.00 & -0.92 \\ -0.92 & 1.00 \end{pmatrix}$$

As expected, matrix  $C$  is symmetric. The variances on the diagonal equal 1 because we have normalized our data. The negative sign of the covariance tells us that the values of  $x_2$  tend to decrease with increasing  $x_1$ .

Our goal is now to find a transformation of the covariance matrix that makes all the elements off the diagonal equal to zero. Fortunately diagonalization is a common problem in linear algebra, and there exist algorithms to perform this task.

### Calculation of the Eigenvectors and Eigenvalues of the Covariance Matrix

One method to diagonalize a covariance matrix  $C$  involves computing its eigenvectors. An eigenvector of a matrix is a vector different from the null vector that does not change its direction if transformed by the matrix. (The transformation of a vector  $v \rightarrow$  with a Matrix  $A$  is the product  $A \cdot v \rightarrow$ .) Since the direction of the vector remains the same, the transformation is just the same as a stretching of the vector by some value  $\lambda$ . This value is the eigenvalue that corresponds to the eigenvector:  $A \cdot v \rightarrow = \lambda \cdot v \rightarrow$ .

The covariance matrix  $C$  of our sample data has the eigenvectors:

$$\vec{v}_1 = \begin{pmatrix} -0.707 \\ -0.707 \end{pmatrix} \quad \text{and} \quad \vec{v}_2 = \begin{pmatrix} 0.707 \\ 0.707 \end{pmatrix};$$

the corresponding eigenvalues are:

$$\lambda_1 = 1.92 \quad \text{and} \quad \lambda_2 = 0.08.$$

Please notice that the length of both of the eigenvectors is  $\sqrt{2} \cdot 0.707^2 = 1$

Any  $m \times m$  covariance matrix has exactly  $m$  eigenvectors. (Well, since any multiple of an eigenvector is again an eigenvector, there are actually infinitely many of them, but only  $m$  are of unit length, and we count only them.) These  $m$  eigenvectors point in different directions; in fact, they are orthogonal to each other. The  $m$  eigenvectors can be glued together to a matrix  $E$ , and with the covariance matrix  $C$ , we have  $E^{-1}CE = D$  where  $D$  is a diagonal matrix — exactly what we were looking for. It is now fortunate that the eigenvectors are orthogonal, because that makes  $E$  an orthogonal matrix, which can be easily inverted: We just need to transpose it, i.e., change rows to columns.

In our example, we get  $E$  from  $v \rightarrow 1$  and  $v \rightarrow 2$ :

$$E^{-1} = E^T = \begin{pmatrix} -0.707 & 0.707 \\ -0.707 & -0.707 \end{pmatrix}^T = \begin{pmatrix} -0.707 & -0.707 \\ 0.707 & -0.707 \end{pmatrix}$$

Indeed, we find:

$$E \cdot E^T = \begin{pmatrix} -0.707 & 0.707 \\ -0.707 & -0.707 \end{pmatrix} \cdot \begin{pmatrix} -0.707 & -0.707 \\ 0.707 & -0.707 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

It turns out that the elements of matrix  $D$  are the eigenvalues of  $C$ :

$$D = E^{-1}CE = E^TCE = \begin{pmatrix} 0.08 & 0.00 \\ 0.00 & 1.92 \end{pmatrix}$$

The eigenvector with the highest corresponding eigenvalue points in the direction in which most of the variance of the measured data is found, so most of the information in the original data set lies along this direction, and this eigenvector is the principle component of the data. The eigenvalue tells us how much of the total variance in the raw data falls along the principal component; in our example, the principal component accounts for a fraction of 0.96 of the total variance because  $\lambda_1/Vartot=0.96$ . (Because of normalization the variance is 1 in each dimension, so it adds up to  $m$  — or 2 in our example.)

The eigenvector with the second largest eigenvalue points in the direction that is orthogonal to the first eigenvector and contains the most of the remaining variance of the data. This, again, is the direction along which most of the remaining information is located. Because  $\lambda_2/Vartot=0.04$ , the information along the second axis may be considered as neglectable.

### Reduction of the Data

The goal of principal component analysis is to describe as much information of the original raw data with as few dimensions as possible. If we omit the second dimension of the transformed data in our sample, we keep as much as 96% of the original information.

But how do we access the direction of the principal component? Once we have calculated the eigenvectors, this task is easy: all the base vectors of the transformed system are linear combinations of the original dimensions, and the coefficients are just the elements of the corresponding eigenvectors. Thus, in our example, the principal component is  $P1=-0.707x_1+0.707x_2$ , and the data set reduced to one dimension becomes (see Figure 10-25).

Consider the information in an IR spectrum with about 1000 channels. If we are able to express say 80% of the original information in only two or three new dimensions (the principal components), the data become manageable and even visually perceivable.

## DATA TRANSFORMATIONS

Probabilities calculated from statistical analyses are based on assumptions underlying the nature of the data. The typical analyses presented in this chapter often assume normality of data and variance homogeneity. When dealing with means of

**Figure 10-25.** The data set is reduced by omitting the information along PC2.

a sufficiently large sample size, the assumption of normality is not critical. However, small sample sizes and a large deviation from normality can result in a significant violation of the normality assumption. When comparing samples from two or more groups, lack of homogeneity of variance (heteroscedasticity) is an important problem that can result in an unreliable analysis. One way of overcoming these problems is the use of *transformations*. Each data point is transformed, resulting in data that more closely fits the normality and variance homogeneity assumptions.<sup>19</sup>

### Example 37.

The means of two treatment groups are to be compared where it is known that large values are associated with proportionally larger standard deviations. The measurements are 50% dissolution time in minutes (Table 10-44).

**Table 10-44. 50% Dissolution Time for Two Formulations**

	Formulation A	Formulation B
	27	65
	55	60
	33	98
	69	47
	36	57
	39	43
Mean	43.17	61.67
SD	15.75	19.59

A two independent sample  $t$  test (two-sided) comparing the means shows:

$$t = \frac{|43.17 - 61.17|}{19.11\sqrt{1/3}} = 1.75$$

A log transformation results in the data in Table 10-45.

The logarithmic, square root, and arcsine transformations will be presented here as examples of the more popular data transformations.

### LOGARITHMIC (LOG) TRANSFORMATION

This transformation (log to the base 10 or log to the base  $e$ ,  $\ln$ , may be used) is most applicable for skewed data of the form illustrated in Figure 10-26. These data typically show a relatively constant coefficient of variation (CV). That is, the larger the value, the larger is the SD; the SD is proportional to the mean

**Figure 10-26.** Example of a skewed distribution.

**Table 10-45. Log Transformation of Data of Table 10-45**

	Formulation A	Formulation B
	1.431	1.813
	1.740	1.778
	1.519	1.991
	1.839	1.672
	1.556	1.756
	1.591	1.633
Mean	1.613	1.774
SD	0.150	0.126

Neither test is significant at the 5% level, but the log-transformed values in this example result in a test with a lower probability level.

**Exercise 9.**

A bioequivalence study comparing two dosage forms, **A** and **B**, with six subjects in a paired design, resulted in the following ratios of  $AUC_a/AUC_b$ :

1.27, 1.06, 0.90, 1.30, 1.15, 0.96

Calculate the mean, standard deviations and a 95% confidence interval for the data, using the untransformed data and a log transformation. For the log transformation, calculate the antilogs for the lower and upper limit of the confidence interval. Repeat the calculations for the mean and standard deviation of the ratio of  $AUC_a/AUC_b$ . (Note that this is the reciprocal of the data presented above.) What can be said about the confidence intervals for the two kinds of ratios,  $A/B$  and  $B/A$ ?

*Answer:*

transformation	Mean	SD	CI
none	1.107	0.1627	1.107±1.171
log	0.000	0.0646	0.04±0.0678
reciprocal:			
none	0.92	0.1376	[0.938, 1.282]
log	-0.0400	0.0646	

( $SD/x$  is constant). This transformation is applicable to data that meet the above conditions and also are greater than 0; the log of 0 or a negative number is undefined.

This probably is the most common transformation for data in the pharmaceutical sciences. Many physical and biological measurements show larger variability as the size of the measurement increases. This is logical for many types of data. For example, the measurement of a large value, such as the assay of a concentrated solution, may be expected to show considerable variability about its mean (e.g.,  $1000 \pm 50$ , a 5% variability). The assay of a dilute solution, 10, cannot show very large variation, particularly on the low side where zero (0) is the lower limit. If the CV were 5% ( $10 \pm 0.5$ ), a log transformation would be suitable. If the data are skewed (see Fig 10-22) and the CV is constant, a log transformation will tend to normalize the data distribution and equalize the variances.

When data are presented as ratios, a log transformation often is appropriate. Unless the data are extremely variable, the conclusions using the original or transformed data should be

**Exercise 10.**

Compute the mean and standard deviation of the following data before and after applying the square-root transformation ( $\sqrt{x}$ ). Draw a histogram of the original and transformed values. Note the greater symmetry of the transformed data.

	Mean	SD
Original data:	5.625	4.272
Transformed data:	2.00	1.206

similar. The conclusions using the transformed data, however, will be more reliable if the transformation is appropriate.

Care should be taken that the log transformation does not help to improve one assumption while making another less valid. For data that are skewed but have constant variance, the normality assumption may improve while causing problems with the variance homogeneity assumption. Fortunately, the log transformation, when indicated, does not seem to cause such difficult and perplexing problems.

**Example 38.**

Use a normal test to compare the proportion of rats who developed tumors in placebo-control and active-drug groups. In the placebo group, 15 of 100 animals developed tumors, whereas in the drug group, 22 of 100 developed tumors. The arcsines of 0.15 and 0.22 are 22.786 and 27.972, respectively. The normal test statistic  $Z$  is:

$$Z = \frac{|27.972 - 22.786|}{\sqrt{821/100 + 821/100}} = 1.28$$

The proportions are not significantly different.

**Exercise 11.**

Calculate the value of chi-square for the test of these two proportions.

Answer: 1.625. Note that  $X^2 = Z^2$  in this example.

For bioequivalence data, a log transformation of  $AUC$  and  $C_{max}$  is currently recommended.

**SQUARE-ROOT TRANSFORMATION**

A square-root transformation is useful for data where the sample means are proportional or equal to the variances. The transformation will cause the data to have approximately homogeneous variance. This transformation may be used to replace the log transformation when the data consist of small numbers. If the numbers are less than 10 and zeros are present,  $x+1$  may be an appropriate transformation.<sup>28</sup> This transformation, like the log transformation, will tend to normalize distributions skewed to the right (distributions with a relative small number of very large values).

**ARCSINE (INVERSE SINE) TRANSFORMATION**

The arcsine (inverse sine) transformation is used for binomial data or data expressed as percentages or proportions. The

transformation is arcsin $p$ , where  $p$ , the proportion or probability, is expressed as a decimal. The variance of a binomial proportion is  $pq/n$ , where  $p$  is the proportion of successes and  $q$  the proportion of failures in  $n$  binomial observations. If  $p$  varies in different treatment groups, the variance will vary. The arcsine transformation applied to the proportions tends to equalize the variances and normalize the data.<sup>19</sup> The variance of the transformed proportion is  $821/n$  when the transformed data are in degrees. This transformation assumes that all proportions transformed have the same value of  $n$ . If  $n$  is approximately equal for the different groups, the transformation may still be used.

## Molecular Structure, Properties, and States of Matter

Thomas Rades, PhD; Keith C. Gordon, PhD and Kirsten Graeser, PhD

MOLECULAR STRUCTURE AND PROPERTIES 177

STATES OF MATTER 189

### MOLECULAR STRUCTURE AND PROPERTIES

#### INTRODUCTION

Pharmaceuticals are made up of molecules, the properties of which are determined by their shape and electronic structure (i.e., the nature of their bonds). These, in turn, are determined by the constituent atoms and how those atoms are held together (bonded). A striking example of this is the element carbon. This can exist in a variety of forms – including nanotubes and buckyballs – but the two forms that illustrate the difference in bonding most strongly are graphite and diamond. Both are entirely composed of carbon atoms, but one is a hard crystalline material, colorless in its pure form (diamond), the other a black greasy material used in pencils and as a lubricant.

Atoms are built from neutrons, protons, and electrons; the former are much more massive than the electrons. The properties of these subatomic units are given in Table 11-1. The fundamental ideas for atomic structure and bonding were developed in the early part of the twentieth century.

#### HISTORICAL PERSPECTIVE

From the early 1800s it had been known that elements had certain properties in relation to their interaction with other elements. This was expounded in Dalton's atomic theory, which stated that

1. Elements are composed of atoms.
2. The atoms for a specific element are unique to that element.
3. Atoms of one element can combine with atoms of other elements to form compounds. Each compound has a specific ratio of the elements of which it is composed, and these have simple integral ratios.
4. Atoms are not created or destroyed in making compounds – they simply associate in differing ways in differing compounds.

By the late nineteenth century, a number of observations had been made that suggested atoms had an internal structure that had some sort of periodicity based on their mass. The weights of the elements had been measured, and it was found that if they were arranged in order, then there were similarities between each eighth element. For example, neon, helium, and krypton were all inert, and lithium, sodium, and potassium reacted in a ratio of 1:1 with chlorine, whereas magnesium and calcium (also eight different) reacted with chlorine in a 1:2 ratio. The English chemist Newland noted that this behavior was similar to the eighth note in a musical octave, and

these findings thus became called the law of octaves. Around 1869 Mendeleev and Meyer developed what we now call the periodic table, in which all of the elements known at that time were listed. Mendeleev left gaps for gallium, scandium, and germanium – he even went so far as to predict the properties of these elements. These elements were discovered and purified subsequent to Mendeleev; for example, gallium was discovered in 1875, scandium was purified in 1937, and germanium in 1885. These elements had many of the properties Mendeleev had predicted.

This became known as the periodic law, and although it is not the weights of the elements but rather the atomic number that is periodic, Mendeleev's periodic table led to the idea of some sort of repeating internal structure within the atoms.

The key issues in examining the periodic table are:

1. Each element has an atomic number ( $Z$ ), which corresponds to the number of protons in the nucleus and is a multiple of the electronic charge.
2. Atomic weight is the average mass for a particular element versus the current standard, which is based on the mass of the carbon-12 isotope. This was given the atomic weight of 12.
3. Isotopes are forms of the same element that differ in the number of neutrons in the nucleus.

At the beginning of the twentieth century, J. J. Thomson proposed a model of the atom based on the data available at the time. In his model (euphemistically called the plum pudding model) the atom was a mass that contained protons and neutrons with the electrons embedded, rather like raisins in a plum pudding. The key issue of this model was that all of the particles occupied the same volume of space. This model was shattered by a series of experiments conducted by Marsden and Geiger in 1909 and interpreted by Rutherford in 1911. The experiment, which became known as the Rutherford backscattering experiment, took high energy particles and fired them at a thin gold foil. The particles in question were alpha particles. These are comprised of two neutrons and two protons, thus carrying a +2 charge. In the plum pudding model, the alpha particles would be unimpeded in penetrating the gold foil since each gold atom was a small mass with no charge because the electrons and protons were in close proximity. However, Marsden and Geiger observed that the high energy alpha particles scattered back towards them. This was a striking result, which Rutherford described as "...quite the most incredible event that has ever happened to me in my life. It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you."<sup>1</sup>

**Table 11-1. Masses and Charges for the Neutron, Proton and Electron**

Subatomic particle	Mass/kg	Relative mass	Charge/C	Relative charge
Proton	$1.673 \times 10^{-27}$	1837	$1.602 \times 10^{-19}$	1
Neutron	$1.675 \times 10^{-27}$	1839	0	0
Electron	$9.109 \times 10^{-31}$	1	$-1.602 \times 10^{-19}$	-1

Rutherford explained these findings by hypothesizing a new model of the atoms, in which the nucleus contained only protons and neutrons and the electrons were buzzing around this central positively charged core. This model certainly was consistent with the results of the gold foil experiments, but it created some difficulties since an electron orbiting a positive proton would be attracted into the centre. Thus, all atoms would be unstable.

### The Bohr model

In 1913 Bohr developed the first model of modern atomic theory. Bohr was trying to develop a model that would explain the nature of emission spectra from atoms such as hydrogen. In the 1880s Rydberg had recognized that the emission spectrum of hydrogen followed a mathematical relationship, such that the wavelength of light ( $\lambda$ ) observed was related to integers,  $n_1$  and  $n_2, \dots$  and a constant called the Rydberg constant ( $R_\infty$ )

$$\frac{1}{\lambda} = R_\infty \left( \frac{1}{n_1^2} - \frac{1}{n_2^2} \right) \quad (1)$$

For example, in a series of emission lines observed at about 400 nm (the Balmer series), the wavelength of each line corresponded to  $n_1 = 2$  and  $n_2 = 3, 4, 5, 6, 7$ , etc.

In Bohr's model (Figure 11-1) he stated that

1. The electrons were restricted to set orbits at fixed distances from the nucleus. These fixed orbits were labeled by a quantum number  $n$ .
2. An electron in one of these orbits has an energy associated with being in that orbit (also called the energy level).
3. The jumping from one orbit to another corresponds to the electron moving from one orbit to another. The Balmer series occurs because the electron in a series of high orbits falls to the orbit of  $n = 2$ .

Bohr's model received further experimental support in a series of experiments conducted by Franck and Hertz on mercury vapor. They found, as they bombarded mercury with electrons of varying energy, that at discrete energies the electrons lost all of their kinetic energy due to absorption of that energy by the mercury atoms.

The Bohr model had a number of shortcomings, not least the unanswered question of why these orbits exist. An elegant explanation of this came in 1925 when de Broglie postulated that a particle such as an electron in an orbit would have a wave associated with it, such that

$$\lambda = \frac{h}{mu} \quad (2)$$

Where:  $\lambda$  is the wavelength;  $h$  is the Planck constant ( $6.63 \times 10^{-34}$  Js);  $m$  is the mass of the particle; and  $u$  is the velocity of the particle.

**Figure 11-1.** The electronic transition from  $n = 2$  to  $n = 1$  emits a photon matching the energy difference between the orbits.

In the circular orbits proposed by Bohr, standing waves will exist if

$$n\lambda = 2\pi r \quad (3)$$

Where:  $n$  is an integer;  $r$  is the radius of the orbit.

In the Bohr model, the centripetal force of the electron spinning about the nucleus must be balanced by the electron's angular momentum (Figure 11-2) so that:

$$\frac{Ze^2}{4\pi\epsilon_0 r^2} = \frac{mu^2}{r} \quad (4)$$

Where:  $Z$  is the charge on the nucleus (Table 11-1) or atomic number;  $e$  the charge of the electron;  $r$  the radius of the orbit;  $m$  the mass of the electron;  $u$  the electron velocity; and  $\epsilon_0$  the permittivity of free space.

The total energy of the electron in the orbit is a sum of its kinetic energy and potential energy. This is given by:

$$\text{Kinetic energy} = \frac{1}{2} mu^2 = \frac{Ze^2}{8\pi\epsilon_0 r} \quad (5)$$

$$\text{Potential energy} = -\frac{Ze^2}{4\pi\epsilon_0 r} \quad (6)$$

$$\text{Total energy} = \text{Potential} + \text{Kinetic} = -\frac{Ze^2}{8\pi\epsilon_0 r} \quad (7)$$

With these equations the radius of the orbit ( $r$ ) may be solved:

$$r = \frac{n^2 h^2 \epsilon_0}{Z \pi m e^2} = \frac{n^2 a_0}{Z} \quad (8)$$

Bohr calculated that  $a_0 = 0.0529$  nm (this is called the Bohr radius).

The total energy for each orbit is related to the inverse of the radius and thus the inverse of  $n^2$ .

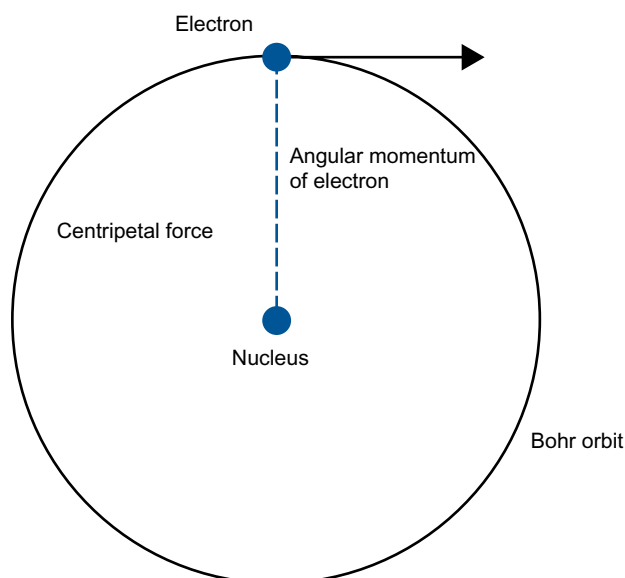

The energy of an orbit is thus:  $E_n \propto \frac{1}{n^2}$  and when the electron jumps from one orbital to another:

$$\Delta E = E_{n_1} - E_{n_2} \propto \left( \frac{1}{n_2^2} - \frac{1}{n_1^2} \right) \quad (9)$$

The wavelength of the transition is related to the energy difference by:

$$\Delta E = \frac{hc}{\lambda} \quad (10)$$

These equations (9 and 10) show that the inverse of the wavelength is related to the inverse of the square of the energy level number, in this case  $n_1$  and  $n_2$  (equation 1). For example,

**Figure 11-2.** Forces acting on the electron in a Bohr model.

the Balmer emission series observed for the hydrogen atom has lines at 656.3, 486.1 and 434.1 nm; these correspond to emission transitions ( $n_2 \rightarrow n_1$ ) of  $3 \rightarrow 2$ ,  $4 \rightarrow 2$  and  $5 \rightarrow 2$ , respectively.

The Bohr model, despite its shortcomings, was effectively the first modern model of atomic theory. The key issue was that the energy was quantized; this was related to the extent of motion of the electron in space (the orbits) and the fact that electrons could jump from one discrete level to another.

## ELECTRONIC CONFIGURATIONS

Now that the existence of internal structure within the atom has been determined, we have to ask the following questions: (1) how are the levels labeled and (2) how do electrons fill the available quantized energy levels. First, these levels are defined by a series of quantum numbers. The principal quantum number  $n$  is referred to as the electron shell. Each shell can contain  $n^2$  orbitals, which have orbital angular momentum quantum numbers  $l$ , where  $l$  can have integer values of 0 to  $n-1$ ; in turn, each value of  $l$  has  $2l+1$  degenerate orbitals to accommodate electrons. Within each degenerate set of orbitals, a further labeling occurs, based on the magnetic quantum number  $m_l$ , which takes integer values from  $-l$  to  $+l$ . For example, for  $n = 1$   $l = 0$  there is only one orbital called the  $s$ , or  $1s$ , orbital. For  $n = 2$   $l = 0$  and 1, there is a  $2s$  orbital ( $n = 2, l = 0$ ) and three  $2p$  orbitals ( $n = 2, l = 1$ , with  $m_l = -1, 0, +1$ ); in total, the  $n = 2$  level has four orbitals (Table 11-2). The orbitals are labeled by letters running  $s, p, d$  and  $f$  for  $l = 0, 1, 2$ , and 3, respectively. These labels originate from the nature of the spectroscopic transitions associated with the orbitals which are sharp, principal, diffuse, and fundamental. The principal quantum number levels may also be labeled with letters as  $K, L, M$  shells for  $n = 1, 2$ , and 3. There is one final quantum number that relates to the electrons filling these orbitals: it is spin, denoted by  $m_s$  and taking values of  $+1/2$  or  $-1/2$ .

The labeling system tells us how the electrons are to be organized in an atom. The second issue is how these levels are filled. The building up or Aufbau principle provides a method of determining how electrons will fill the available orbitals for the ground state (lowest energy) configuration. The filling of orbitals is depicted in Figure 11-3, and a series of electron configurations for the first 25 elements is presented in Table 11-3.

Two additional issues need to be considered in this picture; first, the *Pauli Exclusion Principle* states that no two electrons may have the same four quantum numbers ( $n, l, m_l, m_s$ ) – this limits the occupancy of an orbital to two electrons ( $+1/2$  and  $-1/2$ ) – and secondly, *Hund's rule* states that if degenerate orbitals are filled, the electrons spread themselves out as much as possible. Thus, if three electrons occupy the  $2p$  orbital set, then the configuration is  $2p_x^1 2p_y^1 2p_z^1$  (Figure 11-4).

As atoms interact with each other, the picture becomes somewhat more complex, and indeed, as electrons fill orbitals, they affect the energy of the orbitals and can have a bearing on the configuration. For example, in the case of Cr, in which one might expect a  $4s^2 3d^4$  configuration, this is not observed. Because the half-filling of the  $3d$  subshell imbues additional stabilization, the lowest configuration is  $4s^1 3d^5$ .

**Figure 11-3.** Filling diagram of shells and subshells. Levels are filled by following the dashed path.

The historic observation that reactivity has a periodic nature can be attributed to the electronic structure. For example, if halogens (fluorine, chlorine, bromine, and iodine) are reduced they become anions with a filled shell; that is, they have the electronic configuration of the noble gases. Thus,  $\text{Cl}^-$  and other halogen anions are stable. In a similar fashion, the alkali metals, lithium, sodium, and the like, readily lose an electron to adopt the noble gas closed shell electronic configuration. Thus,  $\text{Li}^+$  and  $\text{Na}^+$  salts may be readily formed, but  $\text{Na}^{2+}$  salts are not observed.

Although the labeling of the orbitals and shells may appear a book-keeping exercise, the quantum numbers have important consequences on the chemical and physical properties of the atoms. Furthermore, the quantum numbers affect the shape and energy of the orbitals; for example,  $s$  orbitals are spherical, but  $p$  and  $d$  orbitals have distinct shapes;  $p$  orbitals appear as dumb-bell shaped (Figure 11-4) and are directed along  $x, y$  or  $z$  axes, depending on the value of  $m_l$ . They also possess sign character; that is, the wavefunction that defines the  $p$  orbital has both a negative and positive part. This is normally depicted by color, as shown in Figure 11-4, using black and white.

## FORMATION OF BONDS

The differing electronic configurations of the atoms mean that they can interact with each other to form larger structures, such as molecules or salts. Depending on the nature of the atoms, there are different interactions possible, at which we will take a closer look in the following section.

**Table 11-2. Properties and Labels Used in Describing Orbitals**

Orbital	Allowed quantum numbers		Number of orbitals
	$l$	$m_l$	
$s$	0	0	1
$p$	1	-1, 0, +1	3
$d$	2	-2, -1, 0, +1, +2	5
$f$	3	-3, -2, -1, 0, +1, +2, +3	7

**Figure 11-4.** Depiction of  $2p$  orbitals.

**Table 11-3. Electronic Configurations for First 25 Elements in Their Ground State**

Atomic number (Z)	Element	n, shell							
			1	2	3		4	3	
			K	L	M	N	M

### Ionic bonds coulomb interactions

One way in which atoms can form larger structures is through ionic bonding. This occurs when two elements combine, whereby one adds and the other one loses electrons to become ionic. For example, Na readily loses an electron to become the cation  $\text{Na}^+$  (note that the electronic configuration of the  $\text{Na}^+$  is a close shell and thus stable), and the chlorine atom can gain an electron to become an anion,  $\text{Cl}^-$  (this also now has a close shell configuration). These two types of ions attract each other because of their opposite charge, and in this way salts are formed. The bonding that holds these ions together is coulombic in nature, and the structure of the salt is a balance of these coulombic forces. In the case of NaCl, these forces balance to create a crystal of many thousands of atoms, in which the ions are held in a face-centered cubic arrangement (Figure 11-5, also see the section on crystalline solids).

### Covalent bonds

Covalent bonds occur when electrons are shared between atoms. If we consider two H atoms interacting as they approach, there is an interplay between the coulomb interactions of the two nuclei and two electrons (which repel) and nuclei and electrons (which attract). At very short distances the coulombic forces of repulsion dominate, and the energy increases. At long distances the atoms cannot sense each other, and there is no interaction; however, at distances of 120 to 200 pm (1 pm =  $10^{-12}$  m), the electrons may be shared between the atoms, and this creates a bond that requires energy to break. The electrons

that started in 1s atomic orbitals now occupy a new orbital, which is called a molecular orbital (MO), which is a result of the interaction between the atomic orbitals. The new molecular orbital forms from the spatial overlap of the 1s orbitals. In general, the strongest overlap occurs where atomic orbitals are similar in energy and occupy the same space as the nuclei approach (Figures 11.6 and 11.7).

**Figure 11-5.** Depiction of a section of the NaCl crystal lattice with the  $\text{Na}^+$  ions as open circles and  $\text{Cl}^-$  as closed circles.

Figure 11-6. Overlap of two 1s orbitals to give a bonding  $\sigma$ -orbital.

Let us take a closer look at these MOs. As the 1s atomic orbitals overlap, two new orbitals are formed. The lower energy orbital is bonding in character and termed a  $\sigma$  MO, but there is also a corresponding antibonding MO, termed  $\sigma^*$  (Figure 11-8). In the case of  $H_2$ , because there are only two electrons, only the bonding  $\sigma$  MO is populated, and a bond is formed. However, if the atom 1s atomic orbitals are filled, as is the case of He ( $1s^2$ ),  $He_2$  cannot form because the bonding interaction of the  $\sigma$  MO is counteracted by the population of the antibonding  $\sigma^*$  MO.

In the case of  $H_2$ , only one type of bond can form because each atom has a  $1s^1$  electron configuration, but for atoms with many electrons, a number of types of molecular orbitals may be generated. If we consider  $N$  atoms, the electron configuration is  $1s^2 2s^2 2p^3$ , with an electron in each of the  $p$  orbitals (Hund's rule). A number of molecular orbitals may be formed by the overlap of the atomic orbitals. If we consider the  $p$ -orbitals, there are two types of bonds that can be formed. For the  $2p_z$  orbitals of each atom, these can overlap directly; the resulting molecular orbital holds electron density between the two  $N$  atoms – the  $\sigma$ -bond. But the  $2p_x$  and  $2p_y$  orbitals can also overlap in a face to face fashion. Each of these is a  $\pi$ -bond, in which electron density is not directly between the atoms but above and below the  $\sigma$ -bond (Figure 11-9). In the case of  $N_2$ , there are two  $\pi$ -bonds that can be formed (Figure 11-10). A  $\sigma$ -bond typically has a bond energy of  $100 \text{ kcal mol}^{-1}$ ; triple bonds (one  $\sigma$ - and two  $\pi$ -bonds) can have bond energies of  $240 \text{ kcal mol}^{-1}$ .

$H_2$  and  $N_2$  are examples of bonding in which both atoms involved are the same, and thus the electrons are shared equally between the nuclei. However, for heteronuclear compounds (in which the atoms differ), the sharing of electrons will not be equal, and the electron density will lie to the more electronegative nucleus. This effect will occur in both  $\sigma$ - and  $\pi$ -bonds, and this results in a polarity in the bonding and dipole moment in the molecule.

The existence of polar bonding has its origin from the electronic configurations of the elements; for example, for halogen gases which are one electron short of a close shell configuration (and the additional stability that is brought by such a configuration), the sharing of electron density in a covalent bond between two differing atoms is not symmetric. The atom with a stronger ability to attract the electron (which can be described

Figure 11-7. Bond length energy diagram, showing the region in which a bond may be said to be formed (gray shading).

Figure 11-8. Depiction of the changes in energy when two 1s orbitals combine to form a  $\sigma$  and  $\sigma^*$  MO.

by the electronegativity of the element) will polarize the bond so that electron density lies closer to a more electronegative atom. This has the important consequence of creating a polar bond which has associated with it a dipole moment (a disparity of charge distribution). Polar bonds and dipole moments are important properties of molecules that have an effect on the bulk properties of the material. The electronegativities for some elements and dipole moments for some simple molecules are shown in Tables 11.4 and 11.5.

### More than one bond from a central atom

Because a large number of pharmaceutically important compounds are carbon-based, we will take a closer look at the carbon atom. Carbon, with its  $2s^2 2p^2$  valence shell, has some interesting properties. Most notable is that carbon readily forms up to four covalent bonds with other carbon atoms and thus, from carbon, many large molecular structures are obtained. It is worth considering how one might draw such structures as a variety of methods are used. The simplest is to draw the carbon atom with four bonds from it arranged at  $90^\circ$ ; this is easy to draw, but it is important to realize (as we will see shortly) that the molecules have a three dimensional shape. This is depicted in Figure 11-11, which shows a model of  $CH_4$ , as well as two ways in which it can be drawn on paper.

A cursory consideration of the electronic structure of the carbon atom might suggest that only two covalent bonds can be formed as the  $2s$  orbitals are filled. However, when atoms approach each other, the atomic orbitals may become reorganized

(Data from Pauling, L. (1932). "The Nature of the Chemical Bond. IV. The Energy of Single Bonds and the Relative Electronegativity of Atoms". *Journal of the American Chemical Society* 54 (9): 3570–3582.)

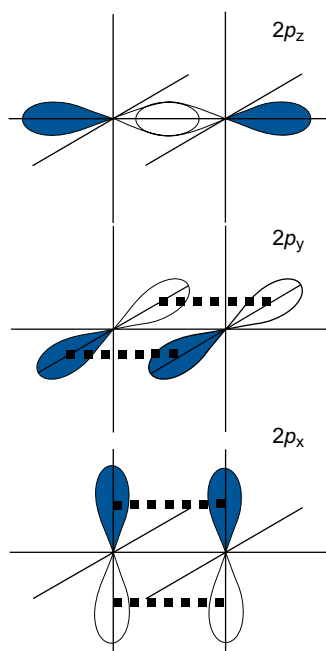

**Figure 11-9.** (a) Overlap of  $2p_x$  orbitals to create a  $\sigma$ -bond, (b) Overlap of  $2p_z$  orbitals to create a  $\sigma$ -bond.

and form hybrid orbitals. These hybrid orbitals may be considered as a combination or average of the atomic orbitals from which they are composed.

One way to think about this is that although the isolated carbon atoms may have a  $2s^2 2p^2$  ground state electronic configuration, as carbon atoms approach each other, this  $2s^2 2p^2$  configuration may not be the energetically favored state. In the case of diamond, which is a network of tetrahedrally bonding carbon atoms (each having four equivalent bonds), the valence shell of the atoms in this bonded state is  $2s^1 2p^3$  and, more importantly, the shapes of the atomic orbitals are not maintained, and new molecular orbitals are generated. These specific orbitals are called  $sp^3$  orbitals, and more generally this type of orbital is called a hybrid orbital because they come from a hybridization of the original atomic orbitals.

The  $sp^3$  orbitals covalently link the carbon atom to other atoms through four  $\sigma$ -bonds. As each of the orbitals is equivalent, they repel each other and adopt a tetrahedral geometry. This sort of bonding is prevalent in alkane structures, that is, hydrocarbons with no double bond character. However, this is not the only way in which the valence electrons of carbon atoms may hybridize. It is possible that only three of the orbitals hybridize (the  $2s$ ,  $2p_x$  and  $2p_y$  for example) to form a  $sp^2$  centre. The three  $sp^2$  orbitals lie in a plane (the  $xy$  plane in this case) with an angle between each bond of  $120^\circ$ . Once again, the hybrid

**Figure 11-10.** The bonding of valence orbitals in  $N_2$ , showing one  $\sigma$ - and two  $\pi$ -bonds.

<sup>1</sup>D (one debye) corresponds to  $1 \text{ D} = 3.344 \times 10^{-30} \text{ cm}$

orbitals are as far apart as is possible. Of course, in such an arrangement there still remains a  $p$  orbital ( $2p_z$ ) at right angles to the  $sp^2$  plane. The result of this hybridization is that the carbon centre may bind through three  $\sigma$ -bonds, but the additional perpendicular  $p$  orbital can form a  $\pi$ -bond. In this way, one of the linkages between two  $sp^2$  carbon atoms will have both a  $\sigma$ - and  $\pi$ -bond to give double bond character. The electrons that occupy the  $\pi$ -bond are often referred to as  $\pi$ -electrons, and they possess a number of interesting electronic properties.

We know that  $sp$  hybridization occurs when only one of the carbon  $2p$  orbitals interacts with the  $2s$  orbital; this creates two  $sp$  hybrid orbitals that form two  $\sigma$ -bonds linear to each other. However, there remain two unused  $p$  orbitals, each of which contains an electron, so that two  $\pi$ -bonds may be formed between adjacent centers. This leads to carbon-carbon triple bonded species, the alkynes.

Hybridization shows how the original atomic orbitals may change shape considerably in forming molecular structures, as depicted in Figure 11-12.

There are a number of important differences between  $\sigma$ - and  $\pi$ -bonds. The most striking of these is that  $\pi$ -bonds are rigid; they cannot rotate because the interaction between adjacent  $2p_z$  orbitals only occurs if these orbitals are in the same plane.

### Resonance and bond delocalization

Benzene and other extended  $sp^2$  bonded structures exhibit some interesting behavior with respect to the  $\pi$ -electrons. The six carbon  $2p_z$  atomic orbitals that create the  $\pi$ -bonds do not have to overlap with only one adjacent  $2p_z$  but can share electron density with both adjacent atomic orbitals. This can happen with each of the  $2p_z$  atomic orbitals in the ring. This delocalization of electron density or extended conjugation imbues the benzene molecule with chemical stability because of a new series of  $\pi$ -molecular orbitals being created. This delocalization of electrons may be depicted by the  $\pi$ -molecular orbitals or by drawing single and double bonds and adding the possibility of resonance structures (Figure 11-13).

**Figure 11-11.** (a) Model of  $CH_4$  and other drawing formats, (b), and (c). Note that (c) implies a three-dimensional structure with the thick wedge sticking out of the page and the dashed wedge sticking into it.

**Figure 11-12.** Depiction of hybrid orbitals (blue) and residual orbitals (black and white).

If one draws the structure of benzene with single and double bonds (the so-called valence bond structure), then the double bonds may be placed in different places. This is not a mere nicety: it actually implies that the structure is more complex than either one of the diagrams. This “resonance” between these two valence bond structures was first suggested by Kekulé in 1872.

Extended  $sp^2$  systems demonstrate this delocalization in their electronic spectra, i.e., their color. The electronic spectrum can show the energy difference between the highest occupied molecular orbital (HOMO, in this case a  $\pi$ -orbital) and the lowest unoccupied MO (LUMO). For ethene, which has a single  $\pi$ -bond, the observed transition from HOMO to LUMO is at 171 nm, which corresponds to a difference in energy between HOMO and LUMO of 166 kcal mol<sup>-1</sup>. For butadiene (which has two  $\pi$ -bonds conjugated) the transition is at 217 nm, corresponding to 131 kcal mol<sup>-1</sup>. For  $\beta$ -carotene, which has 11 conjugated  $\pi$ -bonds, the transition is at 470 nm, corresponding to 60 kcal mol<sup>-1</sup>. These examples demonstrate how the extending conjugation changes the electronic structure because of the delocalization of  $\pi$ -electrons.

Using hybridization and ideas of delocalization, it is easy to rationalize the properties of two of the allotropes of carbon, namely diamond and graphite. In the case of diamond, each carbon atom is  $sp^3$  hybridized and diamond is an extended structure, in which each carbon has four bonds in a tetrahedral arrangement to four other carbon atoms. The rigidity of these  $\sigma$ -bonds creates the hardness diamond has (diamond is the hardest natural material, graded 10 on the scale of mineral hardness, the so-called Mohs scale). In the case of graphite, each carbon atom is  $sp^2$  hybridized, which creates flat structures with delocalized electrons. Thus, the material has very low energy levels between its HOMO and LUMO – hence, it is black in color. Furthermore, graphite readily conducts electricity because of the delocalized  $\pi$ -bonds. The extended structure of graphite is a consequence of the  $2p_z$  orbitals, which bond weakly between sheets of the  $sp^2$  structures; this imbues graphite with its lubricating property.

Extended molecular systems that involve non-carbon atoms can also be bound through  $\sigma$ -bonds, as in C–Cl or  $\pi$ -bonds C=O, and heterocyclic systems, such as pyrrole. Because the electronegativity of atoms such as O, S, Cl, and other non-carbon

**Figure 11-13.** (a) Valence bond resonance structures for benzene, (b) overlap of  $2p$  orbitals that results in delocalized bonds, and (c) resulting molecular orbital delocalized over the entire ring.

atoms differs from that of C, this results in polar bonds in the molecular structure containing these systems.

### Additional types of bonding

A number of other bonding types are recognized that flow from the ideas of covalent and ionic bonding.

The *coordinate covalent bond* arises when overlap between atomic orbitals creates a molecular orbital, but only one of the atoms involved has electrons. This type of bonding is commonly found in amines because the nitrogen adopts an  $sp^3$  configuration, but since it has an extra electron (N is  $2s^2 2p^3$ ) compared to carbon, only three  $\sigma$ -bonds are formed, leaving a lone pair (Figure 11-14). This lone pair can create a bonding interaction if it overlaps with an empty orbital of another species. Boron, which has one less electron than carbon, can bind to an amine (Figure 11-15). As the amine donates electrons, it is termed a Lewis base, and the boron, which accepts electrons, is called a Lewis acid.

Coordinate bonding may also occur in metal complexes in which the binding species, the ligand, donates electrons to form the  $\sigma$ -bonding, and the  $d$  orbitals on the metal play a secondary role in bond formation. *Cis* platinum (Figure 11-16) is probably the best example of a drug that has this bonding characteristic.

### Metalloenes

In 1973 Fischer and Wilkinson shared the Nobel prize in chemistry for the discovery of ferrocene.<sup>2,3</sup> Ferrocene is composed of two cyclopentadienyl rings with an iron in between (Figure 11-17). What is remarkable about ferrocene is that it is very stable; it can be boiled at 249°C. The compound was first reported in 1951 by Kealy and Pauson.<sup>4</sup> Based on the knowledge of bonding that

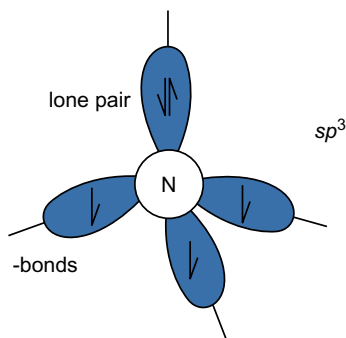

Figure 11-14. The  $sp^3$  hybridized N atom centre.

Figure 11-15. Formation of a coordinate bond between a tertiary amine and trimethylboron.

existed at that time, they proposed a  $\sigma$ -bonded structure. However, they did recognize that such a structure would not have great stability, and thus, that what they had made was unusual. In fact, ferrocene is bonded not by  $\sigma$ -bonds but rather by  $\pi$ -overlap.<sup>5</sup> The cyclopentadienyl ring in ferrocene can be thought of as having five  $sp^2$  hybridized carbon atoms (the ligand formally carries a negative charge). The residual electrons lie in unhybridized  $p$  orbitals. These are able to overlap and bond with the  $3d$  orbitals on the iron (which is formally  $Fe^{2+}$ ), a so-called metallocene or haptic bond. This makes the compound chemically stable, and ferrocene behaves like an aromatic system, such as benzene.

## ISOMERS

One of the critical issues in dealing with molecules is that they can bond to each other in different ways yet have the same formula. For example, the formula  $C_2H_6O$  corresponds to ethanol and dimethyl ether. The former is a colorless liquid, which can be tolerated and metabolized by the human body (having an  $LD_{50}$  in rats of about 7000 mg/kg). The latter is a colorless gas used in aerosol cans and is much more flammable than ethanol and more toxic ( $LD_{50}$  in rats of about 1000 mg/kg). These are examples of structural isomers in which the atoms in the molecule are the same, but they are attached in different ways.

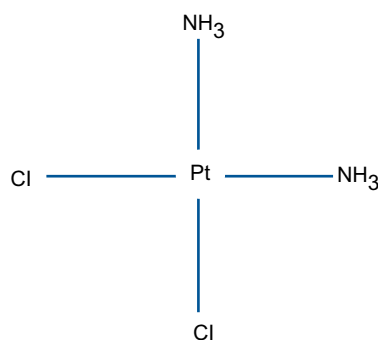

Figure 11-16. *cis* platin. The  $NH_3$  and Cl ligands donate electrons for the four  $\sigma$ -bonds in this structure. The platinum actually adopts a planar structure.

Figure 11-17. (a) The incorrect  $\sigma$ -bonded structure of ferrocene, and (b) the metallocene structure.

However, isomers in molecules can be more subtle than those discussed above. Geometric isomers exist where the bonding attachment between two compounds is the same, but because of the rigidity of the molecule, the atoms are not in identical positions. This is common in alkene systems because the double bond cannot rotate.

In the example shown in Figure 11-18, the compounds have identical attachments, in that each  $sp^2$  carbon is bonded to one hydrogen, one chlorine, and another  $sp^2$  carbon. But in one case the chlorine atoms lie on the same side of the  $\pi$ -bond, and in the other on opposite sides. The same-side isomer is called the *cis* isomer; the opposite-side is the *trans* isomer.

These geometric isomers are a subset of stereoisomers: compounds with the same structure but for which the atoms do not occupy the same arrangement in space. *Cis* and *trans* isomers can also exist if hydrogen bonding is present (see below the example of captopril) or in rings that restrict rotation of the bonds (Figure 11-19).

## Conformations

Open chain compounds can create different conformations because of the ability to rotate the  $\sigma$ -bonds. If we consider  $C_2H_6$ , ethane, the rotation of the central carbon carbon bond may be such that the hydrogen atoms are *staggered* with respect to each other, or *eclipsed*. These are not isomers but different conformers, and they have different energies. They may be depicted using a Newman projection, in which the molecule is viewed down the axis of the bond that is undergoing rotation (Figure 11-20).

The situation is slightly more complicated if there are different substituents attached through the  $\sigma$ -bond of interest. In the case of butane, the central carbon linkage has each carbon atom bonded to two hydrogens and one methyl group (Figure 11-21). The eclipsed and staggered conformations must also consider the interaction of the methyl groups. In this case, when the methyl groups are opposite, the conformation is fully eclipsed and has the highest energy as the repulsive interactions of the methyl groups are maximized. If the methyl groups are opposite hydrogen atoms, the conformation is eclipsed. In the staggered conformations when the methyl groups are a maximum distance apart, the conformation is called *anti*, and when they are staggered but closer, the conformation is called *gauche*.

## Enantiomers

These are molecules that exhibit optical activity, in that they interact with light of different handedness in differing ways. They normally possess the same atoms around a tetrahedral central, such as carbon  $sp^3$ , but they are non-superimposable, and they are called chiral centers (Figure 11-22). These enantiomers are chemically identical but interact with plane polarized light in different ways.

**Figure 11-18.** Depiction of *trans*- and *cis*-1,2-dichloroethene as a molecular model picture and as a chemical structure.

The absolute configuration of a chiral centre (termed *R* and *S* configurations) may be determined by using the following methodology.

1. Allocate substituent priorities.
2. The substituent with the atom bonded to the chiral centre with lightest mass is allocated as priority four, the next heaviest is three, and so on. In the event of equal mass bounded atoms, count down the chain until the substituents differ, and that with the lower mass is allocated the priority number up to four. In the example shown in Figure 11-22, the Cl is priority one; O is priority two; carbon, priority three; and hydrogen, priority four.
3. Rotate the  $sp^3$  centre, such that the lowest priority substituent is pointing away from the viewer, i.e., into the page.
4. Determine if the priority labels are arranged in a clockwise or counter-clockwise fashion with regard to highest priority one to three. A clockwise orientation has an *R* absolute configuration, and a counter clockwise orientation has an *S* configuration (Figure 11-23).

**Figure 11-19.** *Trans* and *cis* isomers of dibromocyclopropane; the strained ring system does not allow for bond rotation.

**Figure 11-20.** Staggered and eclipsed. Depiction of three dimensional models of the staggered and eclipsed conformers of ethane – rotated around into the orientation used in the Newman projection, shown on the right for each conformer.

### Measuring optical activity

The most striking difference between two enantiomers is their interaction with light. In most other respects, such as physical properties like melting and boiling point, they are identical, but in their interaction with light, they may be differentiated.<sup>6</sup> In 1815 Jean-Baptiste Biot noted that some materials could rotate plane polarized light. Subsequent to this, Louis Pasteur discovered that tartrate crystals could be separated by physically picking them out under microscopic examination and

**Figure 11-21.** Depiction of different conformers for butane and the changes in relative energy that occur as the dihedral angle between the methyl groups is altered from 0° (fully eclipsed) to 180° (anti).

Figure 11-22. Models and chemical structures of two enantiomers.

that these two separate types of crystals rotated plane polarized light to the right or to the left in equal amounts. Yet a mixture of the two types of crystals had no effect on the polarization of light. The rotation of plane polarized light is a fairly subtle effect. To understand it, we need to consider the nature of light. We can think of light as an oscillating electromagnetic wave. The wave moves in the  $z$ -direction with the electric field oscillating in the  $xz$  plane and that of the magnetic field in  $yz$ . We need only concern ourselves with the electric field. The question arises, how can a chiral centre affect a plane wave? To answer this, we need to consider the plane wave as being made up of two components; each of these is a vector, but they rotate in a clockwise ( $E_R$ ) and counter-clockwise ( $E_L$ ) direction. When they are aligned (Figure 11-24), the electric field is at a maximum in the  $x$  axis; as they rotate, the strength of the field in the  $x$ -axis diminishes until they oppose each other, and after that the direction of the field changes until both vectors point in the  $-x$  direction. Note that at no time during the precession of the two vectors is there any electric field in the  $y$  axis because they always cancel. What is remarkable about chiral centers is that they interact differently with the  $E_R$  and  $E_L$  vectors. This can be described in a number of ways, but generally it is said that the refractive index ( $n$ ) for each direction differs; that is,  $n_R$  does not equal  $n_L$ . This literally means that the speed of light differs for each of the vectors; in other words, the speed with which  $E_R$  rotates differs from that of  $E_L$ . This is depicted in Figure 11.25, in which the  $E_R$  vectors rotates more slowly than  $E_L$ . The effect of this is that the resulting vector ( $E$ ) has a component in the  $x$ -axis and thus starts to rotate. The longer the path length of the optically active medium, the more it will rotate, and furthermore, as soon as the light exits the medium, the two rotating vectors continue rotating at equal speed, and the light becomes plane polarized again just with a rotation imbued from the interaction with the optical material.

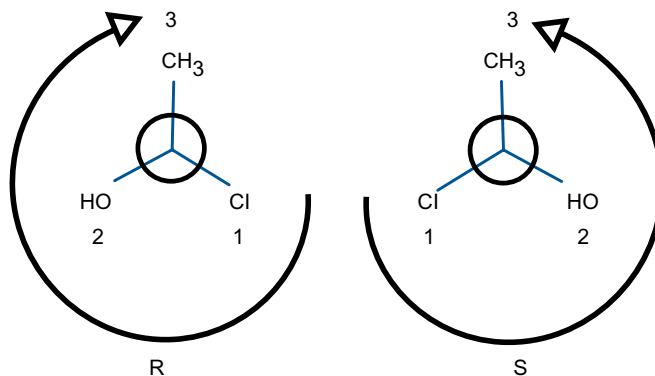

Figure 11-23. The rotated structures from Figure 11-22, showing allocation of substituent priorities and absolute configuration.

The angle of rotation of light ( $\alpha$ ) is given by:

$$\alpha = \frac{1800}{\lambda} (n_L - n_R) \quad (11)$$

Where:  $\alpha$  is called the angle of rotation [degrees per cm of medium];  $\lambda$  is the wavelength of the polarized light [m]; and  $nL$  and  $nR$  the refractive indices of the left and right circularly polarized components of the plane polarized light.

It is very common to use the sodium D line at 589.3 nm for single wavelength determinations of angle of rotation. A more commonly used term is the specific rotation ( $[\alpha]_D^T$ ) which is given by:

$$[\alpha]_D^T = \frac{\alpha}{lc} \quad (12)$$

Where:  $l$  is the pathlength of the solution of optically active material [dm]; and  $c$  the concentration [ $\text{g mL}^{-1}$ ].

Both temperature ( $T$ ) and wavelength ( $\lambda$ ) need to be specified because they have a significant effect on the degree of rotation (see above). This effect is very small. For example, the angle of rotation of the optical material may be  $2.00^\circ$ ; this corresponds to a difference in refractive indices ( $nL - nR$ ) of about  $7 \times 10^{-8}$ .

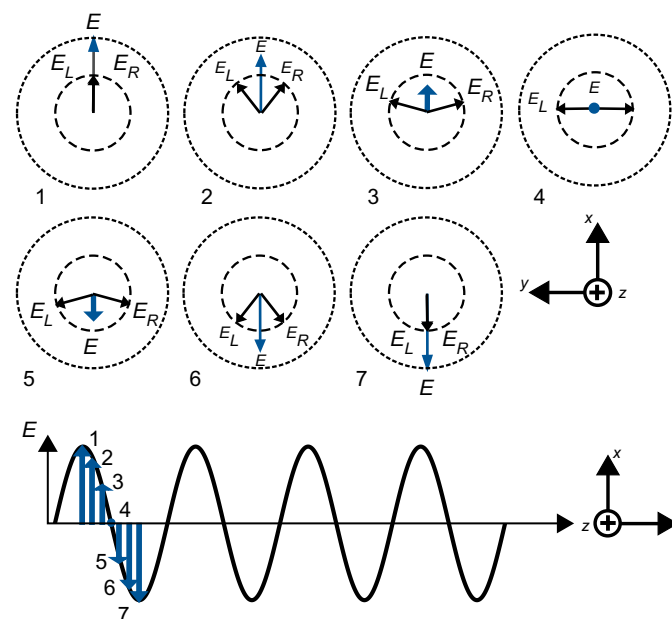

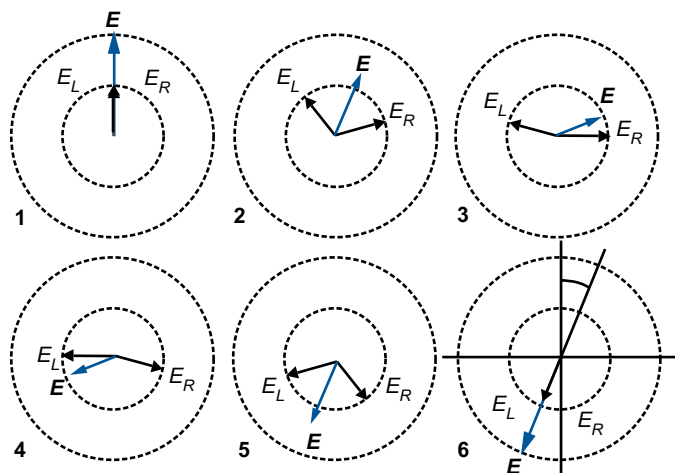

Figure 11-24. Depiction of the plane polarized light wave, made up of left-hand and right-hand rotating circular polarized vectors ( $E_L$  and  $E_R$ ). As the vectors rotate, the amplitude of the resultant electric field goes from a maximum value at 1 through a node at position 4 to a minimum at position 7.

**Figure 11-25.** Depiction of the transmission of plane polarized light through an optically active medium (2-5). As the light passes through the medium, the left-handed circularly polarized light travels more slowly, and so the left and right parts get out of synch. Once the light exits, the medium both parts rotate at the same speed (6), and this results in a restoration of the plane polarized light field, but now it is rotated by an angle ( $\alpha$ ).

In addition to the ability of chiral centers to differentiate the circular components of plane polarized light, molecules with these centers can also absorb circularly polarized light to different extents. That is, the extinction coefficient ( $\epsilon$ ) is such that  $\epsilon_R \neq \epsilon_L$ . This phenomenon is referred to as circular dichroism (CD), and spectra of materials with this effect may be measured. Figure 11-26 shows the absorption, CD, and optical rotatory dispersion (ORD) spectra for a chiral molecule. The sign of the ORD response changes as the wavelength is scanned across the absorption spectrum, and the CD spectrum has a sign, depending on whether  $\epsilon_R > \epsilon_L$  or vice versa. The CD plot is given by the molar ellipticity ( $[\theta]$ ) versus wavelength, where:

$$[\theta] = 3300(\epsilon_L - \epsilon_R) \quad (13)$$

Where:  $[\theta]$  is measured in degrees  $\text{cm}^{-2}$  per decimole and typically has values of approximately 0.08 degrees  $\text{cm}^{-2}$  per decimole.

If the light is rotated to the right, it has a positive value and is said to be dextrorotatory; if it is to the left, it has a negative value and is termed levorotatory. These terms are phenomenological

**Figure 11-26.** The spectral response of an optical absorption and the corresponding ORD and CD curves – note that the direction of the ORD and CD may be reversed depending of which handedness of light interacts with the optical material.

only, and the reasons for the direction of rotation cannot be readily associated with the absolute configuration (*R* or *S*) of the chiral centre.

## MOLECULES WITH MANY CHIRAL CENTERS

It is not uncommon that molecules with more than one chiral centre exist. These molecules are termed diastereoisomers, and they show different physical properties in addition to rotation of plane polarized light. The naming of the molecules will reflect the atom number and the chirality associated with each centre. For example, in Figure 11-27a the molecule, 2,3,4-trihydroxybutanal is shown. The particular configuration depicted is 2*S*, 3*S*, based on the fact that carbon 2 has an *S* configuration and carbon 3 an *S* configuration. A convenient way to depict such structures is to use a method invented by Fischer in 1891. This involves rotating the three dimensional structure so that the carbon-carbon bond containing the two chiral centers is vertical in the plane of the page. The residual carbon backbone is also depicted vertically, although these now point backwards into the page, and the other substituents are coming out of the page. This depiction is then “flattened” to give the so-called Fischer projection. These Fischer projections allow one to conveniently depict multiple chiral centers. The four optical isomers of 2,3,4-trihydroxybutanal may be readily drawn, using Fischer projections (Figure 11-27b). Note that not all are enantiomers of each other, and indeed, if the substituents on the carbon atoms are the same, then *meso* configurations are possible, in which two of the depicted configurations become symmetry equivalent; this occurs in tartaric acid.

## Intermolecular binding forces

Up till now we have focused on the interaction and binding of atoms to molecules. A critical aspect of the behavior of

**Figure 11-27.** (a) Depictions of 2,3,4-trihydroxybutanal from a model structure (left) to the Fischer projection (right); the intermediate structure shows how the molecule is rotated so that the carbon backbone is in the plane of the page or behind it. (b) Fischer projections of 2,3,4-trihydroxybutanal. Absolute configurations are given, the 2*R*, 3*R* and 2*S*, 3*S* are enantiomers; the 2*S*, 3*R* and 2*R*, 3*S* are enantiomers. However, 2*R*, 3*R* and 2*S*, 3*R* are not enantiomers but diastereoisomers.

**Figure 11-28.** Structure of carbamazepine dimer with hydrogen bonding.

pharmaceuticals is the nature of the interactions between molecules, the intermolecular forces. The intermolecular forces may involve specific intermolecular bonds – such as hydrogen bonds – or they may involve weak attractive forces due to the electron distribution in the molecules.

Hydrogen bonding is a very important interaction, in which a pendant hydrogen interacts with the electronegative atom of a neighboring molecule. A good example of this is the anticonvulsant drug carbamazepine (CBZ), which shows distinctive hydrogen bonding between the H atom on the  $\text{NH}_2$  group and the neighboring oxygen of the  $\text{C}=\text{O}$  linkage (Figure 11-28). The energies of these interactions are rather weak, being less than  $10 \text{ kcal mol}^{-1}$ .

Dipole–dipole interactions occur where molecules have an asymmetric distribution of electrons, i.e., they contain polar bonds. These dipoles can align to lower the energy of the assembled molecules (Figure 11-29). Typically the energy of such interactions is weak, being less than  $2 \text{ kcal mol}^{-1}$ .

Dispersion forces occur even in molecules with no discernible dipole. The electrons buzz around the nuclei, and at a particular moment there may be an asymmetric electron distribution

**Figure 11-29.** Molecules with dipole moments (depicted by arrows) align to lower energy through a dipole–dipole interaction.

and a brief temporary dipole. Despite the fleeting nature of these dipoles, an interaction does occur and may be referred to as either dispersion or London forces (after Fritz London who first described them). These are weak, being less than  $1 \text{ kcal mol}^{-1}$ , but they are present in all molecules.

### Visualizing forces

It is now possible and relatively easy to calculate the structures of molecules using computational chemistry<sup>7,8</sup> so the forces that hold the molecules together may be evaluated. Furthermore, it is possible to measure the forces that hold molecules together using spectroscopy. The strength of bonding is associated with the potential energy curve, depicted in Figure 11.7. In the case of a covalent bond, the bond can vibrate at discrete frequencies, and this may be detected by shining light of the appropriate energy at the molecule. For covalent bonds these resonances occur in the infrared region of the electromagnetic spectrum ( $40$  to  $4000 \text{ cm}^{-1}$ ), and most materials may be characterized by their infrared spectra; as the depth and steepness of the bonding interaction decreases, so too does the energy at which the resonances or absorptions occur. In fact, the absorption frequencies may be related to the force constants ( $k$ ,  $\text{N m}^{-1}$ ) that hold the molecule together and the masses (the reduced mass  $\mu$ ,  $\text{kg}$ ) involved in the various vibrations. The upshot of this is that the stronger the bonding, the higher the frequency. If lightweight atoms, e.g., hydrogen, are involved in the vibration, then the frequency of the absorption will be high. The frequency of the absorption ( $\tilde{\nu}$ ,  $\text{cm}^{-1}$ ) is given by

$$\tilde{\nu} = \frac{1}{2\pi c} \sqrt{\frac{k}{\mu}} \quad (14)$$

Where:  $c$  is the speed of light [ $\text{cm s}^{-1}$ ].

Some representative data on bond vibrations are given in Table 11.6.

The use of spectroscopy in understanding structure and bonding is well illustrated by the study of *cis* and *trans* captopril. Captopril, 1-[2(S)-3-mercapto-2-methyl-1-oxopropyl]-L-proline, is a drug for treatment of hypertension and heart failure. It exists in an equilibrium between *cis* and *trans* forms, with the *trans* form being the active form. The ratio of *trans*:*cis* is approximately 6:1 at room temperature in solution. The *trans* and *cis* isomers are created by the two conformers that exist about rotation around a  $\text{C}-\text{N}$  bond, with the *trans* form being locked by a hydrogen bond (Figure 11-30).

The captopril structure contains two carbonyl bonds ( $\text{C}=\text{O}$ ), and the frequencies of vibrations for these is distinct, depending on the isomer formed. This is because the *trans* isomer is hydrogen bonded, which shifts the  $\text{C}=\text{O}$  vibration from  $1637 \text{ cm}^{-1}$  down to  $1591 \text{ cm}^{-1}$ . Wang *et al.*,<sup>9</sup> studied this drug in the solid

**Table 11-6. Vibrational Spectroscopy and Bonding Parameters for Selected Bond Types**

Bond type	$\tilde{\nu}/\text{cm}^{-1}$	$k/\text{Nm}^{-1}$	$\mu/\text{kg}$	Bond strength/ $\text{kcal mol}^{-1}$
C–C	1130	450	$9.96 \times 10^{-27}$	90 <sup>a</sup>
C=C	1600	900	$9.96 \times 10^{-27}$	170
C C	1990	1400	$9.96 \times 10^{-27}$	234
C–H	2880	450	$1.53 \times 10^{-27}$	

<sup>a</sup>Estimated from the bond enthalpy for  $\text{C}_2\text{H}_6$ ,  $\text{C}_2\text{H}_4$  and  $\text{C}_2\text{H}_2$  respectively.

state and were able to determine the energetics between the two isomers.

For intramolecular interactions, the interactions are 10 to 20 times weaker than covalent bonds; thus, the interaction has very low energy infrared absorptions. These occur in the terahertz region of the spectrum (where  $\tilde{\nu} < 100 \text{ cm}^{-1}$ ). Different polymorphs of a drug (see the section on polymorphism) will have very similar infrared spectra because the bonding interactions of the molecule that make up the pharmaceutical are virtually unchanged (unless there is hydrogen bonding), but the terahertz (THz) region of the electromagnetic spectrum is distinctive for each polymorph because the intermolecular forces differ between polymorphs. Carbamazepine shows a number of polymorphs, and these have been characterized using THz spectroscopy.<sup>10</sup> The spectra of the form III polymorph shows distinctive bands at 31, 44 and  $52 \text{ cm}^{-1}$  (Figure 11-31), whereas polymorph I has a band at  $41 \text{ cm}^{-1}$ .

## STATES OF MATTER

### INTRODUCTION

In everyday life we usually consider three states of matter: the solid state (solids), the liquid state (liquids), and the gaseous state (gases). For example, water can be differentiated into the three states: ice, liquid water, and water vapor, and at a given pressure (usually normal or atmospheric pressure, 1.013 bar) it is the temperature that decides in which state water is present; at normal pressure ice melts at  $0^\circ\text{C}$  and boils at  $100^\circ\text{C}$ . What we are observing at these temperatures are phase transitions from the solid state to the liquid state (melting) and from the liquid

**Figure 11-31.** THz spectra of carbamazepine: Upper trace polymorph III, lower trace polymorph I.

state to the gaseous state (boiling). If we lower the temperature of water vapor below  $100^\circ\text{C}$ , we observe condensation (gas to liquid transition) and if we further lower the temperature below  $0^\circ\text{C}$ , we observe freezing of the liquid water to ice.

In this section we will describe the different states of matter (including a few “exotic states”, which nevertheless do play a role in some pharmaceutical applications) and highlight their most important characteristics. We will also discuss how we can describe the different states of matter in phase diagrams and identify a few experimental techniques that can be used to determine the characteristics of a given state of matter. Because most drugs and dosage forms used in the pharmaceutical field are solid at room temperature, we will discuss the solid state in a little more detail than the other states of matter.

### SOLIDS, LIQUIDS AND GASES – A QUESTION OF INTERMOLECULAR FORCES

As outlined above, when we think about states of matter, we usually think of them in terms of solids, liquids, and gases. These distinctions are based on the interactions between the molecules (or in some cases atoms or ions) of the matter in question. Since in the pharmaceutical field we are most often dealing with molecules, the discussions below will mainly consider molecules as the components forming the various states of matter, and the reader should keep in mind that in many cases the word “molecule” could be exchanged for the words “atom” or “ion”.

In the solid state of a drug, the drug molecules are held together by comparatively strong interactions, which do not allow the molecules to change their position but only to vibrate around a fixed position. These intermolecular interactions result in some important properties of solids. A given mass of a solid at a given temperature and pressure has a defined volume and keeps its shape, if no external forces (such as in milling, agglomeration or tableting operations) are acting on the solid material. Similarly, a given mass of a liquid has a defined volume at a given temperature and pressure (like solids, liquids are practically incompressible), but in contrast to a solid, its shape can vary and will take on the shape of the container it is placed in. The reasons for this are again the interactions between the molecules in the liquid state. These are still considerably strong, but the kinetic energy of the molecules is now sufficiently high to allow the molecules to change their positions (not only to vibrate around a fixed position) and to move relative to each other by diffusion or convection. This is also the reason why the density of a liquid is usually lower than that of a solid (with the most important liquid in the pharmaceutical field being the exception: water has its highest density at normal pressure at  $4^\circ\text{C}$ , i.e., in the liquid state). A gas, on the other hand, does not have a defined shape or volume (in fact, gas molecules will fully occupy each volume available to them) and thus has a very low density, depending on the volume it occupies. This is due to the fact that intermolecular interactions in real gases are very weak and, in fact, are considered zero for an ideal gas. Since interactions between the molecules (or between atoms or ions) are very strong or strong in solids and liquids, these two states of matter are also summarized as condensed matter. In contrast, since the molecules in the liquid and gas state are able to change their positions, these two states of matter are summarized as fluid matter.

### CHANGES BETWEEN THE STATES OF MATTER

Upon the heating (at constant pressure), for example, of a solid drug material (usually in a crystalline form, see below), the solid transforms into a liquid (melt) and further into a gas (if it is not chemically degraded in the heating process). Heat ( $Q$ , a form of energy, Unit: Joules, J) is transferred into the material during the heating process. This leads to an increase in the enthalpy  $\Delta H$  [J] of the material.

$$Q = \Delta H \quad (15)$$

It follows that a gas has a higher enthalpy than a liquid and a liquid has a higher enthalpy than a solid for a given material. At the same time, the number of ways in which the molecules can be arranged with respect to each other also increases. This is known as the entropy  $S$  [ $\text{J K}^{-1}$ ] of the system and is often described as the “disorder” of the system. It follows that upon a state change due to heating, both the enthalpy and the entropy of the material increase. Since every system has a tendency to exist in the lowest enthalpy and the highest entropy form, it depends on the temperature  $T$  of a given system (here considered solely as the material in question) in which form it is present. This can be summarized in form of the equation:

$$\Delta G = \Delta H - T\Delta S \quad (16)$$

Where:  $\Delta G$  [J] is the free energy of the system.

If a liquid is heated, the temperature of the liquid will increase. How much the temperature increases as a function of the added heat energy depends on the heat capacity of the liquid. The heat capacity,  $C$ , can be defined as the amount of heat energy,  $Q$ , required to change the temperature,  $T$ , of a given material by a given temperature interval  $\Delta T$  (measured in Kelvin, K):

$$C = Q / \Delta T \quad (17)$$

In this form  $C$  is an extensive variable, i.e., its value will depend on the mass of the material. To convert the heat capacity into an intensive variable, i.e., a variable whose value is independent of the mass of the material (measured in kg) or its amount (measured in mol), the heat capacity is usually expressed as either specific heat capacity,  $C_{sp}$  [ $\text{J K}^{-1}\text{kg}^{-1}$ ], or molar heat capacity,  $C_{mol}$  [ $\text{J K}^{-1}\text{mol}^{-1}$ ].

In any case, the result of heating the liquid for a given period of time is that the temperature of the liquid increases. However, when the liquid starts to boil, i.e., the state of the material changes from the liquid to the gaseous (vapor) state, we observe that the temperature of the material stays constant during this state transition. This temperature is the boiling point ( $T_b$  in Figure 11-32). Similarly, when a solid melts, the temperature of the material stays constant during this state transition (melting point,  $T_m$  in Figure 11-32). This is because when a substance boils, the liquid and vapor state are in equilibrium, and when a substance melts, the solid and liquid state are in equilibrium. Any heat that is applied to the system will be used to bring about the state transition until the liquid (or solid) has completely gone into the vapor state (or liquid state). Only then does the temperature rise further. The energy used for boiling the liquid is known as latent heat of vaporization (or boiling) and in the case of condensation, the energy released is known as latent heat of condensation. The amount of energy used in the vaporization process is identical to the heat of condensation released in the condensation process since these processes are reversible.

**Figure 11-32.** Heating curve of a material undergoing a state transition from solid to liquid and from liquid to gas. Note that the temperature stays constant during the state transitions.

During a phase transition the heat capacity of the material is infinitely high (all heat energy is used to bring about the state change), and such transitions are termed first-order phase transitions. The same holds true for the state transition from a solid to a liquid (latent heat of melting) or from a liquid to a solid (latent heat of freezing). In melting and boiling processes, the change is endothermic (the system absorbs energy), whereas in freezing and condensation processes, the change is exothermic (the system releases energy). At the melting and boiling point, the change in Gibbs free energy ( $\Delta G$ ) is zero. However, as discussed above, the enthalpy and the entropy of the material are increasing (i.e.,  $\Delta H$  and  $\Delta S$  have positive values). Taking into account the relationship between the free energy and the enthalpy and entropy of the systems (see equation 16,  $\Delta G = \Delta H - T\Delta S$ , note the minus sign between  $\Delta H$  and  $\Delta S$ ), we can conclude that a phase transition occurs when the free energy of the gas (or liquid) is lower than that of the liquid (or solid) at a given temperature for the material in question. At a given pressure, the temperature that denotes the boiling or melting point is the temperature at which  $\Delta G$  for this process is zero, i.e., at exactly the boiling or melting point (for a given pressure), the two states can coexist.

So far we have considered the temperature as being decisive for a given material in what state of matter it is present. However, to fully describe a given state of matter, we require a second intensive variable, pressure,  $p$ . If we plot temperature on the  $x$ -axis and pressure on the  $y$ -axis of a coordinate system, and determine the state of a given material at any temperature–pressure combination, we obtain the phase diagram of the material in question. Let us again consider water.

Figure 11-33 shows the (partial) phase diagram of water as a function of pressure and temperature. We can differentiate three areas, those of solid water (ice), liquid water (water), and water vapor. To fully describe the state of water in each of these areas, we need to specify the temperature and pressure at which the material is present. For example, water exists in the liquid state at both temperature–pressure combinations indicated in the diagram by the symbol  $\blacktriangle$  and, in fact, at an infinite possibility of other temperature–pressure combinations in the region of liquid water. The same holds true for the areas of solid water and water vapor. The different areas of the phase diagram are separated by boundary lines, known as the phase boundaries. At combinations of pressure and temperature which lie on these phase boundaries, two states of water exist in equilibrium. The curves a, b, and c in Figure 11-33 are known as the sublimation (or re-sublimation) curve (solid and gas in equilibrium), the melting (or freezing) curve (solid and liquid in equilibrium), and the boiling (or condensation) curve (liquid and gas in equilibrium). Note the orientation of the melting curve b in Figure 11-33: its slope is negative; that is, at constant temperature ice can melt if the pressure is increased (this is the principle of ice-skating). Most other compounds behave oppositely; they can solidify under pressure, so their melting curves will have a positive slope. This is termed the anomaly of water and also explains the observation that ice has a lower density than liquid water.

To determine, for instance, the position of the boiling curve in the phase diagram of water, we have to determine the vapor pressure of water at various temperatures. If we place a liquid in a vacuum at a temperature  $T$ , some of the molecules of the liquid will leave the liquid phase and will go into the free space above the liquid until an equilibrium is reached, in which the same number of molecules from the free space above the liquid will go into the liquid as are leaving the liquid (this is a dynamic equilibrium). As long as there is still liquid water left (note: it is not important how much water is left), the resulting pressure is known as the vapor pressure of the liquid, and will constitute a point on the boiling curve at the temperature  $T$ . Figure 11-34 shows the temperature dependence of the vapor pressure of water. In a closed system the vapor pressure increases with increasing temperature. This is true not only for water but for

**Figure 11-33.** Partial phase diagram of water. The curves a, b, and c are the sublimation (or re-sublimation) curve (solid and gas in equilibrium), the melting (or freezing) curve (solid and liquid in equilibrium), and the boiling (or condensation) curve (liquid and gas in equilibrium), respectively. TP: triple point, CP: Critical point, SCF: region in which water exists as supercritical fluid. shows two different pressure and temperature combinations at which water exists in the fluid state. Note that the temperature and pressure axes are not linear.

all substances, since an increase in temperature increases the likelihood for molecules to leave the condensed phase, as the increased kinetic energy of the molecules counteracts the attractive forces holding the molecules together in the condensed phase. Different liquids have different vapor pressures at given temperatures. A liquid will boil at a temperature at which its vapor pressure equals the pressure exerted onto the liquid by the surrounding pressure of the environment. Taking again the example of water, at 100°C the vapor pressure of water is 101.3 kPa, so under normal (sea level) condition of atmospheric pressure, water will boil. At 20°C, however, the vapor pressure of water is only 2.3 kPa, so it will not boil under these conditions. An interesting consequence of this is that water, for example, on a high mountain (where the atmospheric pressure is lower than at sea level) will boil at a lower temperature than 100°C.

At this point it let us make a quick stop and consider the question why drying (for example, of wet granules, to take a pharmaceutical example) occurs even if the temperature is far below 100°C at normal atmospheric conditions (i.e., below the boiling point of water). To understand this, we have to differentiate between the processes of boiling and evaporation. We have seen that, in a closed system, molecules from the liquid will leave the liquid phase until the equilibrium vapor pressure for the given temperature is reached. However, in an open system (for example, wet granules in a laboratory) some molecules from the surface of the liquid will have a sufficiently high kinetic energy to leave the liquid and are then transported away. This process takes place at any temperature also below the boiling point of the liquid, and its rate depends on factors such as

**Figure 11-34.** Temperature dependence of the vapor pressure of water.

- the surface area between the liquid and the air (evaporation is a surface phenomenon)
- the temperature of the liquid (the number of molecules with a sufficiently high kinetic energy to leave the liquid phase increases with increasing temperature)
- the air above the liquid (if there is an air stream, transport of the molecules away from the liquid is facilitated)
- the humidity of the air above the liquid (evaporation of water molecules from a liquid will be faster if the air is dryer), as well as other factors.

It should be noted that evaporation takes place from the surface of a liquid, whereas boiling takes place also in the liquid (that is the reason why water vapor bubbles are formed in boiling water).

We have seen how we can determine the boiling curve for a liquid to construct the phase diagram of a substance. Similarly, we can determine the sublimation curve, although experimentally this is more difficult due to the much lower vapor pressure of solids. The melting curve can be determined by thermo-analytical methods. This is usually done by determining the cooling curve of a material at various pressures as a function of time.

As we have already discussed for the boiling of a liquid, during the phase transition from the liquid to the solid, the temperature does not decrease. If we are heating a liquid in a closed container, the vapor pressure will also increase. However, since the space above the liquid is limited, further heating will increase the number of molecules in the space above the liquid, and thus the density of the gas phase will increase. At a certain, material-dependent temperature, the density of the gas phase will be equal to the density of the liquid, so that there will no longer be a phase boundary between the liquid and gas phase, and both are now indistinguishable (this is called a supercritical fluid). The temperature (critical temperature) and pressure (critical pressure) combination at which a supercritical fluid is formed is known as the critical point (CP in Figure 11-33). At temperatures above the critical temperature a liquid can no longer exist or be formed by increasing the pressure, and thus the critical point marks the end of the boiling curve. The region in the phase diagram at temperatures and pressures higher than that of the critical temperature is known as the supercritical fluid region (SCF). For water, the critical point is at approximately 374°C and 22.1 MPa, and for CO<sub>2</sub> the critical point is at approx. 31.1°C and 7.38 kPa. Supercritical fluids have gained pharmaceutical importance since this state of matter combines properties of gases, such as low viscosity and high diffusivity, with properties of liquids, such as a high capacity to dissolve other substances.

From Figure 11-33 we can see another critical point in the phase diagram, known as the triple point (TP in Figure 11-33). At this combination of temperature and pressure, all three states of water coexist in a dynamic equilibrium. For water the triple point is at 0.01°C and 0.61 kPa. The triple point also marks the lowest temperature at which a liquid can exist, so the temperature range for liquids to exist is between the triple

point and the critical point of the material. Similarly, sublimation and resublimation can only occur at temperatures below the triple point (see sublimation curve in Figure 11-33). Since sublimation (in the same way as boiling) occurs when the vapor pressure of the solid material equals that of the gas phase, sublimation should only occur under atmospheric conditions if the pressure at the triple point of the system is above 101.3 kPa (1 atm). For example, solid  $\text{CO}_2$  (dry ice) sublimates at atmospheric pressure at  $-78.5^\circ\text{C}$  since its triple point is at  $-56.4^\circ\text{C}$  and 517 kPa. For the same reason, in the pharmaceutically relevant process of freeze drying (which at least in the primary drying phase is based on the sublimation of water), an aqueous solution or dispersion is initially frozen (below the temperature of the triple point of water) and is then subjected to a reduced pressure (below the pressure of the triple point of water). In the earlier mentioned real-life example, however, we also observe that wet clothes on a washing line (i.e., at atmospheric pressure) at or below freezing temperature (so the water in the clothes is frozen to ice) eventually will be dry. We thus observe sublimation also for substances for which the triple point has a pressure below 1 atm. The reason for this is that in an open system like that on a washing line, the partial pressure (see below) of the solid does not attain the vapor pressure of the material at the triple point. The situation is similar to the one discussed above for liquids in an open and closed system (evaporation versus boiling).

## PHASES

In the examples discussed above, we have talked about states of matter, and we have considered the solid, liquid, and gaseous state. In the phase diagrams we have seen that these states of matter constitute different phases of a material. It is, however, possible and, in fact, very likely that a solid material can in its own right exist in different phases. We can define a phase as a volume element of a system, separated from other volume elements of the system by a phase boundary. The physical properties within the phase do not show abrupt changes, which means that the phase is physically homogeneous. If two phases coexist, such as at the phase boundaries in the phase diagram, the physical properties between the phases, however, are different. For example, at normal pressure and  $0^\circ\text{C}$ , the density of ice is approximately  $920\text{ kg/m}^3$ ; and that of liquid water is approximately  $999.8\text{ kg/m}^3$ . Note that water makes an exception from most other materials, in that its higher density is as a liquid rather than as a solid at the equilibrium of liquid water and ice.

Let us again consider the phase diagram of water, but now have a look at a larger temperature and pressure range (Figure 11-35). We can see that different forms of ice can exist (termed ice I to ice VII). These all constitute a solid state of water but are all different in the molecular arrangement of the water molecules. They therefore have different physical properties, and these change abruptly at the phase boundary. These different solid forms of water thus constitute different water phases. While these different ice phases may not be relevant in pharmaceutical applications, they nevertheless show that molecules in the solid state can be arranged in different ways and thus give rise to the existence of different solid phases. At any given temperature and pressure, only one such solid form can be thermodynamically stable, but other forms may exist as metastable forms for considerable times at conditions where another form is the stable form. This will become important when we are considering crystalline solids in more detail later in this chapter.

The phase diagram of water in Figure 11-35 also shows that for a given chemical compound, more than one triple point can exist. In fact, in Figure 11-35 we can see six other temperature–pressure combinations at which three phases coexist in equilibrium. However, unlike the triple point between ice I, water, and water vapor, these are conditions in which either two solid phases and liquid water or three solid phases coexist.

**Figure 11-35.** Phase diagram of water, showing several solid forms of ice (Ice I – VII). Note that the temperature is given in Kelvin [K], and the pressure axis is shown in logarithmic form.

Earlier, we have stated that to fully describe a system in one of the areas of the phase diagram, we have to specify both its pressure and temperature. Pressure and temperature are known as the degrees of freedom of the system. The number of degrees of freedom can be defined as the least number of intensive variables (i.e., of variables that do not depend on the amount of material or its mass) of the system that are independent of other variables of the system and that can be changed without changing the number of phases that are coexisting. For any sample within an area of the phase diagram (e.g., in the area of liquid water or in the area of ice III, etc.), we can freely change pressure and temperature (until we reach a phase boundary) without changing the number of phases present (one phase).

If two phases coexist (such as for systems on the phase boundaries), the situation is different. If we change the pressure of the system, we cannot freely change the temperature but have to change the temperature to a specific value, if we don't want to change the number of phases. In the case of two phases coexisting, the system thus only has one degree of freedom. This is important, for example, in moist heat sterilization, such as sterilization in an autoclave. To have both liquid water and water vapor present in the sterilization process (this is most effective in killing microorganisms) at 106 kPa, the temperature has to be  $121^\circ\text{C}$  (if no air is present in the autoclave). If we raise the temperature to  $134^\circ\text{C}$ , we have to increase the pressure to 312 kPa to maintain the coexistence of liquid water and water vapor.

Finally, if we are at a triple point in the phase diagram, i.e., three phases are coexisting, we cannot change either pressure or temperature without getting a change in the number of phases, which means that here the system has zero degrees of freedom.

From these considerations, Gibbs' phase rule can be formulated as follows:

$$F = 3 - P \quad (18)$$

Where:  $F$  is the number of degrees of freedom; and  $P$  is the number of phases coexisting (one, two, or three).

So far, we have only considered phase diagrams of a single chemical component (e.g.,  $H_2O$ ). It is, however, also possible to have a single phase system which consists of more than one component. Let us now consider, for example, a salt solution. Here we have a single phase system (the salt molecules are dissolved as sodium and chloride ions in water, and the system is homogeneous). However, in this case, we can vary not only pressure and temperature without getting a phase change but also the salt concentration until we get a saturated solution of the salt in water. In this case, we have three independent variables that can be changed without changing the number of phases coexisting. Of course, as with pressure and temperature changes, this can only be done within limits, i.e., until we reach a boundary line in the phase diagram. If we, for example, increase the salt concentration above the saturation solubility of NaCl at the given pressure and temperature, the excess salt will form a second, solid phase, coexisting with the salt solution phase.

In the example of a salt solution, we have to consider two chemical entities,  $H_2O$  and the salt (e.g., NaCl). These chemical entities must be independent of each other. So even though NaCl is dissociating into  $Na^+$  and  $Cl^-$  ions, in the current discussion these do not constitute two chemical entities because the  $Na^+$  concentration is not independent of the  $Cl^-$  concentration. The same holds true, for example, for  $H_3O^+$  and  $OH^-$  ions from the auto-protolysis of water. The independent chemical entities of a system are called components and are defined as the least number of chemically independent entities required to describe the composition of the system. A little tongue-in-cheek, we might say that the phase is physically defined, whereas the component is chemically defined (however, note that chemically a  $Na^+$  ion is very different to a  $Cl^-$  ion). For multicomponent systems we can formulate Gibbs' phase law as follows:

$$F = C - P + 2 \quad (19)$$

Where:  $C$  represents the number of components.

For the examples of a salt solution,  $F = 2 - 1 + 2 = 3$ . We can see pressure, temperature, and salt concentration here as the degrees of freedom of the system. In most cases, phase diagrams of two component systems are given at a constant pressure, usually normal atmospheric pressure (i.e., one degree of freedom is used up). In this case we can express Gibbs' phase law for a two component system as  $F^* = 3 - P$ , with  $F^*$  being the remaining degrees of freedom of the system. An example of such a phase diagram will be discussed later (see the section on eutectics).

## CRYSTALLINE SOLIDS

The solid state of matter is perhaps the most important state in pharmaceuticals since the starting material for most formulations and the majority of orally administered dosage forms are in a solid form (most often as tablets or as powders, pellets, or granules in hard gelatine capsules). We will thus consider this state of matter in some detail, whereas the properties of other states of matter will be discussed more briefly since important properties of these are explored elsewhere in this book.

Crystals are defined by a high degree of order, with a three-dimensional periodicity in position for atoms or ions and, additionally, with configurational periodicity for molecules that form the crystal. Most solid forms of drugs are used in the crystalline state, and most pharmaceutically relevant crystals are formed by organic molecules. Not all solids, however, are crystalline (this will be discussed in more detail in the section on amorphous solids).

The reason for the high degree of order of crystals lies in the strong interactions between the atoms, ions, or molecules that form the crystal. As we have seen earlier, in the case of diamond, carbon atoms form a periodic three dimensional tetrahedral network of covalently bonded  $sp^3$  hybridized carbon

atoms. Diamond is thus an example of a crystal formed by atoms through covalent bonds. Most inorganic materials form ionic crystals. A pharmaceutically relevant example is NaCl. Here the crystal is formed by sodium and chloride ions, held together by ionic interactions. In the case of NaCl, each sodium ion is surrounded by six chloride ions, and each chloride ion by six sodium ions. The number of ions (or atoms or molecules) that each ion has as its nearest neighbors is called the coordination number. The coordination number for NaCl is, therefore, six. For ionic crystals, the coordination number depends on the relative size of the cation and the anion. If the size difference is very large, the most often found coordination number is four, and if the size differences are small, a coordination number of eight is found. Higher coordination numbers are found in metal crystals (eight or twelve), and the coordination number of diamond is four.

If atoms or ions are held together by covalent or ionic interactions, the resulting crystals have very high melting points and are often hard and brittle. In metals, the crystalline structure is formed by cations, where the electrons are delocalized. This is the reason for both the high coordination numbers of metal crystals as well as the ductile behavior of many metals.

Most drugs are organic molecules. The crystals formed by these substances are held together by dipole-dipole interactions, hydrogen bonds, or London forces. Since these are at least an order of magnitude weaker than ionic or covalent interactions, the melting points of molecular crystals are lower than those of the aforementioned crystalline structures. example, the melting points of paracetamol (molecular crystal), NaCl (ionic crystal), copper (metal crystal), and diamond (covalent crystal) are 169°C, 801°C, 1084°C, and 3550°C, respectively.

We have already seen that different types of crystals can have different coordination numbers. In fact, since crystals are periodically organized, we can define a specific unit cell characteristic for each crystal. A unit cell is defined as the smallest unit of a crystal, which, if repeated, could generate the whole crystal. For this we imagine the atoms, ions, or in the case of drug crystals, molecules, as points in a lattice, disregarding their actual shape. Within the crystal structure we now look for the smallest unit which, when endlessly repeated, forms the crystal structure. Since there may be different ways to do this, the unit cell of a given crystal is the one with the shortest dimensions, and that includes angles that deviate the least from a right angle. The unit cell is a geometric construction and does not take into account the size and shape of the crystal forming atoms, ions, or molecules, nor the type and strength of interactions between them. For this reason, it is possible to summarize the types of unit cells into only seven crystal systems, which can be understood as unique unit cell shapes and which can be differentiated with respect to the relative lengths on their axes  $a$ ,  $b$ , and  $c$  and the angles  $\alpha$ ,  $\beta$ , and  $\gamma$  between the axes. These seven crystal systems are called cubic, tetragonal, orthorhombic, monoclinic, triclinic, rhombohedral (or trigonal), and hexagonal (Figure 11-36).

While there are only seven crystal systems, there are 14 Bravais lattices. This is because additional points can be present in a unit cell, other than the points at the corners of the unit cell, without changing the essential symmetry elements of the crystal system. If there is an additional point in the centre of the unit cell, these lattices are called body (or volume) centered (for example, body centered (cubic I in Figure 11-36)). If there are additional points in the centre of each side (face) of the unit cell, they are called face-centered (for example, face centered (cubic F in Figure 11-36), and if an additional point is present at the centre of two opposite faces of the unit cell, they are called base-centered (for example, base-centered (monoclinic C in Figure 11-36). Bravais lattices without extra points are called simple or primitive for example cubic P in Figure 11-36. The 14 Bravais lattices are shown in Figure 11-36.

Every crystalline material belongs to one of these Bravais lattice types but differs in their lattice parameters, and for each unit cell we can define three axes, with a length characteristic for the individual crystal, and three angles, also characteristic for this crystal. For example, NaCl crystals belong to the crystal system: cubic, Bravais lattice type: face-centered. The only lattice parameter we need is the length of one axis,  $a = 5.6402 \text{ \AA}$ , since for a cubic crystal the axes  $a = b = c$ , and the angles  $\alpha = \beta = \gamma = 90^\circ$ . Paracetamol (polymorphic form I) belongs to the crystal system: monoclinic, Bravais lattice type: primitive,  $a = 11.74 \text{ \AA}$ ,  $b = 9.396 \text{ \AA}$ ,  $c = 7.117 \text{ \AA}$  and  $\beta = 97.47^\circ$  ( $\alpha = \gamma = 90^\circ$ , for a monoclinic unit cell).

In the above discussion, we have considered the crystalline structure as infinitely periodic. In reality most crystals, however, will show defect structures, i.e., structures in which there are packing mistakes of some kind, so the crystalline structure of a real crystal will not be perfect. Depending on the number of these defects in a crystalline material, properties of the crystalline substance may vary, for example, its behavior in a milling process. Point defects occur at a single lattice point (Figure 11-37). For example, a single lattice point may be vacant (vacancy) or occupied by a different atom, ion, or molecule from the ones that form the crystal (substitutional point defect; this would constitute a chemical impurity). It is also possible that there may be additional lattice points (interstitial point defects), either from the same or a different atom, ion, or molecule.

The dislocation is an example of a line defect, and the grain boundary is an example of a planar defect (Figure 11-38).

**Figure 11-37.** Point defects in a crystal lattice. V: vacancy, S: substitutional point defect (different atom, ion, or molecule from the ones that form the crystal), I: interstitial point defect (different atom, ion, or molecule from the ones that form the crystal), SI: self-interstitial point defect (same atom, ion, or molecule as the ones that form the crystal).

A grain boundary marks an interface between different crystalline regions, called crystallites. Such a material is termed polycrystalline and is the reality for most crystalline materials, including drug substances.

### Polymorphism

An important property of many chemical entities, including most drug molecules, is that they are able to crystallize in several different crystalline forms, termed polymorphic forms. These different crystalline forms consist of the same molecules, but these are arranged in different ways. If the crystal former is an element (as we have seen in the case of carbon), different polymorphic forms are termed allotropes. For molecular crystals, the crystal is held together by secondary forces, as outlined above. Since these interactions are fairly weak (compared to ionic, metal, or covalent crystals), and because the molecules may adopt different molecular configurations in the crystalline structures, it is not surprising that most pharmaceutical drugs show polymorphism, and are often able to crystallize in more than two, and in some case even more than ten, different crystalline forms. These different polymorphs are also termed polymorphic modifications of the substance in question. It is important to note that different modifications of a drug may not necessarily form crystals with a different type of Bravais lattice. Although this is, of course, possible, it is also possible that two polymorphic forms of a drug both have, for example, a monoclinic unit cell. In this case, however, the lattice parameters of the two polymorphic forms will be different. Also, for some polymorphic forms, for example, of drug substances, the molecules present in the lattices of the different modifications will adopt different molecular conformations (termed conformational polymorphism), while other polymorphic pairs will contain the drug molecules with the same conformation (termed packing polymorphism).

**Figure 11-38.** Dislocation (a line defect) and grain boundary (a planar defect).

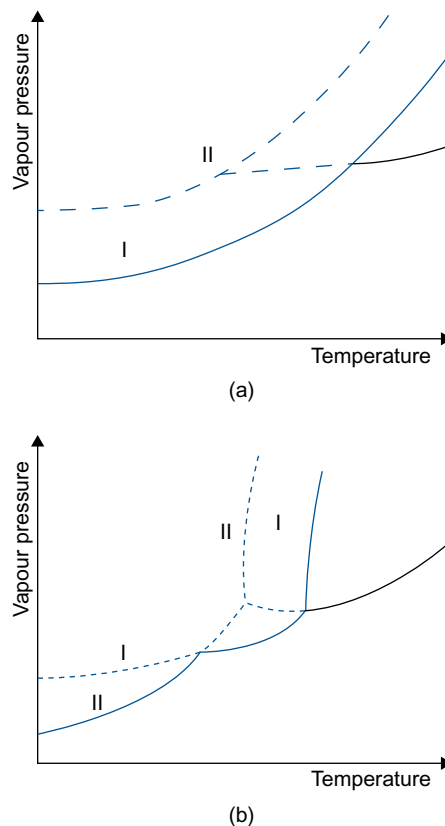

Polymorphism is important in the pharmaceutical field, since the physical properties of different polymorphic forms are often considerably different, which can have consequences for important quality-relevant attributes of a drug substance or dosage form. Differences may be encountered in, for example, dissolution rate, solubility, flow properties, behavior under mechanical stress (for example during milling, tableting, agglomeration), hygroscopicity, etc. These differences may be sufficiently large so that different polymorphic forms may have different bioavailabilities. It is thus possible, or even common, that for a given drug regulatory approval is only given to a specific polymorphic form of the drug.

While often different polymorphic forms of a drug form macroscopically different crystals, such as needle-like versus plate-like crystals (the macroscopic appearance of a crystal is also known as the habit of the crystal), it is important to note that different polymorphic forms may not necessarily look different macroscopically, and thus it may be difficult to differentiate these by visual inspection or in the light or electron microscope alone. It is also possible that if one and the same polymorphic form of a crystal is crystallized, for example, from different solvents or from either a solution or the melt, it may adopt different crystal habits. So while the habit is important, most notably for further processing of the drug powder, it is also important to have techniques available to unambiguously identify the crystalline structure of a drug and its polymorphic form. This will be discussed in the section on methods to characterize solids, where some techniques to identify and characterize polymorphs (or indeed solid state forms in general) will be mentioned.

If a drug can crystallize in different polymorphic forms, it should be noted that at any given condition of pressure and temperature, only one polymorphic form can be the thermodynamically stable form. All other polymorphic forms that may form under these conditions will be only metastable. Metastable here means that these polymorphs can form but eventually will convert to the stable form over time if the environmental conditions are not changed. The metastable forms, on the other hand, are not unstable (in contrast to amorphous forms which will be discussed in the next section), since (sometimes considerable) activation energy is required to bring about a phase transition from the metastable to the stable polymorphic form. For some metastable polymorphs, therefore, the polymorphic transition may be very slow and may take much longer than the shelf life of the drug product containing a metastable polymorphic form. In general, if not precluded by a too low solubility of the stable form, most drugs will be manufactured in solid dosage forms in the stable polymorphic form. However the drug ranitidine-HCl, which can exist in two polymorphic forms, is manufactured using both polymorphs, i.e., the metastable polymorph is “practically” stable enough to allow safe manufacturing.<sup>11</sup>

It is often found that not the most stable, but a less stable (often the least stable) polymorphic form of a substance crystallizes first, for example, upon cooling of a melt. This is known as Ostwald’s rule. While not universally applicable (not being a law, but rather a rule), it nevertheless highlights the importance in drug development to carefully check which polymorphic form of a drug one is indeed dealing with.

Let us consider a given set of two polymorphs of a substance. Because the solid state forms are different, their phase diagrams will also be different, and the overall phase diagram of this polymorphic substance will be the superimposed phase diagram of the two forms. This is illustrated in Figure 11-39. We can differentiate two possible scenarios, shown in Figures 11.39a and b. For the monotropic system (Figure 11-39a), the sublimation curve of form I is below the sublimation curve of form II. Since the stable polymorph is the one with the lower vapor pressure, in the case of a monotropic pair of polymorphs, one form (here form I) is always the stable form until either of the forms melts. Note that after melting there is no difference between the melts of the substance, irrespective of the polymorphic solid form.

**Figure 11-39.** Phase diagrams of (a) a monotropic and (b) an enantiotropic polymorphic system. The solid lines represent stable states.

Should initially form II have been generated by cooling from a melt (according to Ostwald’s rule this is not unlikely to happen in a practical scenario), then if conversion occurs to the stable form I, this conversion will be irreversible. The situation is different for enantiotropic systems (Figure 11-39b). Here form II has a lower vapor pressure than form I at low temperature (so it is the stable polymorph at these temperature conditions), but at higher temperatures there is a crossover in the sublimation curves of the two polymorphs before either of these forms melts. After the crossover, form I now has the lower vapor pressure and is the stable form. This means if we have form II present at low temperature, this is the stable form, but upon heating at a certain temperature, polymorphic conversion will take place and form I is the stable form. If we now cool down form I again, conversion back to form II will occur. In other words, the process is reversible.

## AMORPHOUS SOLIDS

In the previous section we have seen that a crystalline solid is characterized by its long-range positional order. Amorphous solids lack the long-range order seen in crystals although short-range order over several molecular dimensions may exist. The molecular arrangement is thought to represent that of a frozen liquid with the rheological properties of a solid.

Heating of a crystalline material leads to a gradual increase in the thermodynamic properties such as enthalpy and entropy until the melting point,  $T_m$ , is reached (Figure 11.40). As we have seen, a significant increase in thermodynamic properties marks the first order transition (melting) from the solid to the liquid state. Above the melting temperature, the material exists as a molten liquid. This is a reversible process, so upon cooling, crystallization of the melt occurs whereby the molecules rearrange themselves in their crystal lattice. However, if the liquid is cooled sufficiently fast below its melting temperature, crystallization may be prevented so that a super-cooled liquid is formed, and the slope of the

**Figure 11-40.** Thermodynamic relationship of crystalline and amorphous solids as a function of temperature. Shown are the melting temperature ( $T_m$ ), the glass transition temperature ( $T_g$ ), and the Kauzmann temperature ( $T_K$ ).

equilibrium liquid line (Figure 11-40) may be followed, resulting in a gradual decrease of the thermodynamic properties below  $T_m$ .

At temperatures above the glass transition temperature ( $T_g$ , Figure 11-40) the material is said to be in the super-cooled liquid state (sometimes also called the rubbery state), the viscosity of which is typically between  $10^{-3}$  and  $10^{12}$  Pa s. In the super-cooled liquid state, the molecules are able to follow any further decrease of temperature to attain equilibrium conditions. However, cooling of the super-cooled liquid increases the viscosity of the system, and upon further cooling the molecules are not able to reach equilibrium any longer. At this temperature, the  $T_g$ , the molecules are “kinetically frozen in” and the super-cooled liquid solidifies into a glass. (Note that in a glass the molecules still show some mobility.) The  $T_g$  represents the temperature at which the system falls out of equilibrium. Amorphous solids are therefore non-equilibrium solids and the glass transition is a second order phase transition. Unlike melting or boiling, the heat capacity is not infinitely high at the phase transition, but jumps from one value to another. The non-equilibrium state of a glassy amorphous system has special implications: the fundamentals of thermodynamics only apply to systems in equilibrium, and therefore, the behavior of the glassy state cannot be predicted from regular thermodynamics.

Due to the high viscosity of the resulting glass (viscosity is usually greater than  $10^{12}$  Pas), it appears as a solid. The  $T_g$  represents a characteristic thermal event for an amorphous system, but it should be noted that the  $T_g$  is a kinetic property of the material, and its exact position depends, for example, on the cooling rate of the super-cooled liquid, i.e., on its thermal history.

In principal, the amorphous state can be produced in two ways:

1. from a liquid state, either by rapidly cooling the molten liquid or by fast evaporation of a solvent from a solution, hence “freezing in” the molecular arrangement of the liquid (vitrification), or
2. by gradually inducing and increasing defects in the crystal lattice until the amorphous state is generated (amorphization).

The vitrification process (1) is also termed the thermodynamic pathway to form amorphous materials, and the amorphization process (2) has been named the kinetic pathway. A schematic representation of the conversion from crystalline to amorphous is depicted in Figure 11-41.

If the amorphous state is produced via the thermodynamic pathway, the crystalline material has to be transferred to a liquid

state, either by melting or by dissolution in an appropriate solvent. If the kinetic pathway is followed, the crystalline lattice is continuously disrupted by mechanical processing like milling, inducing crystal defects. As long as the crystal defects remain small in number, the material still exhibits crystalline properties. However, if a critical number of defects is introduced, the crystal cannot retain its structure and converts to the amorphous state. The main difference between these two approaches is that while the thermodynamic pathway abruptly destroys the long-range order of the crystal, the kinetic pathway gradually increases the number of crystal defects, thereby creating non-equilibrium crystalline states. Such materials, still crystalline but with increasing number of defects, are termed defective crystals.

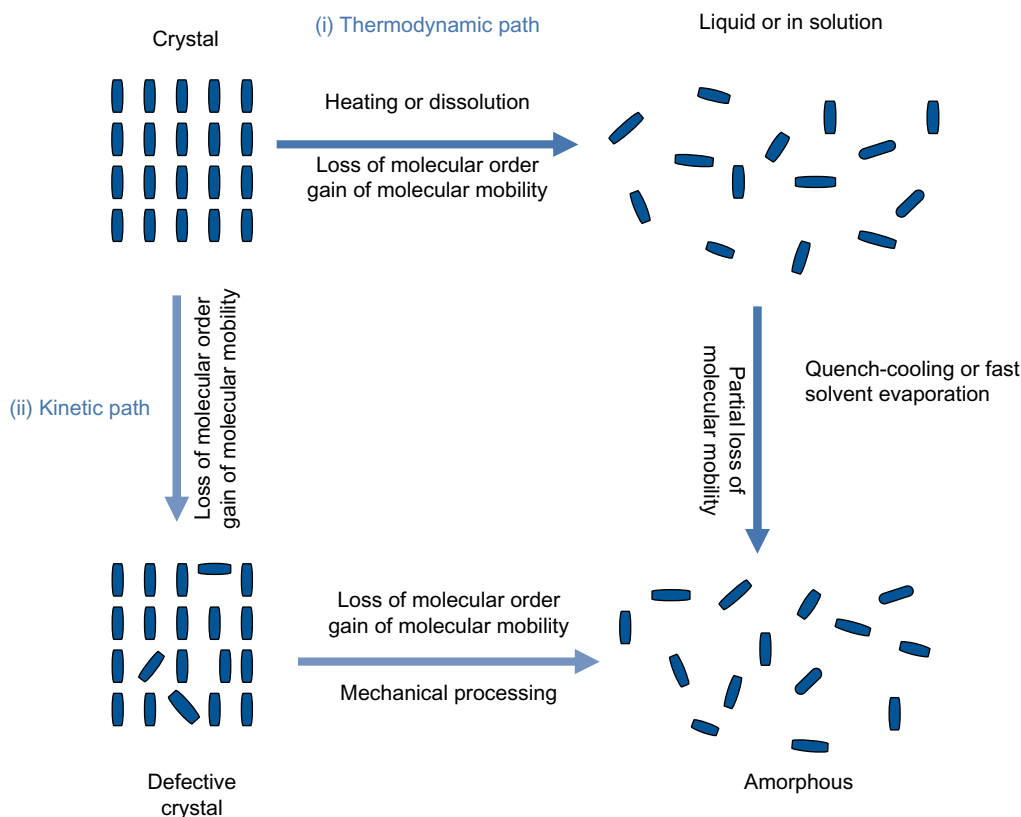

While the thermodynamic pathway is commonly employed in order to deliberately generate the amorphous state, the kinetic pathway is usually associated with the unintentional amorphization of a crystalline material, for example when the actual objective of a milling process is to reduce the particle size of the crystalline material, not to change its solid state form.

It should be noted that not every preparation technique to convert a crystalline drug into its amorphous counterpart is suitable for every drug, e. g. thermolabile drugs cannot be converted to the amorphous form by using heat based methods; drugs that are insoluble in a range of organic solvents cannot easily be spray-dried to amorphize the substance, and some methods (milling) may not completely convert certain drugs into the amorphous state. We have now seen a variety of methods that can be used to generate the amorphous state of a drug. The question arises whether the amorphous state generated is the same in all cases.

Let us take a closer look at the  $T_g$ , an important feature in the amorphous state. Above the  $T_g$  the system is still in an equilibrium state; below the  $T_g$  the system has fallen out of equilibrium. Let us imagine that the  $T_g$  did not exist: in Figure 11-40 we see that the decrease of the temperature would eventually lead to the super-cooled liquid line intersecting with the crystal line. This would cause the super-cooled liquid eventually to have a lower entropy than the crystal upon further cooling. This, however, is not considered possible. The theoretical temperature at which the super-cooled liquid would attain the same properties as the crystal is known as the Kauzmann temperature,  $T_K$  (see Figure 11-40). The kinetic nature of the glass transition is evident from its dependence on the heating and cooling rates, which means that the  $T_g$  does not exist at a defined temperature. Slow cooling rates lead to a prolonged super-cooled liquid state and result in a  $T_g$  with a lower temperature, as displayed by  $T_g$  II in Figure 11-42. As the super-cooled liquid is cooled at a slower rate, the system is able to adjust to the temperature dependent increase in viscosity, resulting in a lower temperature for the glass transition. Glasses created by slower cooling rates also show lower values of enthalpy and entropy than glasses that are created by faster cooling rates. The explanation for this is that due to the lower onset of the  $T_g$ , the super-cooled liquid state is maintained at lower temperatures, therefore decreasing the value of enthalpy and entropy further.

For practical purposes, this means that for a given material an amorphous system which is prepared by one method is not identical to the amorphous system prepared by another method. Even that, if the method is the same but parameters are varied, the resulting amorphous states will not be identical, either. So, unlike “the crystalline state,” which has defined properties, there is no “the amorphous state”. Depending on the preparation method, sample history, geometry and mass, and the experimental heating and cooling rates, the amorphous states can differ considerably in properties, especially in physical stability (recrystallization to the crystalline state).

From Figure 11-40 we can see that the amorphous state has higher thermodynamic properties, like enthalpy and entropy, compared to the crystal. What Figure 11-40 does not show, however, is that the properties of the amorphous state are time-dependent. As time passes, we observe that the amorphous

**Figure 11-41.** Schematic representation of the crystalline to amorphous conversion via the thermodynamic and kinetic pathways.

state decreases in properties such as enthalpy even though the temperature is kept constant. This phenomenon is called relaxation, and it has its origin in the instability of the amorphous state. The molecules may be frozen in, but they still have some molecular mobility left. This is sufficient for the molecules to relax over time and rearrange themselves in a more thermodynamically favorable way. By doing this, they decrease their enthalpy, and this is also considered an important factor in the stability of amorphous systems. This relaxation can be visualized in a DSC thermogram, in which the relaxation appears as an endothermic peak on top of the glass transition event.

In recent years the amorphous state of drugs has gained increasing interest in pharmaceuticals due to its favorable solubility properties, compared to its crystalline counterpart.<sup>12</sup> Many new drugs show insufficient solubility for oral dosage form development. Because of its higher energy, the solubility of amorphous forms is often orders of magnitude higher than for crystals and,

**Figure 11-42.** Thermodynamic relationship of glasses created by different cooling rates. Glass I has been cooled fast, and glass II has been cooled slowly.

thus, this solid form is attractive in dosage form development. However, issues when dealing with the amorphous state, such as physical and chemical instabilities, remain. Also, to date, the prediction of physical and chemical stability of drugs in the amorphous state still proves challenging, since, for example, the application of stress tests is not straightforward for amorphous systems (they don't behave in an Arrhenius fashion).

### SOLIDS WITH MORE THAN ONE COMPONENT

In the previous sections we have discussed crystalline and amorphous solids on the basis of single component systems, i.e., we were considering a single chemical entity (e.g., the drug molecules). In this section we will expand the discussion on solids by introducing a second component.

#### Solvates and co-crystals

Not only can most drugs crystallize in different polymorphic forms, but they can also incorporate other molecules to form crystalline structures. For example, during a crystallization process from a solvent, solvent molecules may be incorporated into the crystalline structure. This occurs if the solvent molecules can interact with the drug molecules through hydrogen bonding or other weak interactions. In this case a new crystalline structure of the drug and the solvent molecules may be formed. These crystalline structures are termed solvates. In the specific case of water as the additional molecule to be incorporated into the crystalline structure, the solvate is called a hydrate. Hydrates can also form from crystalline or amorphous non-hydrate drug substances by addition of water molecules from the air or during a dissolution process in water. Thus, hydrate formation of a drug (if the drug can indeed form hydrates, which is compound specific) may even occur during the oral administration of the drug. This is of pharmaceutical significance, for in most cases the resulting hydrate will have lower water solubility than the respective non-hydrate, which may even result in a lower bioavailability. For example, partial hydrate formation has been made responsible for erratic bioavailability

of carbamazepine and theophylline after administration of the drug in a non-hydrate form.<sup>13,14</sup>

Since the water molecules (or other solvent molecules) are incorporated into the crystalline lattice in a regular structure, the molar ratio of drug to solvent molecules will take on fixed ratios (stoichiometric hydrates). However, this molar ratio does not have to be 1:1 (monohydrates), and for example hemihydrates (the molar ratio of drug to water molecules in a hemihydrate is 2:1) or dihydrates (the molar ratio of drug to water molecules is 1:2) are not uncommon. Some drugs can form different hydrates (for example, mono- and dihydrates) and even within one group of hydrates, polymorphism may occur, further increasing the possibilities of a given material to crystallize in many different forms, with different physico-chemical properties.

Not all hydrates, however, have a fixed stoichiometric ratio between the drug and the water molecules. If the water molecules can be incorporated into channels that may be present in a non-hydrate crystalline structure, many different ratios of water to drug molecules are possible, depending, for example, on the relative humidity of the air surrounding the hydrate. These types of hydrates are called channel hydrates.

If a stoichiometric hydrate loses its water (for example, by heating), the water in most cases will leave the crystal at a defined temperature. If we are measuring the weight loss of a hydrate as a function of temperature (these types of measurements are called thermogravimetric measurements), typical weight loss curves, as shown in Figure 11-43, are obtained for stoichiometric hydrates. In case of a dihydrate, for example, water may be leaving the crystal initially to form a monohydrate

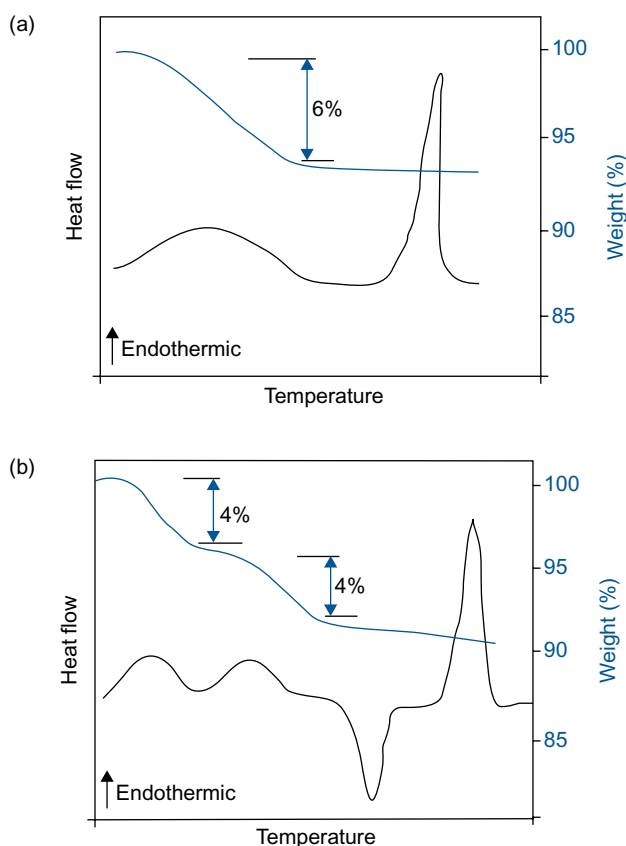

that is then losing the remaining water at a higher temperature, so two steps in the weight loss curve may be observed (Figure 11-43b). For a given mass of material, if the molecular weights of the drug and the solvate molecule (18 g/mol in case of water) are known, the stoichiometric ratio of drug to solvate molecules can be determined by these measurements. In some cases the water only leaves the crystal upon melting of the material. In contrast, for channel hydrates the water molecules are leaving the crystalline structure often before melting and over a broader temperature range. If the water in a stoichiometric hydrate leaves the crystal before melting this may result in a collapse of the crystalline structure altogether, leading to the formation of an amorphous material. In the case of channel hydrates, the result of water leaving the crystal may be a non-hydrate with almost the same crystalline structure as the hydrate (same crystal lattice type and similar, but not identical, lattice parameters), sometimes called a vacant hydrate, before further polymorphic conversion to the stable non-hydrate form occurs.

Of recently increasing pharmaceutical interest are co-crystals.<sup>15</sup> Unlike salts, in which the drug (as an anion or cation, depending on the nature of the drug) is bound by ionic interaction to the counter ion, in a co-crystal the drug and the co-crystal former (see below) are interacting via weaker interactions, in most cases by hydrogen bonding, as is the case for solvates. However, in contrast to solvates, both components of the co-crystal are solid at room temperature. If the hydrogen bond between the two molecules is formed by similar molecular moieties (for example, two carboxylic acid groups), this is known as a supramolecular homosynthon, whereas a hydrogen bond between two different moieties of the two components (for example, a phenol group and an amide group) is known as a supramolecular heterosynthon. Generally, the formation of a heterosynthon leads to a higher likelihood of formation of a stable co-crystal. Typical co-crystal formers used in the pharmaceutical field include maleic acid, tartaric acid, nicotinamide, saccharin, and many others. Since co-crystals have other properties, including solubility, hygroscopicity, and pharmaceutical processability, they offer interesting possibilities in drug development. Co-crystals (for example, the carbamazepine-nicotinamide co-crystal and the carbamazepine-saccharin co-crystals) can also show polymorphism.<sup>16</sup>

### Eutectics

Above we have considered solid state materials containing two components but forming a single phase. Eutectics are an important example of a solid mixture of crystals (in contrast to co-crystals, which are “mixed crystals”, rather than a “crystalline mixture”). Eutectics thus contain two phases. However, in eutectic mixtures the two phases (two materials) are intimately mixed and thus often show different properties from simple physical mixtures of the two components.

Let us consider two crystalline materials, A and B, with meeting points  $T_{m_A}$  and  $T_{m_B}$ , that are miscible in the molten state, i.e., they form a single liquid phase. This is shown in form of a phase diagram in Figure 11-44. If we have a mixture of the two materials at the mixing ratio R1, at a temperature where both materials are molten (so we are in the liquid area of the phase diagram), and we now reduce the temperature of this melt, at the intersection with the melting curve, we will observe crystallization of compound A. As A will crystallize, but not B, this means that the composition of the remaining melt will change and it will become more B-rich. We thus follow the melting curve upon further lowering of the temperature until we reach the lowest point of the melting curve of A. If we lower the temperature further, now B will also crystallize. Similarly, if we have a B-rich mixture, B will crystallize when the temperature is lowered to the melting curve of B. This, in turn, will lead to the remaining melt having relatively more A than the original melt, and we follow the melting curve of B until we reach its lowest point, which is the same as for an A-rich system. The ratio of A and B at this point is called the eutectic mixture for these

**Figure 11-43.** Thermogravimetric weight loss curves (—) and corresponding DSC curves (—) of (a) a hypothetical monohydrate and (b) a hypothetical dihydrate. Note that the water loss also appears as an endothermic event in the DSC thermogram. Other thermal events in the DSC curves (e.g., a polymorphic conversion, or melting) are not accompanied by a weight loss in the thermogravimetric curves. For more information on DSC, see the section Methods to characterize solids.

Figure 11-44. Phase diagram of two materials, A and B.

two compounds, and the temperature in the phase diagram is known as the eutectic temperature ( $e$ ), the lowest temperature at which both compounds crystallize together. In other words, at the eutectic point both crystalline A and B and the melt are in equilibrium. For the eutectic mixture of sodium chloride and water, this occurs at a salt concentration of 22.4 percent and a eutectic temperature of  $-22^{\circ}\text{C}$ .

For a given two compound system, the ratio of the compounds at the eutectic mixture can be estimated from the theoretical melting curves of the two compounds, using a simplified form of the Schröder–Van Laar equation:

$$\ln x = \frac{\Delta H_0}{R} \left( \frac{1}{T_0} - \frac{1}{T} \right) \quad (20)$$

Where:  $x$  is the mole fraction of one compound in the mixture;  $\Delta H_0$  and  $T_0$  are the corresponding heat of fusion [ $\text{J mol}^{-1}$ ] and melting temperature [K] of the pure compound, respectively;  $T$  is the melting point of the binary mixture at  $x$ ; and  $R$  is the gas constant [ $8.314 \text{ J K}^{-1} \text{ mol}^{-1}$ ].

However, it should be noted that for this approach to be valid, a number of assumptions are made: there is no solid solution formation between the two compounds (see below), the melt has to be an ideal mixture, and the heat capacities of the pure compounds in the melt and as a solid should be fairly similar.

In the phase diagram shown above, we did not consider the possible formation of a solid solution between the two compounds. If this occurs, then there will be partial miscibility between the compounds in the solid state, and rather than pure compound A and pure compound B crystallizing together at the eutectic point, we will have the crystallization of an A-rich and a B-rich phase of the two corresponding solid solutions. This plays a major role in the formation of metal alloys.

### Amorphous mixtures

We have discussed above that the amorphous form of a solid is thermodynamically unstable and tends to crystallize back to the stable crystalline form or a metastable polymorphic form. In order to make use of the advantages, including a higher dissolution rate and solubility that amorphous solids offer, especially for poorly water soluble drugs, it is therefore often necessary to stabilize the amorphous form. One way of achieving this is to use two components (for example, a drug and an excipient) in the formation of a solid amorphous material. In most cases this will be an amorphous, hydrophilic polymer. If an amorphous polymer (such as, for example, polyvinylpyrrolidone (PVP), PVP-vinylacetate copolymer (PVPVA), hydroxypropylmethylcellulose (HPMC), HPMC-acetatesuccinate (HPMCAS), and various polymethacrylates) is melted together with the drug to form a single phase melt, this can be cooled down rapidly to form a single phase amorphous material, known as a glass solution (do not confuse the amorphous glass

solution with the crystalline solid solution, mentioned above). In this solid form the drug and the polymer are molecularly mixed with each other. For this to be successful, it is required that the two compounds show mutual solubility, for example, have similar solubility parameters. It is often advantageous for the physical stability of glass solutions if some interactions between the drug and polymer occur (usually hydrogen bonding), since this will lower the molecular mobility (especially of the low molecular weight drug) and thus will slow down the processes of nucleation and crystal growth, which lead to the crystallization of the amorphous material. The polymers used for the formation of glass solutions often have a high glass transition temperature ( $T_g$ ) so that the resulting glass transition temperature of the glass solution will be higher than the  $T_g$  of the pure amorphous drug, further stabilizing the drug against crystallization. If the glass transition temperatures of the two pure amorphous components are known, the resulting glass transition temperature of the glass solution in various mixing ratios of the two compounds can be estimated based on the Gordon Taylor equation:

$$T_{g12} = \frac{\omega_1 \cdot T_{g1} + K \cdot \omega_2 \cdot T_{g2}}{\omega_1 + K \cdot \omega_2} \quad (21)$$

Where:  $T_{g12}$  is the glass transition temperature [K] of the mixture;  $T_{g1}$  and  $T_{g2}$  are the glass transition temperatures [K] of the single amorphous compounds (e.g., the drug and the polymer);  $\omega_1$  and  $\omega_2$  are the weight fractions of each compound in the mixture; and  $K$  is a constant, depending on the glass transition temperatures and amorphous densities of the single compounds:

$$K = \frac{T_{g1} \cdot \rho_1}{T_{g2} \cdot \rho_2} \quad (22)$$

Where:  $\rho_1$  and  $\rho_2$  are the densities of the single amorphous components.

It should be noted, though, that this equation assumes volume additivity, i.e., the absence of specific molecular interactions and, as such, can often only be used as an estimate for the actual glass transition temperature of the glass solution.

In most cases the  $T_g$  of the glass solution is predicted by using the  $T_g$  of the drug and polymer. However, in real situations a third component can be present: moisture. It is known that moisture can accelerate crystallization from the amorphous state, and this effect can be explained by the plasticizing effect of water. The  $T_g$  of water is approx. 139 K, which is significantly lower than the  $T_g$  of commonly used pharmaceutical materials. In the same way that a high  $T_g$  polymer is added for stability, a low  $T_g$  compound can lower the  $T_g$  of the system. If the Gordon-Taylor equation is extended to a third component, it is obvious that even small amounts of a low  $T_g$  compound can have a significant effect on the  $T_g$  and, hence, on stability. Therefore, moisture should be excluded during manufacturing and storage of amorphous systems.

If the two components (for example, the drug and the polymer) are not miscible on a molecular level, the formation of a solid suspension may occur upon cooling of a melt of the two components. These systems will show two glass transition temperatures, one for the drug (or possibly a drug rich phase, if there is partial miscibility) and one for the polymer (or the polymer rich phase).

### METHODS TO CHARACTERIZE SOLIDS

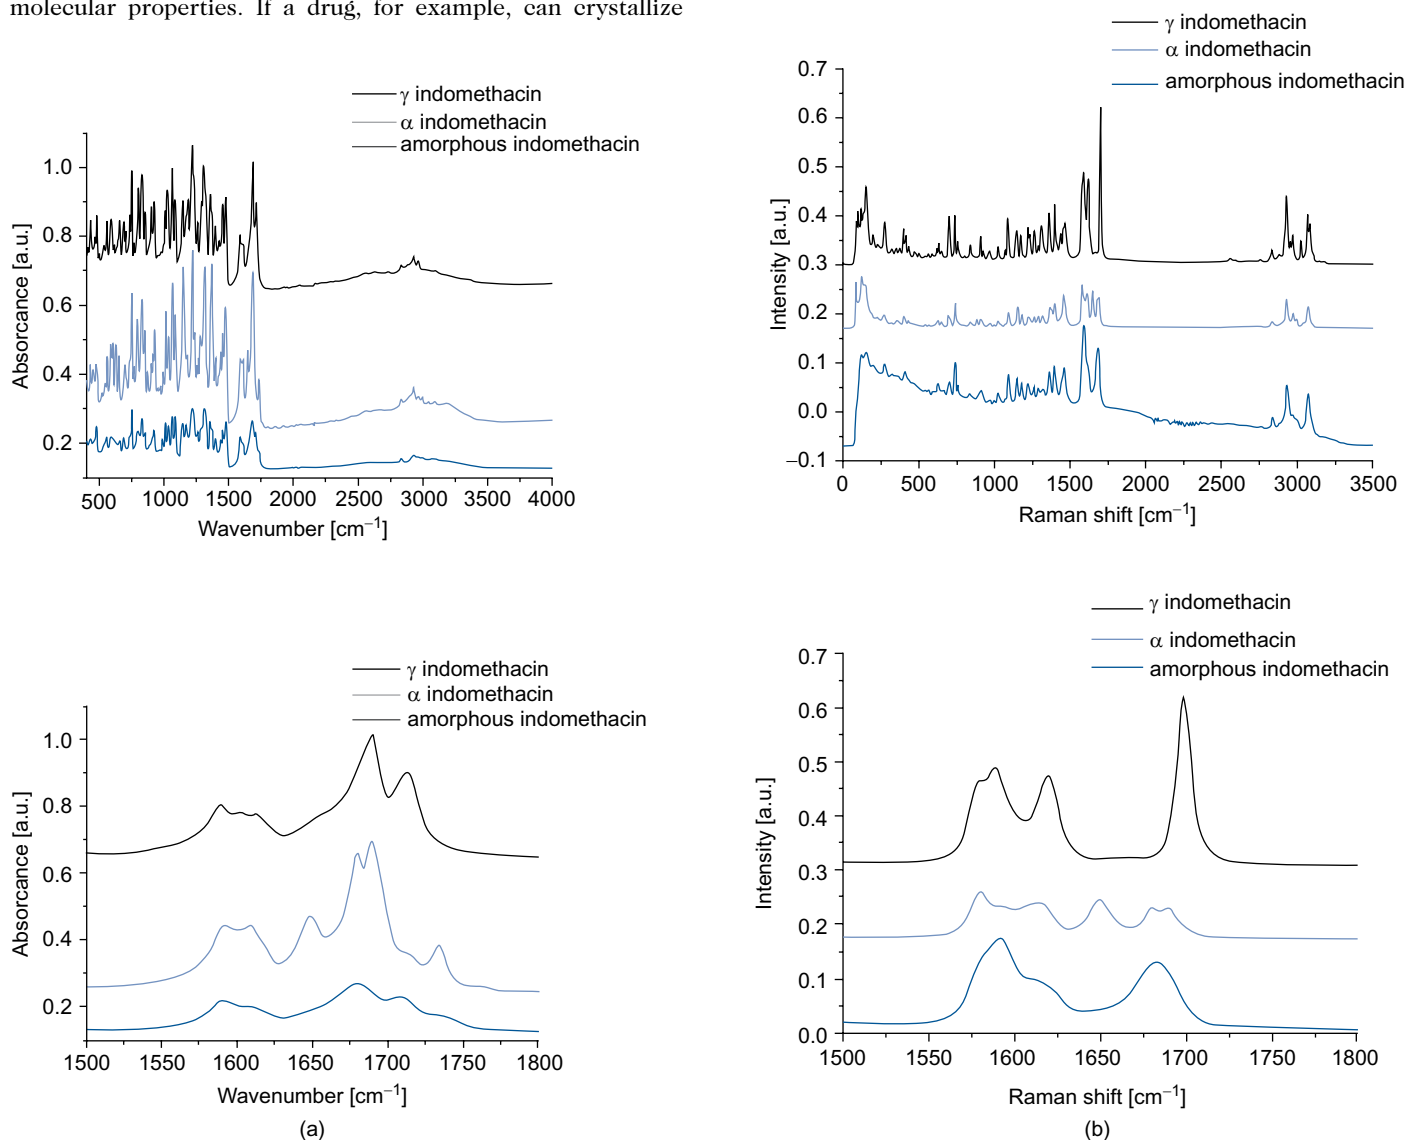

It is beyond the scope of this chapter to provide a detailed description of the various methods that have been developed to characterize the properties of solids. However, in a brief fashion we will have a look at several important techniques that allow the characterization of the many forms in which the solid state of matter, for example, of a given drug may manifest itself.

We have seen that a pharmaceutical solid can be present during development or in a final dosage form in various polymorphic forms. It can also be present in form of hydrates or

other solvates. Salt formation is possible, as is the formation of a co-crystal. Solvates, salts and co-crystals in their own right can show polymorphism. The drug may also be partly or fully amorphous, either on its own or in form of a glass solution or amorphous suspension. All of these solid state forms will differ in many of their physical properties, and this can be relevant for the drug and dosage form if, for example, solubility, dissolution rate, and chemical and physical stability are affected. It is thus obvious that we require a thorough identification and, in many cases quantification, of the various solid state forms of a drug that we may encounter in preformulation, formulation, during storage and upon administration of the dosage form. It is also obvious that this task is more complex for solids than, for example, if the drug is present in liquid form or in a solution, for in these cases all differences of the solid state forms disappear.

The list of analytical techniques that are useful to investigate solid state properties is almost endless, and it is convenient to differentiate the techniques available to the pharmaceutical scientist according to the different levels at which they probe the solid material. Most spectroscopic techniques, such as Raman and infrared spectroscopy, but also solid state NMR, near infrared spectroscopy and others are probing predominately molecular properties. If a drug, for example, can crystallize

in different polymorphic forms, these forms still contain the same molecules, and as such, the resulting spectra should be identical. Indeed, that is (almost) the case. However, the fingerprint regions of the resulting spectra will also be influenced by the neighboring molecules, for example, by the unit cell of the crystalline forms. Because these are different between different polymorphic forms, the resulting spectra, for example, for IR and Raman measurements, will also (subtly) be different. If the polymorphic pair shows configurational differences between the molecules, the differences in the resulting spectra will be larger than if the configuration of the drug molecules is the same in both polymorphs. It is often necessary to use multivariate data analytical tools, such as principal components analysis or partial least squares analysis, to identify the different solid state forms using IR or Raman spectroscopy. It is advisable, in any case, to use such techniques if a quantification of different solid state forms that are present at the same time is desired. Generally, differences in the spectra between a non-solvate and a solvate form are larger than between two polymorphic forms, and differences between the spectra of a crystalline and an amorphous form may be even larger, with the spectra in IR

**Figure 11-45.** (a), Infrared spectra of amorphous indomethacin, and the  $\alpha$ - and  $\gamma$ - polymorphic crystalline forms of indomethacin. The lower figure shows the wavenumber region of 1500–1800  $\text{cm}^{-1}$  (C=O stretch), where differences between the different solid state forms can be clearly visualised. Individual traces are offset for clarity. (b), Raman spectra of amorphous indomethacin, and the  $\alpha$ - and  $\gamma$ - polymorphic crystalline forms of indomethacin. The lower figure shows the wavenumber region of 1500–1800  $\text{cm}^{-1}$  (C=O stretch), where differences between the different solid state forms can be clearly visualised. Individual traces are offset for clarity.

and Raman measurements being less well defined (peak broadening and peak merging) for amorphous forms, compared to their crystalline counterparts. Figure 11-45 shows example IR spectra (Figure 11-45a) and Raman spectra (Figure 11-45b) of different solid state forms of the drug indomethacin.

The next level of analytical techniques, and in many ways the “gold standard” techniques to characterize and quantify different solid state forms of a drug, are the techniques that probe an assembly of molecules. These techniques have been termed “particulate level techniques,” and include X-ray diffraction (mostly used in the forms of X-ray powder diffraction, XRPD), and various thermal analytical techniques (of which differential scanning calorimetry, DSC, plays the largest role in pharmaceutical analysis). These will be described briefly below. It should be noted, however, that also terahertz spectroscopy, probing the phonon modes of solids, is a particulate level technique, as are the various microscopic and electron microscopic techniques.

X-ray powder diffraction is one of the most important analytical techniques used in solid-state analysis. An X-ray powder pattern is the result of scattering of an incident monochromatic X-ray beam by the lattice of the crystalline material. The resulting diffractogram is based on constructive and destructive interference of the diffracted X-ray beams. This phenomenon is described by Bragg’s law:

$$n\lambda = 2d\sin\theta \quad (23)$$

Where:  $n$  is the order of reflection (an integer);  $\lambda$  is wavelength of the incident beam [Å];  $d$  is distance between the planes in the crystal [Å]; and  $\theta$  is angle of beam diffraction.

Constructive interference takes place when the scattered X-rays are in phase, i.e., the phase difference that the scattered X-rays reflected from two neighboring planes of the crystal lattice is an integer (Figure 11-46). Each crystalline material will exhibit a diffractogram, which is unique to the specific compound and its solid state form, and individual peaks may be attributed to the crystalline structure. As amorphous solids do not possess an ordered lattice, no diffraction occurs and no diffraction pattern is obtained. Rather, a diffuse “amorphous halo,” showing one or several broad maxima, is observed. XRPD is particularly useful to detect small amounts of crystallinity in an amorphous sample, for the residual crystallinity results in small diffraction peaks on an amorphous halo. However, the technique is of limited use for the detection of low levels of amorphous content since the halo will be obscured by the stronger crystalline diffraction peaks.

XRPD is one of the most commonly used techniques in the pharmaceutical industry for solid-state analysis because it may be used for the identification and quantification of polymorphs, solvates, hydrates and amorphous forms, based on their unique diffraction patterns. It does not require large sample sizes, and unlike thermal methods, it is a non-destructive technique. This is potentially advantageous in the early stages of pharmaceutical development, and despite its limitations in detecting low levels of amorphous material, XRPD has been used both qualitatively and quantitatively in the characterization of partially

**Figure 11-46.** Diffraction of X-ray beams by planes of a crystal lattice. A, B, and C are points in the crystal planes.  $d$  is the distance between two planes.

crystalline systems. Quantification of the crystalline content can be achieved by measuring the area or the height of the main peaks in the diffractogram and of the amorphous content by measuring the amorphous scattering in the diffractogram. However, quantitative analysis using XRPD has to be carried out carefully, for physical characteristics such as sample height, surface character and shape, and the presence of microcrystallinity may influence the outcome of the measurements. Figure 11-47 shows example diffractograms of different solid state forms of the drug indomethacin.

DSC is used in the study of both crystalline and amorphous materials. Two types of DSC instruments are available: power-compensated DSC and heat-flux DSC. In power-compensated DSC a reference and a sample pans are placed on two individual furnaces, and the temperature difference between them is maintained at zero by varying the heat that is required to keep both pans at the same temperature. The parameter recorded is the difference in energy input which is required to maintain the samples at the same temperature, for example, during a melting process. In heat-flux DSC one heating element is used for sample and reference. Heat is applied to both via an electrically heated thermoelectric disc, and the temperature difference between sample and reference is monitored. The obtained signal is converted to heat flow [mW] via the following relationship:

$$\Delta Q = \frac{T_s - T_r}{R_\gamma} \quad (24)$$

Where:  $Q$  is heat energy [J];  $R_\gamma$  is the thermal resistance [KJ<sup>-1</sup>];  $T_s$  is the sample temperature [K]; and  $T_r$  is the reference temperature [K].

In DSC, thermal events connected to the sample are presented in a thermogram, in which endothermic and exothermic energy deviations from the reference pan are recorded as a function of time or temperature. Endothermic events include processes such as evaporation, melting, and some solid–solid transitions. In contrast, the recrystallization of an amorphous form and other solid–solid transitions are exothermic. It is possible to use DSC not only to determine the temperature of these events but also to calculate the heat of the respective reaction.

As we have seen above, any change in the enthalpy of a system at constant pressure can be described by the change in heat. Hence, the area under a DSC peak is directly proportional to the heat absorbed or released by the thermal event if the sample mass is known.

The determination of the heat capacity,  $C_p$ , for the amorphous state is of particular interest, for the glassy and the super-cooled liquid state exhibit different values for their respective  $C_p$ s, and

**Figure 11-47.** X-ray powder diffraction patterns of amorphous indomethacin, and the  $\alpha$ - and  $\gamma$ - polymorphic crystalline forms of indomethacin. Individual traces are offset for clarity.

the heat capacity will change in a stepwise fashion at the glass transition temperature. The extent of the difference in heat capacity ( $\Delta C_p$ ) is an important characteristic for amorphous materials. The enthalpy of a system increases as its temperature is increased. The heat capacity can be obtained as the slope of a plot of enthalpy versus temperature at constant pressure:

$$C_p = \left( \frac{\delta h}{\delta T} \right)_p \quad (25)$$

The advantages of DSC for analytical purposes lie in the requirement of only small sample sizes (typically 2–6 mg), the broad temperature range, and in the speed of the experiments (heating rates of 5–20 K/min are typically employed). DSC can be used to analyze both crystalline and amorphous materials, and unlike XRPD, it is possible to directly detect the amorphous content through the presence of a  $T_g$ .

The thermal behavior of a solid sample may be analyzed, for example, in terms of

- melting point and melting enthalpy of polymorphic crystalline materials
- conversion temperature of two enantiotropic polymorphic forms
- enthalpy and temperature of the loss of solvate molecules from solvates
- heat capacity difference and temperature of the glass transition of amorphous material
- enthalpy and temperature of any crystallization events of amorphous material
- temperature of decomposition
- extent of interactions in mixtures (e.g., with excipients).

Quantification, for example, of amorphous content in a sample is also possible. However, despite the many advantages that make DSC one of the most widely used techniques, it has to be considered that the analyzed sample is subjected to thermal treatment, which destroys or at least changes the sample and may induce thermal artifacts. Therefore, care has to be taken in the interpretation of thermograms to avoid misleading conclusions. Moreover, DSC thermograms are often difficult to interpret if multiple overlapping thermal processes are involved. Every DSC thermogram is a compromise between sensitivity and resolution as both are dependent on the heating rate, but in opposite ways. To increase the sensitivity, the scan rate may be increased; however, this may lead to decreased resolution,

**Figure 11-48.** DSC thermograms of amorphous indomethacin, and the  $\alpha$ - and  $\gamma$ - polymorphic crystalline forms of indomethacin. The thermogram of the amorphous form shows a glass transition and recrystallization event, in addition to the melting. Individual traces are offset for clarity.

for the scan rate may be too rapid to separate close thermal events. Figure 11-48 shows example DSC thermograms of different solid state forms of the drug indomethacin.

Modulated temperature DSC (MTDSC) is an alternative to conventional DSC.<sup>17</sup> In MTDSC a sine wave modulation is applied to a linear temperature program. The obtained heat flow signal is analyzed by applying a discrete Fourier Transform algorithm, which results in the deconvolution of the measured heat flow signal into reversing and non-reversing components. The non-reversing signal comprises the kinetically controlled events that are dependent on the absolute temperature alone, and the reversing signal is a function of the samples' heat capacity and rate of temperature change. The heat flow signal of a sample will be a combination of these two components. The total heat flow signal may, therefore, be expressed as

$$\frac{dQ}{dt} = \frac{C_p}{dT} + f(t, T) \quad (26)$$

Where:  $dQ/dT$  is the heat change over time (heat flow) [ $J s^{-1}$  or  $W$ ];  $C_p$  is the “thermodynamic” heat capacity [ $J K^{-1}$ ];  $T$  is the temperature [ $K$ ]; and  $f(t, T)$  is the kinetic response.

Conventional DSC records the reversing and non-reversing heat flow simultaneously and is not able to resolve them. MTDSC is able to separate the heat capacity (reversing) and kinetic (non-reversing) components, due to their different responses to the underlying and modulated heating rates. Processes that occur at defined temperatures, such as crystallization, evaporation, relaxation, and decomposition will appear in the non-reversing heat flow signal. As the reversing component is related to the samples' heat capacity, for example, the glass transition event is visible in the reversing signal. This enables the separation of the glass transition event from any endothermic relaxation.

## LIQUID CRYSTALS

We have seen that crystalline solids are defined by long range order in three dimensions. In contrast, liquids lack long-range order (as do amorphous solids). When some solid materials are heated, they do not directly show a phase transition to the liquid state but instead enter into a different state of matter, between the solid and the liquid state. This state of matter is called the liquid crystalline state. Liquid crystals (also called mesophases) show structural properties which are intermediate between those of crystalline solids and liquids. It should be noted, however, that liquid crystals are not simply a mixture of solids and liquids but, indeed, a separate state of matter. Also, it is important to note that not every organic material is able to exist in a liquid crystalline state. We will discuss a few structural considerations of molecules that can exist in the liquid crystalline state below. These molecules are termed mesogens and usually are anisotropic organic molecules, mostly of rod-like shape.

In a thermogram we observe a first order phase transition, when we, for example, cool a melt that at a certain temperature transforms into a liquid crystal. Similarly the transition from a solid to a liquid crystal is a first order transition. Being situated between the solid and the liquid state of matter, liquid crystals also are a condensed state of matter.

There are two principal types of liquid crystals: thermotropic liquid crystals (TLC) and lyotropic liquid crystals (LLC). TLCs are formed by heating a crystalline solid. In contrast, LLCs are formed by the addition of a liquid (in most pharmaceutical cases, water), to a usually solid mesogen. If we are applying Gibbs' phase law, we can say that the minimum number of components in a TLC is one and in a LLC is two, if a single phase liquid crystal is formed. The degrees of freedom to describe a TLC is two (temperature and pressure) and for a LLC is three (temperature, pressure, and the concentration of the mesogen).

### Lyotropic liquid crystals

LLCs can be understood as associations of differently shaped micelles. Micelles are colloidal assemblies of amphiphilic

molecules, e.g., surfactant molecules and phospholipids, i.e., molecules that have a polar head group and a lipophilic, non-polar tail group. We can differentiate the following types of LLC, shown in Figure 11-49:

**Lamellar phase (Figure 11.49a):** This is pharmaceutically perhaps the most important liquid crystalline phase and consists of a layered packing of indefinitely extended disc-like micelles, leading to a bilayer structure as repetition unit. As such, the lamellar phase has a one-dimensional, long-range, positional order (from layer to layer) but only long-range orientational order within the layers. It is also possible that a lamellar liquid crystalline phase may be dispersed in excess water (so that we get a two phase system). The resulting lamellar liquid crystalline particles form concentric bilayers and are termed liposomes. Phospholipids are pharmaceutically relevant examples of lamellar liquid crystal forming molecules.

**Hexagonal phase (Figure 11.49b):** This type of LLC consists of hexagonally packed rod-like micelles. As such, the hexagonal phase has a two-dimensional, long-range, positional order (normal to the symmetry axis of the rods) but only long-range, orientational order within the rods. Depending on the nature of the solvent (polar or non-polar), hexagonal phases can exist in a normal and in a reversed form. In the normal form the polar head groups of the mesogens are pointing outwards, and in the reversed form inwards into the rod-like micelles that are forming the hexagonal phase. As we have just discussed for the lamellar phase, also the hexagonal phase of some amphiphilic molecules may be dispersed into colloidal particles, known as hexosomes.

**Cubic phase (Figure 11.49c):** This type of LLC consists, in the simplest case, of a cubic packing of spherical micelles. As such, the cubic phase has a three-dimensional, long-range,

**Figure 11-49.** Schematic representation of several types of lyotropic liquid crystals. (a) lamellar phase, (b) hexagonal phase, (c) cubic phase, and (d) lyotropic nematic phase.

positional order, like a crystalline solid. In contrast to a solid crystal, however, the mesogens in the micelles forming the cubic phase show rotational-diffusional motion and not merely vibrations, as in the case of crystals. Micellar cubic phases can also exist in a normal and in a reverse form, depending on the nature of the solvent. Moreover, bicontinuous cubic phases exist, which cannot simply be interpreted as assemblies of spherical micelles, and some bicontinuous cubic phases may also be dispersed into particles called cubosomes.

**Lyotropic nematic phase (Figure 11.49d):** This LLC is composed of rod-like micelles and shows a long-range orientational order with respect to the symmetry axis of the micelle. There is no long-range positional order in this type of LLC.

As we could expect from the increasing degree of order, the viscosity of the liquid crystals increases as we go from lyotropic nematic to lamellar, hexagonal, and cubic liquid crystals. Many surfactant and phospholipid mesogens may also show liquid crystalline polymorphism, i.e., they are able to self-assemble into different LLCs, depending on the concentration of the mesogens and temperature.

### Thermotropic liquid crystals

The typical structure of a rod-like mesogen able to exist in a thermotropic liquid crystalline state is

The rod-like shape of the mesogen is usually formed by two ring systems ( $R_1$  and  $R_2$ , which can be aromatic or aliphatic and may also consist of condensed ring systems). These ring systems are connected by a polar central group ( $C$ ) and linked to two terminal groups ( $T_1$  and  $T_2$ ), of which at least one usually is an alkyl chain. However, not all these structural elements necessarily have to be present in a mesogen. Additionally, lateral substituent groups may be present in the mesogen molecular structure ( $LS_1$  and  $LS_2$ ).

As was the case for LLC, several types of TLC can be differentiated. It is beyond the scope of this chapter to give a detailed description of all TLC types that have been described in the literature (there are over 20 different types of smectic TLC alone). We will thus restrict the description of different TLCs here to three types: nematic phases, chiral nematic phases (cholesteric phases), and fluid smectic phases (including smectic A and smectic C). Schematic representations of these TLCs are shown in Figure 11-50.

Above, we have already described a lyotropic nematic phase, formed by elongated micelles. In case of a thermotropic nematic phase, individual rod-like molecules (not micelles) show an orientational long-range order, again in the absence of any positional long-range order. The orientation of the long axes of the rod-like molecules, however, is not the same for all molecules and varies around a preferred orientation, known as the director of the nematic phase ( $n$ ). This can be expressed using the order parameter  $S$ :

**Figure 11-50.** Schematic representation of several types of thermotropic liquid crystals: (a) nematic, (b) smectic A, (c) smectic C, and (d) chiral nematic (cholesteric) phase.

$$S = 0.5 < 3 \cos^2 \Theta - 1 > \quad (27)$$

Where:  $\Theta$  is the angle between the director and the orientation of the molecular length axis of the molecule (see Figure 11.51).

This is, of course, an average value, depending, for example, on the temperature. In the ideal case of complete parallel arrangement of the molecules,  $S$  would have the value of 1.

The chiral nematic phase can be regarded as a special form of a nematic phase. If the mesogen is chiral (see above), the director field may adopt a helical superstructure, so that we have nematic layers whose directors are shifted by a constant angle from layer to layer. The distance between two nematic layers with the same director is known as the pitch of the chiral nematic phase. Since the pitch height of some cholesteric mesophases is in the order of the wave length of visible light, they may be colored, and since the pitch height is sensitive to temperature, such liquid crystals may be used as sensitive thermometers, with a specific color indicating a specific temperature.

Smectic phases have a layered structure, similar to the lamellar structure of LLCs. However, in contrast to the lamellar phase, the smectic phase usually does not form a bilayer structure. Depending on the angle the rod-like molecules have with respect to the layer, we can differentiate the smectic A phase (in which the molecules are oriented perpendicular to the layers) from the smectic C phase (in which the molecules are tilted with respect to the layers).

Several drugs have been identified to be able to exist as thermotropic liquid crystals at elevated temperatures,<sup>18</sup> including fenoprofen sodium, fenoprofen calcium,<sup>19</sup> and itraconazole.<sup>20</sup>

Both LLC and TLC can be identified by characteristic appearances (textures) in the polarizing light microscope, as well as by electron microscopic investigation. Also, the liquid crystals show characteristic peak sequences when investigated by X-ray diffraction. Since the distances between the repetition units in liquid crystals are larger than in crystals, the diffraction angles are smaller and, therefore, small angle X-ray diffraction is usually used as an analytical technique, in contrast to wide angle X-ray diffraction, which is usually used in powder diffractometry of crystalline solids.

## LIQUIDS

The liquid state of matter is an intermediate state between the solid (and potentially the liquid crystalline state) and the gaseous state of matter. It is thus not surprising that the liquid state of matter shares some commonalities with both solids and gases. As for solids, liquids are practically incompressible under pressure (except if very high pressures are used) and have a high density. This is the reason that solids and liquids are summarized as condensed states of matter. Usually, however, the density of liquids is lower than that of solids for a given material, with water being an important exception, as we have discussed above. Unlike solids, however, the molecules in a liquid can move and change places by diffusing under the influence of heat energy (diffusion). This is a property that liquids have in common with gases and the reason that gases and liquids are summarized as fluid states of matter. While liquids show in general a much higher tendency to be miscible with each other than solids, not all liquids are miscible (unlike gases, which are always completely miscible with each other), and in many cases mixing two liquids will lead to the formation of a two phase system of the two immiscible liquids or

**Figure 11-51.** Schematic showing the angle  $\Theta$  between the director ( $\hat{n}$ ) and the orientation of the molecular length axis of a molecule in a nematic liquid crystal.

a two phase system of a liquid A-rich phase and a liquid B-rich phase if the liquids show partial miscibility. In these cases the two liquids will form an interface with a corresponding interfacial tension. Since the interfacial tension  $\gamma$  is the intensive variable of the interfacial free energy  $G_S$  (with the interfacial area  $A$  being the extensive variable;  $G_S = \gamma A$ ), two phase liquid systems have a higher energy if the interfacial area between the liquids is increased. An example for this is an emulsion, in which one liquid phase is dispersed in the form of droplets in the other. The system will try to minimize its free energy, and thus the dispersed droplets will fuse together (coalescence) over time to reduce the interfacial energy by reducing the interfacial area. To reduce the surface free energy of emulsions and thereby to stabilize the dispersed nature of the emulsion, surfactants can be added to the emulsion to reduce the interfacial tension between the two liquid phases.

Generally, the principle “like dissolves like” can be applied, and liquids with similar polarity (for example, water and ethanol, or benzene and cyclohexane) will be miscible, whereas liquids with different polarities (for example, water and benzene) will be immiscible or show partial miscibility.

Another property liquids have in common with gases is that they are isotropic. This means their physical properties are uniform in all directions or orientations. This is not the case for crystalline solids and liquid crystals, which are anisotropic (with the exception of cubic crystals and liquid crystals). The anisotropic nature of most crystals (and liquid crystals) is also the reason for their optical birefringence, making them visible in the polarized light microscope. Conversely, liquids will be invisible in the polarized light microscope under cross polarization.

If we investigate a liquid with X-ray diffraction, we only measure the characteristic halo we have already discussed in the context of amorphous solid materials (amorphous materials are also isotropic and show no long-range order, which would give rise to peaks in a diffractogram). However, also like amorphous materials, liquids are not without near order, and certain distances between the molecules of a liquid may be preferred over others, due to intermolecular interactions. This can also be determined from X-ray diffraction measurements, by calculating the radial distribution function  $g(r)$ , which can be generated by a Fourier transformation of the diffraction pattern, and presents the average spatial distribution in a liquid (or in an amorphous solid).

An important property relevant for many pharmaceutical applications of liquids is their viscosity. Viscosity is the resistance to flow or, in other words, the resistance of the liquid to be deformed under a shear stress (due to the intermolecular interactions of molecules in a liquid). If a shear stress (a force  $F$  [N] applied parallel to the fluid’s surface  $A$  [m<sup>2</sup>],  $F/A$  [N/m<sup>2</sup>]) is applied to a liquid, this will result in a velocity gradient in the liquid ( $d\mathbf{v}/d\mathbf{x}$  [s<sup>-1</sup>]). The ratio between the two is called viscosity  $\eta$  [Pa s]

$$\eta = (F / A) / (d\mathbf{v} / d\mathbf{x}) \quad (28)$$

This equation is usually rearranged to give Newton’s law of viscosity:

$$F / A = \eta d\mathbf{v} / d\mathbf{x} \quad (29)$$

Liquids can be differentiated by their viscosities and the type of viscosity they have. A Newtonian liquid (ideal viscosity) is a liquid in which  $\eta$  remains constant if the shear stress or shear rate is increased. Water and ethanol are examples of Newtonian liquids. Not all liquids, however, show ideal flow behavior, and these liquids are called non-Newtonian liquids. Many pharmaceutically relevant liquids are non-Newtonian. If the viscosity decreases with increasing shear stress, the liquid shows pseudoplastic flow behavior (also called shear thinning), and in the opposite case, when the viscosity increases as shear stress is increased, the liquid shows dilatant flow behavior (also called shear thickening). Time, however, does not change the viscosity for a given shear stress for pseudoplastic and dilatant liquids (nor for Newtonian liquids). This is, however, not always the case. A pseudoplastic liquid shows a certain viscosity for a certain shear stress. If the stress is kept constant, for

some liquids a further decrease in viscosity can be observed. When the shear stress is removed, the system does not immediately return to its original state, but the viscosity gradually increases. This behavior is termed thixotropy. For pharmaceutical suspensions this is advantageous, for the suspension can be homogenized by shaking and can be poured easily. After some time, the viscosity increases again, stabilizing the suspension against sedimentation.

While many polymer solutions used in pharmaceutical applications are pseudoplastic liquids, concentrated pastes may show dilatant flow behavior, and many suspensions and “semi-solids”, such as creams and ointments, show thixotropy. Note that a semisolid is a pharmaceutical term used to describe creams, ointments, etc. These are solids at rest, but they start to flow (become liquid) at low shear stresses.

To describe pseudoplastic and dilatant liquids, we can extend Newton's viscosity equation to a power law, known as the Ostwald–de Waele equation:

$$F/A = K(dv/dx)^n \quad (30)$$

Where:  $K$  is the flow consistency index [ $\text{Pa s}^n$ ]; and  $n$  is the flow behavior index [no unit].  $n = 1$  for a Newtonian liquid,  $n < 1$  for a pseudoplastic liquid and  $n > 1$  for a dilatant liquid.

The viscosity of liquids decreases with increasing temperature, due to the higher molecular mobility. Gases, in contrast, not only have much lower viscosities than liquids but also show an increase in viscosity as temperature is increased (due to higher collision rates of the gas molecules at elevated temperatures). For example, water has a viscosity of  $1.002 \times 10^{-3} \text{ Pa s}$  at room temperature and  $0.35 \times 10^{-3} \text{ Pa s}$  at  $80^\circ\text{C}$ . Air, on the other hand, has a viscosity  $1.79 \times 10^{-5} \text{ Pa s}$  at room temperature. Amorphous solids in the glassy state have viscosities in the order of  $10^{12} \text{ Pa s}$  or higher.

## GASES

Gases play an important role in the pharmaceutical field, for example, in the use of medical gases (e.g., oxygen, nitrous oxide, carbon dioxide, compressed air, etc.), as functional excipients in aerosols and inhalers, and in quality control of drugs and dosage forms. Further, oxygen from the air may contribute to oxidative degradation of drugs, and water molecules from air can initiate hydrolytic degradation. Water molecules in air (especially at high relative humidity) may also decrease the physical stability of amorphous drugs or glass solutions, as we have seen, since water is a potent plasticizer, lowering the glass transition temperature of amorphous materials and thus increasing the likelihood of crystallization.

The gaseous state of matter is characterized by very weak interactions between the molecules (for real gases), which in fact are assumed to be completely absent for ideal gases (see below). The consequence of this is that in gases the molecules constantly change their positions by diffusion or convection and have a very low viscosity and density. This makes gases easily compressible under pressure (in contrast to liquids and solids). Also, in contrast to solids and liquids, different gases are always completely miscible with each other. For example, air is a mixture of several gases: approximately 78.1 percent nitrogen, 20.9 percent oxygen, 0.9 percent argon, 0.03 percent carbon dioxide, and small concentrations of neon, helium, methane, and other gases.

If we are completely disregarding the weak interactions between gas molecules, we can fully describe the behavior of gas by the ideal gas law. Historically, the properties of gases have been described in a set of laws, which we will have a quick look at first:

Boyle's law states that the product of absolute pressure ( $p$ ) and volume ( $V$ ) is constant ( $K_1$ ) at constant temperature:

$$pV = K_1 \quad (31)$$

Charles' law states that if a given mass of a gas is heated at constant pressure, the volume of the gas is directly proportional ( $K_2$ ) to its absolute temperature ( $T$ ):

$$V/T = K_2 \quad (32)$$

Avogadro's law states that equal volumes of pure gases at constant temperature and pressure contain the same number of particles ( $n$ ):

$$V/n = K_3 \quad (33)$$

The volume that one mole of gas molecules occupies (the molar volume) is 22.4 L at  $0^\circ\text{C}$  and a pressure of 1 atm. The number of molecules in a mol of gas is:  $6.022 \times 10^{23} \text{ mol}^{-1}$ .

These three laws can be regarded as special cases of the ideal gas law:

$$pV = nRT \quad (34)$$

Where:  $R$  is the ideal gas constant [ $8.314 \text{ J/(mol K)}$ ]. Note that  $K_1$  in Boyle's law is  $nRT$ ,  $K_2$  in Charles' law is  $nR/p$ , and  $K_3$  in Avogadro's law is  $RT/p$  in the ideal gas law.

Finally, if we take into account the ideal gas law (which assumes no interactions between the molecules forming the gas), we arrive at Dalton's law, which states that the total pressure ( $p_t$ ) of a mixture of gases equals the sum of their partial pressures ( $p_1$  to  $p_n$ ):

$$p_t = p_1 + p_2 + \dots + p_n \quad (35)$$

Related to Dalton's law is Henry's law, which states that at constant temperature the amount of a gas ( $n$ ) that dissolves in a given volume  $V$  ( $c = n/V$ ) of a given liquid is directly proportional ( $K_4$ ) to the partial pressure of that gas in equilibrium with the liquid ( $p_1$ ).

$$c/p_1 = K_4 \quad (36)$$

While all the above laws hold true for many gases over reasonable temperature and pressure ranges, and thus can be used fairly well to describe the behavior of gases, they do not take into account the fact that interactions between the gas molecules do take place and that the gas molecules occupy a part of the total volume of the gas (albeit usually a very small part). Deviations of the behavior of gases from the ideal situation become more important as, for example, pressure is increased or temperature is decreased. We can also understand this by the fact that gases can be liquefied if the temperature is lowered (this would not be possible if the gas molecules did not interact with each other). On the other hand, many gases behave very closely to ideal gases, and this can be seen, for example, if we determine the molar volumes of some gases. For the gases that make up more than 99 percent of air, we find that nitrogen, oxygen, and the noble gases indeed have molar volumes of 22.4 L. Other gases, though, already at  $0^\circ\text{C}$  and a pressure of 1 atm, have molar volumes that differ slightly from that of ideal gases. Methane and carbon dioxide, for example, have molar volumes of 22.3 L and ammonia of 22.1 L.

As stated above, for real gases we have to take into account that the gas molecules occupy a certain volume in the given volume of a gas and that interactions between the gas molecules can occur. These interactions, for example, could be dipole-dipole interactions if the gas molecules contain polar bonds (these interactions are termed Keesom forces). Even in the absence of permanent dipoles in the gas molecules, interaction can occur through transiently induced dipoles (London forces). Note that in the literature the expression “van der Waals force” is sometimes used to describe Keesom and London forces and sometimes specifically for London forces.

The van der Waals equation is one model that takes into account the non-zero volume of the gas molecules and the possible interactions between the gas molecules:

$$nRT = (p + an^2/V_m^2)(V_m - b) \quad (37)$$

For one mol of gas the equation simplifies to

$$RT = (p + a/V_m^2)(V_m - b) \quad (38)$$

Where:  $p$  is the pressure;  $T$  is the temperature;  $R$  is the ideal gas constant;  $V_m$  is the molar volume; and  $n$  is the number of molecules.

The parameters  $a$  and  $b$  are parameters that have to be empirically determined for each gas. The parameter  $a$  appears in the pressure term of the equation and relates to intermolecular interactions, whereas the parameter  $b$  appears in the volume term of the equation and relates to the fact that the gas molecules themselves occupy a certain volume of the gas.

It should be noted that the van der Waals equation is just one of many models that have been developed to better describe the behavior of gases, especially at extreme conditions, and that many other models exist. This is, perhaps, an opportune moment to remind us that a model is a mathematical description of a physical reality, and not the physical reality itself. It is up to the given situation (and possibly the required precision) as to which model is best used in a particular situation.

## PLASMA

We will finally briefly discuss the plasma state of matter. Plasma is actually the most common state of matter in the universe (for example, stars are matter in the plasma state). Plasma is formed by a phase transition from gases if these are heated to very high temperatures. At a certain temperature the electrons of the gas molecules or atoms leave the atoms, leading to an ionization of the gas. Plasma thus contains charged molecules or atoms and free electrons and conducts electricity (unlike gases). Due to the very high temperature of plasma, it is not particularly useful in the pharmaceutical field. Not all atoms however, need to be ionized for plasma to gain its typical properties. So most plasma consist of ions, electrons, and neutral molecules, which nevertheless are in an activated state, e.g., in the form of radicals (molecules containing one or more unpaired electrons).

It is also possible to create the plasma state from gases by electric discharge under reduced pressure, leading to "cold plasma". Cold plasma created in this way has found medical applications<sup>21</sup> and, for example, cold plasma from argon or oxygen has been used to irradiate polymer coats of tablets and granules.<sup>22,23</sup> This plasma irradiation leads to the emission of intensive UV radiation, which can lead to changes in the polymer structure, influencing, for example, drug release kinetics from these tablets or creating gastro-retentive, floating drug delivery systems.<sup>24</sup>

### INTRODUCTION

Thermodynamics rests upon three basic laws that took over 500 years to establish. Although quantum mechanics has defined the limits of its scope, the concepts embodied in the three laws have remained unchanged for over a century. Thus, thermodynamics provides unassailable, certain answers. As such, the great value, but also the main challenge, is using the simple concepts to understand complicated physical and biological phenomena. There are many texts available on the subject of thermodynamics ranging from introductory to complex, rigorous treatments. The approach in this chapter will involve the development of the concepts with pharmaceutically relevant examples. The purpose is to demonstrate how to make judicious assumptions to allow use of the rigorous definitions in thermodynamics to reveal the certainty in the complex field of pharmaceuticals.

To begin, the definitions of system, surroundings, universe, and boundaries are introduced. These, as well as all other definitions, must be clearly understood, otherwise thermodynamics will not be properly used. A *system* is that part of the *universe* under consideration and, as such, is separated from the *surroundings* or, equivalently, the rest of the universe. The focus of the analysis will center on how the properties of a system are altered through an interaction with the surroundings. Properties are those qualitative characteristics (e.g., type of phase, which may be solid, liquid, or gas) and quantitative characteristics (e.g., temperature, pressure) that describe the system. The interaction between the system and surroundings is controlled by the boundary and is revealed in the change in properties.

When a sufficient number of properties of the system have been specified with fixed values, then the system is at equilibrium. Certain systems at equilibrium have a simple equation that provides a relationship among the values of the properties. For example, a system containing an ideal gas (one component) has the properties of pressure,  $P$ , volume,  $V$ , number of mols,  $n$  and temperature,  $T$  (K), related by:

$$PV = nRT \quad (1)$$

where  $R$  is the gas law constant. Such a relationship is referred to as an *equation of state* because it specifies the relationship among the quantitative properties of a system in a definite state. Furthermore, if the system is at equilibrium, only three properties need to be specified, as the fourth may be calculated from the equation of state. Most pharmaceutically relevant systems are extremely complicated, because there are typically many components; the properties of each must be specified for the system to be at equilibrium.

### THE FIRST LAW

The first law of thermodynamics is a statement of the principle of conservation of energy; energy may neither be created nor be destroyed. It is mathematically written as:

$$dE = \delta q - \delta W \quad (2)$$

where  $dE$  is the differential change in the internal energy,  $\delta q$  is the differential change in the absorbed heat, and  $\delta W$  is the differential change in the expended work or work done.

The change in internal energy of a system in going from state A to state B is given by:

$$\Delta E = \int_A^B dE \quad (3)$$

The internal energy is a state function. A change in the value of a state function depends only on the initial and final state and does not depend on how the change in state was achieved. The symbol,  $d$ , is used and represents an exact differential. Another example of a state property is the temperature; that is, the change in temperature only depends on the initial and final temperatures and does not depend on how the temperature was changed (that is, the path followed). A cyclic change in a system describes a series of changes where the initial and final states have the same values for the state properties; one may say, the system “comes to a full circle.” For all cyclic processes, the change in all state properties is zero. Finally, the first law provides only a relation for the change in the internal energy and does not provide an absolute value. Thus like temperature, a zero point must be defined as well as a scale for a unit of energy, which were arbitrary until the scientific community reached a consensus.

Although it seems too obvious to point out that if the system has the same value of energy in the initial and final state that the change in energy would be zero, there are quantities that may not be zero even when a system undergoes a cyclic change. Two examples are heat flow and work done, which in the first law are described by inexact differentials, and the unique symbol,  $\delta$ , is used. Neither the heat nor the work is a state function and thus, the integral of the differential depends on the path taken. Mathematically, they are written as:

$$q = \int_A^B \delta q \quad (4)$$

$$W = \int_A^B \delta W \quad (5)$$

The work and heat may only be determined if more information is provided concerning how the change in the state of the system was achieved.

## WORK AND HEAT

The concept of *work* in thermodynamics is expressed as a product of an *intensity factor* and a *capacity factor*; for example, mechanical work is given as:

$$\delta W = Fdl \quad (6)$$

where the differential quantity of work done,  $\delta W$ , is the product of the force,  $F$  (intensity factor), and a differential change in distance,  $dl$  (capacity factor). Other types of work encountered in introductory physics include *gravitational* (gravitational potential and mass), *electrical* (potential difference and quantity of charge), and *volume expansion* or *PV work* (pressure and volume) Table 12.1. In pharmaceuticals, *surface work* (intensity and capacity factors are surface tension and area) is fundamental to understanding the instability of dispersed dosage forms. Chemical reactions can also be cast into the formalism of thermodynamic work as in the production of energy (work) in the conversion of ATP to ADP where the intensity factor is the chemical potential and the capacity factor is the number of moles. The essence of thermodynamics lies in understanding the conversion of one type of energy into another. Thus, in the following practical examples, the formalism is developed to reveal how these conversions can be described.

Some peculiarities of the work are that it appears only at the boundary and thus may be thought of as flowing into or out of the system. Work may be generated only through a change in the state of the system, and it is an algebraic quantity that may be positive or negative with units of energy,  $\text{Kgm}^2/\text{s}^2$ . The convention chosen here is that if the system does work on the surroundings, the work is a positive quantity; conversely, if the surroundings does work on the system, the work is a negative quantity.

The other quantity appearing in the first law is *heat*. It shares many properties with work. Specifically, it also appears at the boundary and only with a change in the state of the system. By definition, heat flow into the system is taken to be a positive quantity, which results in an increase in the internal energy of the system. For a system where there is no work done,  $\delta W = 0$ , the change in internal energy is given by the heat flow, so  $q$  often is referred to as a transfer of thermal energy.

Before providing the relationship among internal energy, heat flow, and temperature, the above definitions will be used in some examples of PV work associated with mechanical ventilation of the lung. It is important to note that the following represents one model constructs. Many others can be developed to describe breathing, where different assumptions are made. Because each construct involves assumptions, none is strictly correct. Nevertheless, the approach does provide insight and mechanistic understanding of the process of breathing.

In Figure 12-1a, a system (shown with dotted background) is shown as two connected chambers, each with a movable boundary (double lines) and a rigid boundary (single line). Everything else is in the surroundings. One side of the system has a spring, which represents the lung, and the other side represents air external to the lung but still is part of the system. In the initial state, the spring has no tension. In mechanical ventilation, a positive pressure is applied to inflate the lung, which

**Figure 12-1.** Schematic representation of the lung in the (a) initial state and (b) final state. The dotted region represents the system, which is separated from the surroundings by the boundary.

can be thought as a depression of the piston. As the piston is depressed, the pressure rises and gas will flow from the right to the left.

More information about the type of boundary must be provided. The pistons are allowed to move and thus that portion of the boundary is *movable*; other portions are *rigid*. For the first case, the boundary will be stipulated to be *diathermal*, which allows the passage of heat, and in the later case, it will be *adiabatic*, thereby preventing heat flow. Finally, the boundary is *closed* rather than *open*, so no mass transfer is allowed.

From the literature, the residual volume of an adult lung (i.e. volume without contraction of the diaphragm) is about 500 ml (0.5 L or 0.0005  $\text{m}^3$ ) at a temperature of 37 °C (310 K) and 1 atmosphere pressure (1 atm = ca  $1.0 \times 10^5$  Newtons/ $\text{m}^2$ ,  $\text{N}/\text{m}^2$  or Pascal, Pa). The lung on the left will be inflated with the 0.0005  $\text{m}^3$  air from the right hand side, also assumed to be at 310 K. Thus in the system, the initial total volume will be 0.001  $\text{m}^3$  of air, which can be taken to be an ideal gas. This allows the use of the equation of state to calculate the total number of moles of gas. That is:

$$n = PV/RT = [(1.0 \times 10^5 \text{ N/m}^2)(0.001 \text{ m}^3)] / [(8.314 \text{ J/molK})(310 \text{ K})]$$

$$n = 0.0388 \text{ moles} \quad (7)$$

In Figure 12-1b, the system is shown in the final equilibrium state. In the final state, the movement of the gas from the right chamber into the ‘lung’ caused the spring to stretch. In fact, with mechanical ventilation, a positive pressure is applied to inflate the lung, which is typically about 35 cm of water. The latter is a peculiar unit for pressure, because it seems to have units of ‘length’. However, a column of water with a height of 35 cm exerts a pressure, which is calculated as:

$$\Delta P = \text{density} \times \text{acceleration constant} \times \text{height of liquid}$$

$$= (1000 \text{ kg/m}^3)(9.8 \text{ m/s}^2)(0.35 \text{ m})$$

$$= 3430 \text{ N/m}^2 \quad (8)$$

**Table 12-1. Types of Work and the Associated Intensity and Capacity Factors.**

Work	Intensity factor	Capacity factor	Typical units	SI units
Mechanical	Force	Distance	Newton-meter	$\text{Kgm}^2/\text{s}^2$
Gravitation	Acceleration	Mass	( $\text{Meter}^2/\text{s}^2$ )-kilogram	$\text{Kgm}^2/\text{s}^2$
Electrical	Electrical potential	Charge	Volt-Coulomb	$\text{VC} = \text{Kgm}^2/\text{s}^2$
Pressure-volume	Pressure	Volume	( $\text{Newton}/\text{meter}^2$ )- $\text{meter}^2$ Also $\text{Pa}\cdot\text{m}^3$	$\text{Kgm}^2/\text{s}^2$
Surface work	Surface tension	Area	$\text{Newton}/\text{m}\cdot\text{meter}^2$	$\text{Kgm}^2/\text{s}^2$
Chemical work	Chemical potential	Moles	( $\text{Joules}/\text{moles}$ )-moles	

An initial state and final state have been given, which allows the change in state to be determined. It perhaps is worth emphasizing that thermodynamics provides only information on the change between the initial and final state. The initial pressure was  $1.0 \times 10^5 \text{ N/m}^2$ , and the final pressure is higher at  $1.034 \times 10^5 \text{ N/m}^2$ . Because the pressure is higher and the temperature is assumed constant (isothermal), there must have been a reduction in volume. That is:

$$W = \int PdV \quad (9)$$

This type of change in state is described as an isothermal compression of an ideal gas. The work can be obtained using the following equation:

$$W = \int PdV \quad (10)$$

However, to calculate the work, more information is needed as to how the lung was inflated; really how the gas was compressed. In essence, the path must be given. An unrealistic, but simple path would be to assume that the gas was instantaneously compressed to the final pressure of  $1.034 \times 10^5 \text{ Pa}$ , which was maintained constant. The work done by compressing the gas with a constant pressure can be calculated as follows, where the pressure is moved in front of the integral:

$$W = P_{\text{ext}} \int dV = P_{\text{ext}} (V_f - V_i) = (1.034 \times 10^5 \text{ N/m}^2)(-0.000034 \text{ m}^3) \\ = -3.41 \text{ J} \quad (11)$$

The negative quantity reflects the fact that the surroundings did work on the system.

Assuming a different path, which represents perhaps a better assumption, the pressure is initially at  $1.0 \times 10^5 \text{ N/m}^2$ , but the applied pressure increases continuously as the compression occurs. To integrate the  $PdV$  term in the expression for the work, the pressure, which now changes, can be replaced using the equation of state,  $P = nRT/V$ . The expression becomes:

$$W = \int (nRT/V)dV \quad (12)$$

We have stipulated that the temperature is constant, and so  $n$ ,  $R$ , and  $T$  can be moved in front of the integral:

$$W = nRT \int (dV/V) = nRT \ln(V_f/V_i) \\ = (0.0388 \text{ mol})(8.314 \text{ J/molK})(310 \text{ K}) \ln(0.000967/0.001) \\ = -3.36 \text{ J} \quad (13)$$

First, it should be noted that the changes in state properties, which are exact differentials, were used to calculate the work. Second, the changes in the state properties for the two processes are identical-i.e. independent of path. Third, the amount of work required to compress the system differs and therefore is seen to be dependent on how the compression was carried out.

By virtue of the definition of an ideal gas, the internal energy is only a function of temperature. Because our system was isothermal with no change in temperature, the internal energy of the system is constant, i.e.,  $\Delta E = 0$ , and therefore from the first law:

$$q = W \quad (14)$$

Therefore, during the isothermal compression of an ideal gas with a constant pressure, the heat was  $-3.41 \text{ J}$ , which as a negative quantity represents the amount lost to the surroundings. Compression with a continually rising pressure, the heat was  $-3.36 \text{ J}$ , representing a smaller absolute value of heat loss to the surroundings. The latter case is actually unique in that it represents the minimum heat and work required to achieve the change in state. Moreover, we could return the system to the original state by following the same path in the opposite direction. That is, an isothermal expansion resulting in  $3.36 \text{ J}$  of work done by the system and  $3.36 \text{ J}$  of heat flow into the system. This unique type of change in the system is referred to as being "reversible". All other paths are denoted as irreversible. It should also be noted that all changes in the real world are "irreversible", whereas many of the calculations of thermodynamics involve the assumption of reversibility. As such, thermodynamics

often provides the theoretical maximum, which can be used to limit practical possibilities.

The spring was placed in our diagram to represent the stretching of lung tissue. From this construct, the elasticity of the tissue can be assessed. The work in stretching a spring is given by the product of an intensity factor (spring constant,  $k$ ) and a capacity factor (length,  $l$ ):

$$W_{\text{El}} = \int kdl \quad (15)$$

where the elastic work will equal the PV work, if this is the only biologically relevant aspect of lung expansion (it is not), then,

$$W_{\text{El}} = W_{\text{PV}} = -3.36 \text{ J} \quad (16)$$

Because alveoli double in volume with lung expansion and a typical size of alveoli is  $300 \mu\text{m}$  or  $3 \times 10^{-4} \text{ m}$  (relative length change,  $\Delta l/l = 0.5$ ), Young's modulus,  $Y$ , of the lung can be estimated to be:

$$Y = W_{\text{El}}/(\Delta l/l) = |-3.36/0.5| = 6.72 \text{ Nm} \quad (17)$$

This is equivalent to a spring that stretches 1 meter when adding a 1 kg weight,  $(1 \text{ kg})(9.8 \text{ m/s}^2)(1 \text{ m}) = 9.8 \text{ Nm}$ . It should be not lost to the reader that a quantitative analysis has just been provided for the conversion of one form of work or energy (PV) to another form of work (elastic), which is can be generalized to any process of energy conversion.

To demonstrate the influence of other types of barriers, consider the process of compression with an adiabatic barrier that does not allow the flow of heat,  $q = 0$ . In this case, the work done causes an increase in the internal energy. For compression against a constant pressure, the work is still  $-3.41 \text{ J}$ , but the change in internal energy must now be calculated as:

$$\Delta E = \int dE = -W = 3.41 \text{ J} \quad (18)$$

Therefore, work was done on the system resulting in an increase in internal energy of  $3.41 \text{ J}$ . This increase in internal energy will result in a change in temperature and/or volume.

The relationship between internal energy and temperature is expressed by the heat capacity. The value of the heat capacity depends on the path, that is, whether the temperature change occurred under constant volume or constant pressure. For heat capacity at constant volume,  $C_v$ , the definition is:

$$C_v \equiv dq_v / dT \quad (19)$$

Rearranging:

$$\int dq_v = \int C_v dT \quad (20)$$

and integrating with the assumption that the heat capacity is constant over the range of  $\Delta T$ :

$$q_v = C_v \Delta T \quad (21)$$

However, the heat flow at constant volume will equal the change in internal energy, because the work is zero when only PV work is allowed.

$$\Delta E = q_v + \int PdV = q_v = C_v \Delta T \quad (22)$$

In our example, the change in temperature may be calculated, since the value of  $C_v$  for a monatomic ideal gas is  $(3/2)R$ , where  $1/2R$  is allotted to each mode of translation motion in the  $x$ ,  $y$ , and  $z$  direction. Because air is composed of nitrogen and oxygen, which are diatomic molecules, a better estimate of  $C_v$  would be  $(5/2)R$ , which provides an additional  $1/2R$  to the two possible modes of rotational motion. The actual value of the heat capacity can also be found on the internet,  $20.76 \text{ J/Kmol}$ , which is very close to  $(5/2)R$ . Thus, the temperature change is calculated by:

$$\Delta T = \Delta E/nC_v = (3.41 \text{ J})/[(0.0388 \text{ mol})(20.76 \text{ J/Kmol})] = 4.23 \text{ K} \quad (23)$$

With the number of moles and final pressure and temperature, the volume may be calculated,  $0.00098 \text{ m}^3$ , which is larger than that obtained for the isothermal compression, but consistent with the higher temperature.

**Figure 12-2.** Pressure given as a function of volume for an ideal gas. The stars with associated letters represent states of the system, the solid lines represent isotherms and the dotted lines represent paths along which the system changes.

At this point, there can be some concern about the use of the heat capacity at constant volume to calculate the temperature change for a process when the volume was not constant. However, internal energy and temperature are state properties, and so their values do not depend on the path, and so we choose the most convenient path for the calculation. This is shown in Figure 12-2. The path taken in the above example was A to B to C, but the change in state properties can be calculated as if the system underwent an isothermal compression from A to E and then a constant volume increase in pressure and temperature from E to C, because the result does not depend on path. With this path, there is no conceptual problem in using the heat capacity at constant volume to describe the temperature change from point A to point C (noting there is no change in  $\Delta E$  for the isothermal process of A to E) (See Figure 12-2).

To review, the first process was irreversible, isothermal compression at constant volume, where the system began at point A, the pressure was instantaneously increased to reach point B (not an equilibrium state), and then the system underwent compression to point D. In the second process, the system was reversibly compressed as it moved along curve T1 from point A to point D. Curve T1 is an isotherm, which consists of a set of equilibrium states that have the same temperature (310 K). The system was moved through these states of equilibrium by carrying out the process in a reversible manner. The work associated with these two processes is given by the area under the curves (process 1: area of rectangle beneath line from B to D; process 2: area under curve T1 in moving from points A to D). The latter has a smaller area corresponding to a smaller work. The third process was an irreversible, adiabatic compression, which would follow the path of A to C, but because there is no heat flow, the system would have a higher ending temperature and corresponding volume as indicated by point C.

It is also possible to solve for the ending temperature by using the path of A to D to C. A to D is an isothermal compression but D to C is an expansion at constant pressure. The heat capacity at constant pressure is defined as:

$$C_p \equiv (dq_p / dT) \quad (24)$$

where  $q_p$  is the heat flow associated for a constant pressure process. This may also be integrated with the analogous integrated form being:

$$q_p = C_p \Delta T \quad (25)$$

Because many changes occur under the condition of constant pressure, it was expedient to define another state function, the *enthalpy*,  $H$ .

$$H \equiv E + PV \quad (26)$$

The definition is given in terms of state properties of the system; however, to determine the change in the system, the differential is taken, resulting in:

$$dH = dE + d(PV) \quad (27)$$

Expansion of the latter term yields:

$$dH = dE + PdV + VdP \quad (28)$$

but because the pressure is constant,  $VdP = 0$ , the change in enthalpy becomes:

$$dH = dE + PdV \quad (29)$$

However, from the first law the change in energy of systems restricted to  $PV$  work is:

$$dE = \delta q_p - PdV \quad (30)$$

where  $\delta q_p$  is the heat absorbed under constant pressure. Combining the latter two equations reveals:

$$dH = \delta q_p \quad (31)$$

or with integration:

$$\Delta H = q_p \quad (32)$$

which implies that the enthalpy is no more than the heat absorbed by the system under the condition of constant pressure. Please note that the enthalpy change can be related to the normally path dependent heat flow,  $q_p$ .

In the final example, a cyclic change will be examined as shown schematically in Figure 12-3. The system begins at point A, and path 1 is a reversible adiabatic compression to point B. Path 2 consists of a reversible increase in volume at constant pressure to point C. Path 3 in C going to D is a reversible adiabatic expansion, and path 4 is an reversible isobaric compression. This may typify inflating the lung with a given volume of air, which then undergoes heating. The air in the lung is then exhaled and then undergoes cooling. For this problem at point A, the pressure is  $1.0 \times 10^5$  Pa, the temperature is 300 K, and the number of moles is 0.04, and at point C, the temperature is 310 K. For simplicity, the temperature will be taken to be 305 at points B and D.

*Problem:* The problem is to find the pressure and volume at each point, and for each process find  $w$ ,  $q$ ,  $\Delta E$ , and  $\Delta H$ , as well as the values for the entire cycle ( $w_c$ ,  $q_c$ ,  $\Delta E_c$ ,  $\Delta H_c$ ).

*Answer:* Step 1: Adiabatic compression

To begin, the volume at A is given by:

$$V = nRT/P = (0.04)(8.314)(300)/(1.0 \times 10^5) = 0.001 \text{ m}^3 \quad (33)$$

Although the work may be found by:

$$w = \int PdV = \int (nRT/V)dV \quad (34)$$

This is not helpful in and of itself because the pressure, volume, and temperature change with an adiabatic compression. It can be noted that the heat flow is zero ( $\delta q = 0$ ), so:

$$-\delta W = dE = C_v dT = -(nRT/V)dV \quad (35)$$

**Figure 12-3.** Pressure given as a function of volume for an ideal gas. The system undergoes a cyclic change beginning and ending at point A following the paths given by the solid lines.

The variables in the latter two terms can be separated and then integrated as:

$$\int (C_v/T)dT = -\int (nR/V)dV \tag{36}$$

To yield:

$$C_v * \ln(T_2/T_1) = -nR * \ln(V_2/V_1) \tag{37}$$

Simplifying:

$$(T_2/T_1)^{(C_v/nR)} = V_1/V_2 \tag{38}$$

With  $C_v = 5nR/2$  and  $V_2 = 0.00096 \text{ m}^3$ .

We note that  $\Delta E = \int nC_v dT = nC_v \Delta T = (0.04)(5/2)R*(305-300) = 4.16 \text{ J}$ , which is also negative of the work. Finally, we note that  $\Delta H$  must be zero, because there is no heat flow.

Step 2: Isobaric expansion to a final temperature of 310. With the pressure constant, then:

$$T_3/T_2 = V_3/V_2 \tag{39}$$

Solving for  $V_3$ :

$$(310/305)*0.00096 = 0.000976 \text{ m}^3 \tag{40}$$

Work is straightforward with the pressure constant:

$$P_2 = P_3 = nRT/V = 1.057 \times 10^5 \text{ Pa}$$

$$W = P \int dV = P\Delta V = (1.057 \times 10^5) (0.000976 - 0.00096) = 1.69 \text{ J} \tag{41}$$

The change in internal energy,  $\Delta E$ :

$$\Delta E = C_v * \Delta T = 0.04*(5/2)R*(310 - 305) = 4.16 \text{ J} \tag{42}$$

The heat flow may be calculated from the work and change in internal energy:

$$q = \Delta E + W = 4.16 + 1.69 = 5.85 \text{ J} \tag{43}$$

The change in enthalpy is equal to the heat flow at constant pressure, thus:

$$\Delta H = qp = 5.85 \text{ J}$$

$$\text{But } \Delta H = \Delta E + \Delta(PV) = \Delta E + \Delta(nRT) = 4.16 + (0.04 * 8.314 * 5) = 5.85 \text{ J} \tag{44}$$

Step 3: Adiabatic expansion to a final temperature of 305 K, which much like step 1.

$$\Delta E = \int C_v dT = (0.04)(5/2)R(305 - 310) = -4.16 \text{ J} \tag{45}$$

At zero heat flow ( $\Delta H=0$ ):

$$W = -\Delta E = 4.16 \text{ J} \tag{46}$$

Step 4: Isobaric compression, which is much like step 2.

$$W = P \int dV = (1.0 \times 10^5) * (0.001 - 0.001014) = -1.4 \text{ J} \tag{47}$$

All of the values are given in Table 12-2 and Table 12-3.

In the Table 12-3 final example, the thermodynamic approach that led to the discovery of lung surfactant is given. In 1972, Clements and co-workers reported the following experiment. An experimental animal was anesthetized and the expansion of the lung was measured as a function of applied pressure. The lungs were then rinsed with water to remove a frothy substance at the surface, and the measurement was repeated. It was noted that the work, which is associated with lung expansion:

$$W = \int PdV \tag{48}$$

**Table 12-2. Values of the Pressure, Temperature, and Volume for the Cyclic Change Described in Text and Schematically Illustrated in Figure 12-3.**

Point	A	B	C	D
P, Pa	$1.0 \times 10^5$	$1.057 \times 10^5$	$1.057 \times 10^5$	$1.0 \times 10^5$
V, m <sup>3</sup>	0.001	0.00096	0.000975	0.001014
T, K	300	305	310	305

**Table 12-3. Values for the Work and Heat and the Change in Energy and Enthalpy for Each Step for the Cyclic Change Described in Text and Illustrated in Figure 12-3.**

Step	1	2	3	4	Total
W, J	-4.16	1.69	4.16	-1.4	0.29
Q, J	0	5.85	0	-5.85	3.04
$\Delta E$ , J	4.16	4.16	-4.16	-4.16	0
$\Delta H$ , J	0	5.85	0	-2.74	0

as revealed in the area under the curve of a plot of pressure as a function of volume, was significantly greater in the lung that was rinsed relative to the control. It was argued that rinsing the lung would not be expected to affect tissue elasticity, and thus, an additional contribution to the work of expansion must exist. Moreover, they noted that the frothy material extracted from the lung caused a reduction in the surface tension at the air/water interface. They proposed that the total work of lung expansion involves a contribution from elasticity and from surface work:

$$W_{PV} = W_{El} + W_{sur} \tag{49}$$

Where:

$$W_{sur} = \int \gamma dA \tag{50}$$

Additional work revealed that the material responsible for lowering the surface tension was a mixture of lipids and proteins, which was called, lung surfactant. The production of lung surfactant occurred late in the pregnancy, because it is not required until birth, when the infant must inflate the lungs to replace the amniotic fluid with air. The conclusion was that prematurely born infants had insufficient lung surfactant, which could be treated by providing a replacement. In the early 1990's, the first replacement therapy was introduced. Moreover, the improvement in premature infant survival that has since been realized can be attributed in part to this discovery and subsequent development and administration of these products.

## ENTROPY AND THE SECOND LAW

Although the first law provides the framework for calculating the change in energy associated with chemical reactions or physical changes in state, there is insufficient information to allow prediction of the likelihood of whether the change will occur. Consider a system composed of two parts that are at different temperatures,  $T_1$  and  $T_2$ , separated by an impermeable, adiabatic partition. When the partition is removed, heat will flow from the part at a higher temperature to the part at a lower temperature. According to the first law, the energy of the whole system, the sum of parts one and two, has not changed.

Intuitively it is known that the above change will occur regardless of the fact that the first law does not provide a method of predicting the occurrence. Such changes are described as *spontaneous*, for the obvious reason that they occur without additional stimulation. It should be noted that this spontaneous change involved an increase in the disorder or, if you will, the randomness of the system. Thus, the system initially was separated into two parts at different temperatures, but after thermal contact, a uniform temperature was reached. The *entropy*,  $S$ , is the function that provides a quantitative description of the randomness or disorder of the system and is fundamental for predicting the spontaneity of chemical reactions and physical changes. The entropy is a state function that depends only on the initial and final state of the system.

The definition of the entropy change is given by the seemingly surprising form:

$$dS = \delta q_{\text{rev}} / T \quad (51)$$

where the subscript *rev* denotes that the heat flow occurs in a reversible manner. By carrying out the integration, the change in entropy for a reversible, isothermal change from state 1 to state 2 is given by:

$$\Delta S = \int \delta q_{\text{rev}} / T = q_{\text{rev}} / T \quad (52)$$

With the introduction of entropy, the second law may be stated as follows: For any spontaneous process in an isolated system, there is an increase in the value of entropy. Alternatively, the first and second laws may be combined with the classic thermodynamic statement, "the energy of the universe is constant; the entropy is increasing."

Historically, Carnot analyzed the efficiency of such a theoretical cycle, which has come to be known as the Carnot cycle. This can be found in most texts on thermodynamics, although it typically involves isothermal and adiabatic processes in the context of what is known as a heat engine. Nevertheless, the premise is that by permitting the flow of heat into a system, work may be done by the system. The second law dictates that not all of the heat may be converted into work, even if all changes occur in a reversible manner. In fact, the maximum work,  $W_{\text{max}}$ , that may be obtained is specified by the heat flow into the system and the temperature difference over which the heat engine is operating; that is:

$$W_{\text{max}} = q_1(T_1 - T_2) / T_1 \quad (53)$$

where  $T_1 > T_2$ . The proof of this equation can be established by calculating the heat and work for each step and noting that not all of the heat energy may be converted into work. This can be seen from Table 12-3. The heat flow into the system occurs with the second step. The efficiency of an engine  $\epsilon$ , is given by the amount of work extracted divided by the heat flow into the system:

$$\epsilon = W_{\text{tot}} / q_1 \quad (54)$$

where  $W_{\text{tot}} = W_{\text{max}}$  for reversible changes. The efficiency is proportional to the difference in temperature between the heat reservoirs. In addition, there is no work done unless there is a difference in temperature between the heat reservoirs. Finally, 100% efficiency is obtained only when  $T_2 \rightarrow 0$ , which as will be noted from the third law, is impossible.

The above analysis elucidates the connection between entropy and heat flow. The second law provides the quantitative limit on the amount of work that can be done with a cyclic operation performed in a reversible manner.

Given the above background, the entropy changes associated with several reversible processes may be determined. Consider the vaporization of water in the context of the lung, which is known to carry out the important function of humidifying air. Let us assume that initially that the inhaled air contains no water vapor, but is at 310 K, and the final state is air saturated with water at 310 K. To calculate the amount of water that must be evaporated to saturate the air, the saturation vapor pressure of water in air can be found. The value from the internet is 47 mm Hg. Using the approach from above, the moles of water that must undergo the phase change from a liquid at 310 to a vapor at the same temperature is 37 mm Hg or (37 \* 133 Pa/mm Hg =) 4921 Pa. The number of moles is found with the ideal gas law:

$$n/V = P/RT = (4921)/(8.314*310) = 1.91 \text{ moles/m}^3 \quad (55)$$

or for a typical inhalation volume of 0.001 m<sup>3</sup>, 1.91 × 10<sup>-3</sup> moles.

The entropy of vaporization,  $\Delta S_{\text{vap}}$ , is given by:

$$\int dS = \int \delta q / T_b \quad (56)$$

which may be determined from  $\int \delta q = q_p = \Delta H$ , but this is the value at the boiling point. We will return to this point below, but for now, consider the problem as occurring at the boiling point.

The molar heat of vaporization of water at the boiling point is 40.65 kJ/mol. Thus:

$$\int dS = \Delta H_{\text{vap}} / T_m \quad (57)$$

$$\Delta S = 40650/373 = 109 \text{ J/mol K}$$

In our problem, the number of moles was 1.91 × 10<sup>-3</sup> leading to the total entropy change of 0.208 J/K. The positive change in entropy confirms the intuition concerning such an event; gases are in a state of more disorder than liquids, thus the entropy also is greater in the vapor state in comparison to the liquid state.

The discussion, thus far, has been limited to reversible processes that are strictly impossible to achieve in the laboratory (even though such a process may be approximated very closely). The question arises as to what the entropy change is for an irreversible change. Here the entropy change is given by:

$$dS > \delta q_{\text{irr}} / T \quad (58)$$

Thus, all real processes may be written as:

$$dS \geq \delta q / T \quad (59)$$

This concept may be extended to determine the condition of spontaneity. Consider a system that is transformed irreversibly from state 1 to state 2 and then reversibly from state 2 back to state 1. The overall change is given by:

$$\int_{\text{State 1}}^{\text{State 2}} \delta q_{\text{irr}} / T + \int_{\text{State 2}}^{\text{State 1}} \delta q_{\text{rev}} / T < 0 \quad (60)$$

$$\int_{\text{State 1}}^{\text{State 2}} \delta q_{\text{irr}} / T + \int_{\text{State 1}}^{\text{State 2}} dS < 0 \quad (61)$$

which may be rearranged, with changing the limits of integration, to yield:

$$\int_{\text{State 1}}^{\text{State 2}} \delta q_{\text{irr}} / T < \int_{\text{State 1}}^{\text{State 2}} dS \quad (62)$$

or, equivalently, for infinitesimal changes:

$$\delta q_{\text{irr}} / T < dS \quad (63)$$

This is known as the *Clausius inequality*. For isolated systems, where boundaries do not permit the passage of energy or matter,  $\delta q_{\text{irr}} = 0$ , the result is given:

$$dS > 0 \quad (64)$$

That is, for every spontaneous change in an isolated system there is an increase in the entropy.

The second law may be generalized in another way. The total entropy for any process is given by the sum of the entropy of the system and the surroundings; that is:

$$dS_{\text{tot}} = dS_{\text{sys}} + dS_{\text{surr}} \quad (65)$$

For reversible processes, the entropy change in a system is the negative of the entropy change produced in the surroundings. The total entropy, therefore, is zero. For irreversible processes, the total entropy, system plus surroundings, increases. The mathematical statement of this relationship is:

$$\sum \Delta S_{\text{tot}} = 0 \text{ reversible process} \quad (66)$$

$$\sum \Delta S_{\text{tot}} > 0 \text{ irreversible process} \quad (67)$$

## THE THIRD LAW

The third law of thermodynamics simply defines the zero point of the entropy scale. The entropy of a pure, perfectly crystalline substance is zero at absolute zero. Intuitively, a system that has perfect three-dimensional order should have no entropy at the lowest possible temperature. The defining of a zero for the entropy is unlike the other state functions introduced previously. Thus, the value of the entropy,  $S$ , of a system in any state, in principle, may be calculated.

What would be the entropy of a crystalline solid at 150 K,  $S_{150}$ ? This may be calculated as:

$$\Delta S = S_{150} - S_0 \quad (68)$$

$$\Delta S = \int (c_p / T) dT - 0 \quad (69)$$

or:

$$\Delta S = S_{150} \quad (70)$$

If the heat capacity over the range of 0 to 150 K is known, the value of the entropy may be calculated.

## FREE ENERGY

The concept of *free energy* is probably the most useful aspect of thermodynamics. The criteria for determining the spontaneity of a chemical reaction or phase change were presented above; however, it involved carrying out the change in an isolated system. One can imagine how inconvenient and often impossible it would be to apply such a constraint to the laboratory setting. For this sake, additional state functions have been defined to allow prediction of the spontaneity of a change in state. The rationale for the development of other functions was to allow maximum flexibility in their application. The two functions introduced are *Helmholtz free energy*,  $A$ , and *Gibbs free energy*,  $G$ . The functions for predicting spontaneity are:

1. Isolated system:  $dS > 0$
2. Isothermal and isochoric system:  $dA < 0$
3. Isothermal and isobaric:  $dG < 0$
4. Constant volume and entropy:  $dE < 0$

Helmholtz free energy is defined as:

$$A \equiv E - TS \quad (71)$$

Helmholtz free energy is the energy available to do pressure-volume work for reversible isothermal processes; a decrease in the Helmholtz free energy is equal to the capacity of the system to do work. An alternative view is that, for systems at constant volume and temperature, a change in state is spontaneous if, and only if, there is a decrease in the Helmholtz free energy. Thus, with the introduction of  $\Delta A$ , the spontaneity of changes occurring at constant volume and temperature may be predicted.

As most reactions carried out in the laboratory are under conditions of constant pressure and temperature, Gibbs free energy is the most useful function and is defined as:

$$G \equiv E + PV - TS \quad (72)$$

which can be converted into a more usable form by an analogous method used with the Helmholtz function. Taking the differential and applying the constraints of constant pressure and temperature yields:

$$dG = dE + PdV - TdS \quad (73)$$

but  $dE = \delta q - \delta W = TdS - \delta W$ ; thus, upon substitution:

$$-dG = \delta W - PdV \quad (74)$$

A decrease in Gibbs free energy is equal to the non-PV work done by the system or, equivalently:

$$dG = -\delta W_{(\text{non-PV})} \quad (75)$$

which also provides the conditions of a spontaneous change under the constraints of constant temperature and pressure. A direct application of the relationship between Gibbs free energy and non-PV work is used in potentiometry.

These relationships for predicting spontaneity often are expressed in a differential form, which presents the state functions in a concise manner as well as facilitating their use to specific problems. The four differential equations are:

$$dE = TdS - PdV \quad (76)$$

$$dH = TdS + VdP \quad (77)$$

$$dA = -SdT - PdV \quad (78)$$

$$dG = -SdT + VdP \quad (79)$$

These expressions represent the four fundamental equations of thermodynamics, which in reality are four ways of looking at one fundamental equation describing the conditions of spontaneity.

$Q$ —One mol of liquid water is vaporized reversibly at 100° and 1 atm pressure. The molar heat of vaporization is 40.65 kJ/mol; what are  $qp$ ,  $\Delta H$ ,  $\Delta E$ ,  $\Delta A$ ,  $\Delta G$ , and  $\Delta S$ ?

$A$ —The value of  $qp$  actually is given in the question, as the heat required to vaporize 1 mol of liquid is the definition of the molar heat of vaporization; thus,  $qp_3 = 40.65$  kJ. Recognizing that the pressure is constant,  $\Delta H = qp = 40.65$  kJ. To calculate  $\Delta E$ , the work first must be determined. The work is given by:

$$W = \int PdV = P\Delta V \quad (80)$$

$$W = P(V_g - V_l)$$

However, the volume of the gas,  $V_g$ , is much larger than the volume of the liquid,  $V_l$ , which implies that the work is given by:

$$W \approx PV_g \quad (81)$$

Assuming the gas is ideal, the work is:

$$W = nRT = (1 \text{ mol})(8.314 \text{ J/mol K})(373 \text{ K}) = 3100 \text{ J} \quad (82)$$

From the above,  $\Delta E$  may be calculated from:

$$\Delta E = q - w = 40650 - 3100 = 37550 \text{ J} \quad (83)$$

The change in entropy was determined above:

$$\Delta S = \Delta H / T_m = 40650 / 373 = 109 \text{ J/k.} \quad (84)$$

Helmholtz free energy is given by:

$$\Delta A = \Delta E - T\Delta S = 40650 - (373)(109.0) = -3100 \text{ J} \quad (85)$$

which also may have been obtained by recognizing that:

$$\Delta A = -W_{\text{rev}} = -3100 \text{ cal} \quad (86)$$

Finally, the change in Gibbs free energy is determined from:

$$\Delta G = \Delta E + P\Delta V - T\Delta S = 37550 + 3100 - (373)(109) = 0 \text{ cal} \quad (87)$$

which, too, may have been obtained by recognizing the absence of non-PV work.

## STANDARD MOLAR GIBBS FREE ENERGY

The fundamental equation for Gibbs free energy has been given as:

$$dG = -SdT + VdP \quad (88)$$

Consider the change in free energy with pressure at constant temperature. One may begin by defining a standard free energy,  $G^\circ(T)$ , which corresponds to the free energy of the ideal gas under a pressure of 1 atm. Because the temperature is constant, the change in free energy is given by:

$$\int dG = \int VdP \quad (89)$$

between the limits of 1 atm and the pressure,  $P$ . For an ideal gas, the volume is a strong function of pressure; thus, with substitution, and after integration, the result is:

$$G(T, P) - G^\circ(T) = \int (nRT / P) dP \quad (90)$$

Simplifying yields:

$$G = G^\circ + nRT \ln P \quad (91)$$

Dividing through by the number of mols gives:

$$G/n = G^\circ/n + RT \ln P \quad (92)$$

Molar free energy,  $G/n$ , is encountered so frequently it is given a special symbol,  $\mu$ , and Equation 82 is written as:

$$= \mu^\circ + RT \ln P \quad (93)$$

The molar free energy also is referred to as the *chemical potential*.

## NON-IDEALITY

Equation 93 describes the molar free energy of an ideal gas, but for real gases the molar free energy is not related directly to the pressure. Thus, a function, the *fugacity*,  $f$ , has been introduced, which provides the same functional form of equation for a real gas:

$$= \mu^\circ + RT \ln f \quad (94)$$

The fugacity is related to the pressure by the following equation, which is provided without derivation:

$$\ln f = \ln P + (1/nRT) \int (V - V_{id}) dP \quad (95)$$

where  $V_{id}$  represents the volume of an ideal gas. This equation may be justified by considering the assumptions of an ideal gas, which are that the molecules are point particles without volume, and no intermolecular attractive or repulsive forces. Both of these effects have a direct impact on the measured volume; thus, the fugacity may be conceived as a function that corrects for inaccuracies of these assumptions. Clearly, the fugacity approaches the pressure as the real volume approaches the ideal volume.

A similar approach is applied when dealing with mixtures. Consider the molar free energy of a mixture of gases. From Raoult's law, the partial pressure,  $P_i$ , of a gas is given by:

$$P_i = x_i P \quad (96)$$

where  $x_i$  is the mol fraction of the  $i$ th component and  $P$  is the total pressure. Molar free energy is:

$$= \mu_i^\circ(T) + RT(\ln P + \ln x_i) \quad (97)$$

For the purposes of evaluating mixtures, it generally is more convenient to define a new standard state,  $\mu_i^\circ(T, P)$ , which consists simply of the pure gas at 1 atm, thereby yielding:

$$\mu_i = \mu_i^\circ(\text{pure})(T, P) + RT \ln x_i \quad (98)$$

In fact, this equation is applicable not only to the gas state but any ideal state of aggregation. This becomes more apparent by letting the mol fraction go to unity (that is, a pure substance), whence the logarithmic term goes to zero and the molar free energy is equal to the standard-state molar free energy.

For solutions, there is a corresponding term that describes the departure for an ideal mixture, the *activity*,  $a$ . Equation 88 is applicable only for ideal mixtures. However, with the introduction of the activity,  $a$ , the above expression may be written as follows, which is general for all mixtures:

$$\mu_i = \mu_i^\circ(T, P) + RT \ln a_i \quad (99)$$

For solutions,  $\mu_i^\circ(T, P)$  is the molar free energy of the liquid in the pure state.

## EQUILIBRIA

*Equilibrium* is related intimately to spontaneity, thus the functions above used to predict the spontaneity also may be used for establishing conditions of equilibrium. In essence, if no spontaneous change is predicted, the system is at equilibrium. Consider the following chemical reaction for an ideal gas:

For this reaction, the equilibrium constant is written as:

$$K = P_B^b / P_A^a \quad (101)$$

Let the molar free energy of each component for the condition of equilibrium be defined as  $G_A$  and  $G_B$ , and as  $G_A'$  and  $G_B'$  for the nonequilibrium state. The changes in free energy at equilibrium and in a nonequilibrium state are given as:

$$\Delta G = bG_B - aG_A \quad (102)$$

$$\Delta G' = bG_B' - aG_A' \quad (103)$$

The change in free energy between these two states is given by the difference between the changes in free energy; that is:

$$\Delta G' - \Delta G = b(G_B' - G_B) - a(G_A' - G_A) \quad (104)$$

The difference between  $G_B'$  and  $G_B$  may be calculated for an ideal gas with the use of the fundamental equation given above:

$$dG = VdP - SdT \quad (105)$$

which is related, under the condition of constant temperature, as:

$$dG = VdP \quad (106)$$

$$\Delta G = \int VdP \quad (107)$$

$$\Delta G = \int (nRT/P)dP \quad (108)$$

After integration between limits of the two states, it yields:

$$\Delta G = nRT \ln(P_B'/P_B) \quad (109)$$

Substituting into the Equation 104, to find the overall change in  $\Delta G$ :

$$\Delta G' - \Delta G = bRT \ln(P_B'/P_B) - aRT \ln(P_A'/P_A) \quad (110)$$

The quantity under the logarithm is given a special definition because it may be generalized to other cases not involving ideal gases; thus, the reaction quotient is defined as:

$$Q = [B']^b / [A']^a \quad (111)$$

where including the equilibrium constant yields:

$$\Delta G' - \Delta G = RT \ln Q - RT \ln K \quad (112)$$

Under conditions of both constant pressure and temperature,  $dG$  and  $\Delta G = 0$ ; thus:

$$\Delta G' = RT \ln Q - RT \ln K \quad (113)$$

In a similar fashion to the standard enthalpies of formation of specific compounds, a standard Gibbs free energy,  $\Delta G^\circ$ , for the above reaction, may be defined as the free energy associated with the conversion of  $a$  mols of reactants to  $b$  mols of products when the pressure and temperature are held constant, or  $\Delta G' = \Delta G^\circ$  and  $\ln Q = 0$ . The concentrations (or in this example, the pressures) are equal to unity, thus:

$$\Delta G^\circ = -RT \ln K \quad (114)$$

This equation is of great importance because it provides the energy per mole of any chemical reaction, provided the equilibrium constant is known under standard conditions. Alternatively, the equilibrium constant may be calculated if the free energy is known. The universal applicability of thermodynamics also is displayed. Although it was derived for an ideal gas, it is equally applicable to reactions conducted in solution or even in the solid state.

A special case of the van't Hoff equation is known as the *Clapeyron equation*. The interesting feature is that the free-energy change with temperature, in connection with phase changes, is approached in a different manner, with the same result. Consider a liquid in equilibrium with a vapor, such that the free energy associated with each phase, liquid and vapor, may be written from the fundamental equations as:

$$dG_l = -S_l dT + V_l dP \quad (115)$$

$$dG_v = -S_v dT + V_v dP \quad (116)$$

However, because the phases are in equilibrium,  $dG_l = dG_v$ , or equating the above relationships:

$$-S_l dT + V_l dP = -S_v dT + V_v dP \quad (117)$$

these can be rearranged to yield:

$$(S_v - S_l) dT = (V_v - V_l) dP \quad (118)$$

or with separation of the differential with the incremental changes to give:

$$dP/dT = (S_v - S_l) / (V_v - V_l) \quad (119)$$

or equivalent:

$$dP/dT = \Delta S / \Delta V \quad (120)$$

The interesting aspect of this equation is that the derivative,  $dP/dT$ , is related to the discontinuous changes that occur with a phase change. Although this relation was derived for a liquid-vapor equilibrium, it is general and may be applied to any phase change.

The relationship may be manipulated further by recalling that  $\Delta S = \Delta H/T$ , where  $T$  is the temperature at the point of equilibrium. Thus, by substitution, the following is obtained:

$$dP/dT = \Delta H / T \Delta V \quad (121)$$

An approximation may be made, as before, by noting that  $V_v - V_l \approx V_v$ , which for 1 mol of an ideal gas is  $V_v = RT/P$  and affords:

$$dP/dT = P \Delta H / RT^2 \quad (122)$$

The expression may be rearranged, thereby providing a means for measuring the change in enthalpy and entropy:

$$dP/P = (\Delta H/RT^2)dT \quad (123)$$

This is known as the *Clausius–Clapeyron equation*. Assuming  $\Delta H$  is constant over the small temperature range between  $T_2$  and  $T_1$ , this expression may be integrated yielding:

$$\ln(P_2/P_1) = (\Delta H/R)[(1/T_1) - (1/T_2)] \quad (124)$$

*Q*—If the equilibrium constant is  $1.3 \times 10^{-2}$  at  $25^\circ$  and  $1.7 \times 10^{-1}$  at  $150^\circ$ , what are  $\Delta H^\circ$ ,  $\Delta G^\circ$ , and  $\Delta S^\circ$ ?

*A*—The temperature of  $25^\circ$  is taken as the standard temperature; Gibbs free energy is given by:

$$\Delta G^\circ = -RT \ln(k/298) = -(1.987)(298) \ln(1.2 \times 10^{-2}) = 2.62 \text{ kcal/mol.} \quad (125)$$

The standard enthalpy change may be calculated from the temperature dependence as follows:

$$\Delta H^\circ = R \ln[K(423)/(K(298))]/[(1/T_1) - (1/T_2)] = 5.15 \text{ kcal/mol} \quad (126)$$

Finally,  $\Delta S^\circ$  may be calculated, knowing the free energy and enthalpy changes, from:

$$\Delta S^\circ = -(1/T)(\Delta G^\circ - \Delta H^\circ) = -(1/298)(2620 - 5150) = 8.48 \text{ eu (entropy units)} \quad (127)$$

*Q*—Justify the following expression of the temperature dependence of the vapor pressure of a liquefied gas:

$$\ln P = -\Delta H_{\text{vap}}/RT + C \quad (128)$$

where  $C$  is a constant.

*A*—Taking the indefinite integral of Equation 86:

$$\int dP/P = \int (\Delta H_{\text{vap}}/RT^2)dT \quad (129)$$

the result is obtained directly:

$$\ln P = (-\Delta H_{\text{vap}}/RT) + C \quad (130)$$

## SOLUBILITY

Consider a system consisting of solid drug in equilibrium with a saturated solution. The molar free energy of the solute is the same everywhere, thereby permitting the following:

$$\mu_{2,\text{solution}}(T,P,a_2) = \mu_{2,\text{solid}}(T,P) \quad (131)$$

from which:

$$\mu_{2,\text{liquid}}^\circ(T,P) + RT \ln a = \mu_{2,\text{solid}}(T,P) \quad (132)$$

where  $\mu_{2,\text{liquid}}^\circ$  is the chemical potential of the pure liquid solute. Solving for the activity of the pure liquid solute yields:

$$\ln a_2 = [\mu_{2,\text{solid}}(T,P) - \mu_{2,\text{liquid}}^\circ(T,P)]/RT \quad (133)$$

The relationship between activity and solubility is given as follows:

$$a_2 = \gamma_2 X_2 \quad (134)$$

where  $\gamma_2$  is the activity coefficient of the solute in water. From this analysis, the mole fraction solubility is seen to depend only on the chemical potential of the solute. Thus, the ideal solubility of a drug is the same in every solvent. Furthermore, the difference in solubility observed between solvents is related to the nonideality of the solute, which is quantitatively determined by the activity coefficient.

The cause of nonideality arises from intermolecular interactions, which may be favorable leading to high solubility and a low activity coefficient. Alternatively, the interactions may be unfavorable, which lead to low solubility and high activity coefficient. For this reason, the activity coefficient quantitatively describes the escaping tendency of the solute from the solution.

## HEAT OF SOLUTION

When a compound is dissolved in a solvent, the resulting enthalpy change of the system is referred to as the *heat of solution*.

The heat evolved or absorbed reflects the energy required to disrupt the cohesive forces of the solid and the energy generated from interaction of the solute molecules with solvent molecules. There are two ways of expressing the enthalpy change per mol of material dissolved: the integral and differential heats of solution. The two conventions arise from the dependency of the heat of solution on the amount of solvent used to dissolve the solute. Thus, the *integral heat of solution* describes the enthalpy change when 1 mol of solute is dissolved to yield a specified concentration, perhaps a 1 molar solution, whereas the *differential heat of solution* provides a value of the enthalpy change when the amount of solute dissolved is negligible.

One way of understanding the difference between these representations, and also a way of remembering, is as follows:

- The integral heat of solution gives the enthalpy change for a discrete or integral change in concentration of the solution.
- The differential heat of solution provides the enthalpy change for an infinitesimally or differential ( $dC$ ) change in concentration.

*Q*—If the differential heat of solution of two polymorphic forms of a drug were measured in water at standard temperature and pressure (STP) and form A had a larger heat than form B, which is more stable at STP?

*A*—More energy is required to dissolve form A; therefore, it must be the more stable polymorph at STP.

## TEMPERATURE DEPENDENCE OF EQUILIBRIUM CONSTANTS

A related aspect is the question of the temperature dependence of the equilibrium constant or, from a different perspective, the temperature dependence of the change in free energy. Using the fundamental equations, it can be shown that Gibbs free energy is related to the following state functions:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad (135)$$

The determination of the temperature dependence is obtained through the Gibbs–Helmholtz equation, which is derived as follows. First, both sides are divided by the temperature:

$$\Delta G^\circ/T = \Delta H^\circ/T - \Delta S^\circ \quad (136)$$

then the derivative with respect to temperature is taken:

$$\partial(\Delta G^\circ/T)/\partial T = \partial(\Delta H^\circ/T)/\partial T \quad (137)$$

$$\partial(\Delta G^\circ/T)/\partial T = -\Delta H^\circ/T^2 \quad (138)$$

This is referred to as the *Gibbs–Helmholtz equation*, which provides the relationship between the change in Gibbs free energy with temperature and the enthalpy change. However, the standard free-energy change also is related to the equilibrium constant, which, in general, also is temperature dependent, as:

$$\partial(\Delta G^\circ/T)/\partial T = -\partial(R \ln K)/\partial T \quad (139)$$

Combining Equations 137 and 138 yields:

$$-\partial(R \ln K)/\partial T = -\Delta H^\circ/T^2 \quad (140)$$

which may be rearranged and integrated over the limits of  $T_1$  and  $T_2$ , assuming that  $\Delta H^\circ$  is not a function of temperature, which is a reasonable approximation for a small temperature range:

$$\int \partial(\ln K) = -\int (\Delta H^\circ/RT^2)dT \quad (141)$$

Thus, the temperature dependence of the equilibrium constant is given as:

$$\ln [K_2/K_1] = (\Delta H^\circ/R)[(1/T_1) - (1/T_2)] \quad (142)$$

where  $K_1$  and  $K_2$  are the equilibrium constants at temperature  $T_1$  and  $T_2$ , respectively. This is known as the *van't Hoff equation*; this equation is extremely important because of its wide applicability, to not only equilibrium constants of chemical reactions, but also other phenomena such as solubility, complexation, dissociation, and vapor pressure.

*Q*—If the equilibrium constant is 13.6 at STP, at what temperature will it be 20 if the standard enthalpy for the reaction is 8.3 kcal/mol?

*A*—Using the following equation:

$$(-R/\Delta H^\circ) \ln(K_2/K_1) + 1/T_1 = 1/T_2 \quad (143)$$

$$1/T_2 = (-1.987/8300) \ln(20/13.6) + 1/298 \quad (144)$$

$$T_2 = 3.26 \times 10^{-3} = 306 \text{ K} = 33^\circ$$

At this point the information presented is useful if every reaction was carried out under standard conditions of 298 K and 1 atm pressure; however, most reactions are not. Nevertheless, the heat of the reaction may be calculated at any other temperature by the temperature dependence of the heat capacity.

Consider the problem of the heat of reaction for the freezing of water at  $-10^\circ$  (263 K). One should note that a simple phase change may be treated in a manner analogous to a chemical reaction for the purposes of calculating the enthalpy change.

The approach to the problem is to calculate the enthalpy change associated with the temperature change of the reactant (water) from  $0^\circ$  to  $-10^\circ$  and the product (ice) from  $-10^\circ$  to  $0^\circ$ , and then use the value for the enthalpy change at the melting point. The following schematic illustrates the approach and also provides insight into the concept of path independence of state functions.

Specifically, the molar enthalpy for the reaction at 310 K is given by:

$$\Delta H(310) = \Delta H_I + \Delta H_{II} + \Delta H_{III} \quad (146)$$

with:

$$\begin{aligned} \Delta H_I &= \int c_p(H_2O, 1) dT = c_p(1) \Delta T \\ \Delta H_I &= (74.5)(373 - 310) = 4693 \text{ J/mol} \\ \Delta H_{II} &= 40,650 \text{ J/mol (found in table 12-3)} \\ \Delta H_{III} &= \int c_p(H_2O, s) dT = c_p(s) \Delta T \end{aligned} \quad (147)$$

The value for the heat capacity of water vapor is about 1.9 kJ/kgK or 34.2 J/molK:

$$\Delta H_{III} = (34.2)(310 - 373) = -2052 \text{ J/mol} \quad (148)$$

Thus, the enthalpy for the conversion of water to ice at  $-10^\circ$  is given by the sum or:

$$\Delta H(310 \text{ K}) = 4693 + 40650 - 2052 = 43291 \text{ cal/mol} \quad (149)$$

As shown, the direction around the circle dictates the limits of integration (final less initial), thus care must be taken not to confuse them. The heat capacity was assumed to be independent of temperature, which in this case is reasonable for such a small temperature change ( $10^\circ$ ). However, in general, heat capacity is a function of temperature, which will not present severe difficulties if the functional relationship is known. In this case the temperature dependence may be substituted into the equation and then integrated with the appropriate limits. For example, the molar heat capacity of oxygen over the range of 300 to 1500 K has been determined experimentally and is approximated closely by:

$$c_p = 6.0954 + 3.2533 \times 10^{-3} T - 10.171 \times 10^{-7} T^2 \quad (150)$$

The change in the molar heat of formation for oxygen from temperature  $T_1$  to  $T_2$  would then be given by:

$$\int dH = \int (6.0954 + 3.2533 \times 10^{-3} T - 10.171 \times 10^{-7} T^2) dT \quad (151)$$

$$\begin{aligned} \Delta H &= [6.0954(T_2 - T_1) + (1/2)(3.2533 \times 10^{-3})[T_2^2 - T_1^2] + \\ &\quad (1/3)(-10.171 \times 10^{-7})(T_2^3 - T_1^3)] \end{aligned} \quad (152)$$

## PARTITIONING BEHAVIOR

In an analogous manner, the activity coefficients may be related to the partition coefficient. Consider a solute distributed between two immiscible solvents, A and B. At equilibrium, the chemical potential of the solute is the same in each phase, thus:

$$\mu_{2A} = \mu_{2B} \quad (153)$$

and:

$$\mu_2^\circ + RT \ln a_A = \mu_2^\circ + RT \ln a_B \quad (154)$$

The standard state for the solute in both solvents A and B,  $\mu_2^\circ$ , must be the same because it is based on the pure liquid solute, the activities must be equal.

$$a_A = a_B \quad (155)$$

The partition coefficient is defined in terms of the mole fractions of infinitely dilute solutions:

$$P_{o/w} = (X_o)^\infty / (X_w)^\infty = \gamma_w / \gamma_o \quad (156)$$

where the activities of the solute in each phase have been cancelled. Noteworthy, in using this system of standard states is that for ideal oil and water solutions of solutes, the partition coefficient is unity, because the activity coefficients,  $\gamma_o$  and  $\gamma_w$ , are equal to one.

These two concepts have been combined by Yalkowski and his coworkers to predict the aqueous solubility of drugs. They proposed the following:

$$\ln(X_{2w}) = \ln(X_{2oct}) - \ln(P_{o/w}) \quad (157)$$

where  $X_{2w}$  is the mole fraction in water,  $P_{o/w}$  is the octanol/water partition coefficient, and  $X_{2oct}$  is the mole fraction solubility of the solute in octanol. From above, the  $P_{o/w}$  is given by the ratio of the activity coefficients,  $\gamma_w / \gamma_o$ . However, the drug in octanol generally forms an ideal solution, i.e.,  $\gamma_o = 1$ . As such, the octanol/water partition coefficient is a measure of the activity coefficient of the drug in water. Finally, the mole fraction of the solute in an ideal solution of octanol may be determined from the heat of fusion and the melting point. The resulting predictive equation for the water solubility, which has yielded highly correlated data, is:

$$\ln X_2 = -(\Delta H_{fus}/R)(1/T - 1/T_m) - \ln P_{o/w}^\infty \quad (158)$$

The melting point and heat of fusion may be readily measured, and the partition coefficient can be estimated by group contribution methods. Thus, a conceptually elegant foundation has been developed into a practically useful scheme to estimate the water solubility of drugs from the thermal properties and the octanol/water partition coefficient of drugs.

## PROTEIN BINDING

As a final example of equilibria, the protein-binding of drugs should be mentioned. Consider the case where a protein has a single binding site for a drug. A mass-balanced equation may be written as:

$$[P] + [D] = [PD] \quad (159)$$

where  $[P]$  is the concentration of unbound protein,  $[D]$  is the concentration of unbound drug, and  $[PD]$  is the concentration of the drug-protein complex. The equilibrium constant may be written for this reaction as:

$$K_a = [PD] / [P][D] \quad (160)$$

where  $K_a$  is the association constant. Assuming ideality, the standard free energy for the above equilibrium may be immediately identified as:

$$\Delta G^\circ = -RT \ln(K_a) \quad (161)$$

This concept often is taken a step farther in order to characterize the nature of the binding site of the drug. This has application in structure-activity relationships used for predicting pharmacological activity.

Suppose the association constants of two structurally related drugs,  $K'_a$  and  $K''_a$ , were determined experimentally. The standard free energy of each association is given as  $\Delta G^{\circ'}$  and  $\Delta G^{\circ''}$ . The effect of the change in the chemical structure on the energetics of the association then can be calculated from the association constants as:

$$\Delta\Delta G^\circ = \Delta G^{\circ''} - \Delta G^{\circ'} = RT \ln(K'_a / K''_a) \quad (162)$$

where  $\Delta\Delta G^\circ$  is the standard free-energy change of protein-binding associated with the specific chemical modification.

Q—At room temperature and a protein concentration of 2  $\mu\text{M}$ , the fraction of penicillin G and penicillin V bound was found to be 0.65 and 0.80, respectively. Calculate the change in the standard free energy of binding associated with the replacement of the benzyl group in penicillin G by the phenoxy moiety in penicillin V.

A—The fraction bound may be related to the equilibrium constant by assuming there is only one binding site on each protein molecule. The fraction of drug bound,  $F$ , is defined as:

$$F = [DP]/([D] + [DP]) \quad (163)$$

and because the concentration of the drug-protein complex is given by:

$$[PD] = K_a[P][D] \quad (164)$$

This may be substituted into the above equation yielding

$$F = K_a[P][D]/([D] + K_a[P][D]) \quad (165)$$

After canceling terms and solving for  $K_a$ , the desired expression is obtained:

$$K_a = F/[P](1 - F) \quad (166)$$

The association constants for each drug then are calculated:

$$\begin{aligned} K_a G &= (0.65)/[2\mu\text{M}](1 - 0.65) = 0.93\mu\text{M}^{-1} \\ K_a V &= (0.80)/[2\mu\text{M}](1 - 0.80) = 2.0\mu\text{M}^{-1} \end{aligned} \quad (167)$$

From the association constants, the change in standard free energy associated with replacing the benzyl group with a phenoxy moiety is:

$$\begin{aligned} \Delta\Delta G^\circ &= \Delta G^\circ(V) - \Delta G^\circ(G) = RT \ln(0.93/2.0) \\ \Delta\Delta G^\circ &= -453 \text{ cal/mol K} \end{aligned} \quad (168)$$

The change in the standard free energy is negative, in agreement with the concept that binding of the phenoxy group is more favorable than the benzyl group.

# Chapter 13

## Solutions and Phase Equilibria

Pardeep K. Gupta, PhD

SOLUTIONS AND SOLUBILITY 219

PHARMACEUTICAL SOLVENTS 229

COLLIGATIVE PROPERTIES OF SOLUTIONS 232

METHODS TO INCREASE SOLUBILITY OF POORLY SOLUBLE DRUGS 237

### SOLUTIONS AND SOLUBILITY

A solution is a chemically and physically homogeneous mixture of two or more substances. The term *solution* generally denotes a homogeneous mixture that is liquid, even though it is possible to have homogeneous mixtures that are solid or gaseous. Thus, it is possible to have solutions of solids in liquids, liquids in liquids, gases in liquids, gases in gases, and solids in solids. The first three of these are most important in pharmacy, and ensuing discussions will be concerned primarily with them.

In pharmacy different kinds of liquid dosage forms are used, and all consist of a dispersion of one or more substances in a liquid phase. Depending on the size of the dispersed particle, they are classified as *true solutions*, *colloidal solutions*, or *disperse systems*. If sugar is dissolved in water, it is supposed that the ultimate sugar particle is of molecular dimensions and that a true solution is formed. On the other hand, if very fine sand is mixed with water, a suspension of comparatively large particles, each consisting of many molecules, is obtained. Between these two extremes lie the colloidal solutions, the dispersed particles of which are larger than those of true solutions but smaller than the particles present in suspensions. Colloidal solutions, in general, are considered to be thermodynamically stable. In this chapter only true solutions will be discussed.

It is possible to classify broadly all solutions as one of two types. In the first type, although there may be lesser or greater interaction between the dispersed substance (the solute) and the dispersing medium (the solvent), the solution phase contains the same chemical entity as found in the solid phase; thus, upon removal of the solvent, the solute is recovered unchanged. One example would be sugar dissolved in water where, in the presence of sugar in excess of its solubility, there is an equilibrium between sugar molecules in the solid phase with sugar molecules in the solution phase. A second example would be dissolving silver chloride in water. Admittedly, the solubility of this salt in water is low, but it is finite. In this case the solvent contains silver and chloride ions, and the solid phase contains the same material. Removal of the solvent yields the initial solute in unchanged form.

In the second type the solvent contains a compound that is different from the one in the solid phase. The difference between the compound in the solid phase and solution is due generally to some chemical reaction that has occurred in the presence of solvent. An example would be dissolving aspirin in an aqueous solvent containing some basic material capable of reacting with the acid aspirin. Now the species in solution would not only be undissociated aspirin, but aspirin also as its anion, whereas the species in the solid phase is aspirin in only its undissociated acid form. In this situation, if the solvent were removed, part of the substance obtained (the salt of aspirin) would be different from what was present initially in the solid.

### SOLUTIONS OF SOLIDS IN LIQUIDS

#### Reversible Solubility Without Chemical Reaction

From a pharmaceutical standpoint, solutions of solids in liquids, with or without accompanying chemical reaction in the

solvent, are of the greatest importance, and many quantitative data on the behavior and properties of such solutions are available. This discussion will be concerned with definitions of solubility, with the rate at which substances go into solution, and with temperature and other factors that control the rate and extent of solubility.

#### Solubility

When an excess of a solid is brought into contact with a liquid, molecules of the former are removed from its surface until equilibrium is established between the molecules leaving the solid and those returning to it. The resulting solution is said to be saturated at the temperature of the experiment, and the extent to which the solute dissolves is referred to as its *solubility*. The extent of solubility of different substances varies from almost imperceptible amounts to relatively large quantities, but for any given solute the solubility has a constant value at a given constant temperature.

Under certain conditions it is possible to prepare a solution containing a larger amount of solute than is necessary to form a saturated solution. This may occur when a solution is saturated at one temperature, the excess of solid solute is then removed, and the solution cooled. The solute present in solution, even though it may be less soluble at the lower temperature, does not always separate from the solution, and there is produced a supersaturated solution. Such solutions, formed by sodium thiosulfate or potassium acetate, for example, may be made to deposit their excess of solute by vigorous shaking, scratching the side of the vessel in contact with the solution, or introducing into the solution a small crystal of the solute. Supersaturated solutions are considered to be thermodynamically unstable systems and, therefore, usually return to a saturated solution by excluding the excess solute.

#### Methods of Expressing Solubility

When quantitative data are available, solubility may be expressed in several ways. For example, the solubility of sodium chloride in water at 25°C may be stated as

1. 1 g of sodium chloride dissolves in 2.786 mL of water. (An approximation of this method is used by the USP.)
2. 35.89 g of sodium chloride dissolves in 100 mL of water.
3. 100 mL of a saturated solution of sodium chloride in water contains 31.71 g of solute.
4. 100 g of a saturated solution of sodium chloride in water contains 26.47 g of solute.
5. 1 L of a saturated solution of sodium chloride in water contains 5.425 moles of solute. This also may be stated as a saturated solution of sodium chloride in water is 5.425 molar with respect to the solute.

In order to calculate item 3 above from items 1 or 2, it is necessary to know the density of the solution, which in this case is 1.198 g/mL.

To calculate item 5, the number of grams of solute in 1000 mL of solution (obtained by multiplying the data in item 3 by 10) is divided by the molecular weight of sodium chloride, namely 58.45.

Several other concentration expressions are also available. Molality is the number of moles of solute in 1000 g of solvent and could be calculated from the data in item 4 by subtracting grams of solute from grams of solution to obtain grams of solvent, relating this to 1000 g of solvent and dividing by molecular weight to obtain moles.

Mole fraction is the number of moles of a component divided by total number of moles in that solution. Mole percent may be obtained by multiplying mole fraction by 100. Normality refers to the number of gram equivalent weights of solute dissolved in 1000 mL of solution.

In pharmacy, use also is made of three other concentration expressions. Percent by weight (% w/w) is the number of grams of solute per 100 g of solution and is exemplified by item 4 above. Percent weight in volume (% w/v) is the number of grams of solute per 100 mL of solution and is exemplified by item 3 above. Percent by volume (% v/v) is the number of milliliters of solute in 100 mL of solution, referring to solutions of liquids in liquids. The USP indicates that the term percent, when unqualified, means percent weight in volume for solutions of solids in liquids and percent by volume for solutions of liquids in liquids.

In pharmacopeial texts, when it has not been possible, or in some instances not desirable, to indicate exact solubility, a descriptive term is used. Table 13-1 indicates the usual meaning of such terms.

### Rate of Solution

It is possible to define quantitatively the rate at which a solute goes into solution. The simplest treatment is based on a model depicted in Figure 13-1. A solid particle dispersed in a solvent is surrounded by a thin layer of solvent having a finite thickness,  $l$ , in units of length e.g. centimeters. The layer is an integral part of the solid and, thus, is referred to characteristically as the *stagnant layer*. This means that, regardless of how fast the bulk solution is stirred, the stagnant layer remains a part of the surface of the solid, moving wherever the particle moves. The thickness of this layer may get smaller as the stirring of the bulk solution increases, but it is important to recognize that this layer will always have a finite thickness, however small it may get.

Physical model representing the dissolution process.

Using Fick's First Law of Diffusion, the rate of solution of the solid can be explained, in the simplest case, as the rate at which a dissolved solute particle diffuses through the stagnant layer to the bulk solution. The driving force behind the movement of the solute molecule through the stagnant layer is the difference in concentration that exists between the concentration of the solute,  $C_1$ , in the stagnant layer at the surface of the solid and its concentration,  $C_2$ , on the farthest side of the stagnant layer. The greater the difference in concentrations ( $C_1 - C_2$ ), the faster the rate of dissolution, assuming that the thickness of the stagnant layer stays constant.

According to Fick's Law, the rate of solution is also directly proportional to surface area of the solid,  $A$  in  $\text{cm}^2$ , exposed to solvent and inversely proportional to the length of the path through which the dissolved solute molecule must diffuse.

Figure 13-1. Alternating current Wheatstone bridge for measuring conductivity.

Mathematically, then, the rate of solution of the solid is given by

$$\text{Rate of solution} = \frac{DA}{l}(C_1 - C_2) \quad (1)$$

where  $D$  is a proportionality constant called the *diffusion coefficient* in  $\text{cm}^2/\text{s}$ . In measuring the rate of solution experimentally, the concentration  $C_2$  is maintained at a low value compared to  $C_1$  and hence is considered to have a negligible effect on the dissolution rate. Furthermore,  $C_1$  most often is the saturation solubility of the solute. Hence Equation 1 is simplified to

$$\text{Rate of solution} = \frac{DA}{l} (\text{saturation solubility}) \quad (2)$$

Equation 2 quantitatively explains many of the phenomena commonly observed that affect the rate at which materials dissolve.

1. Small particles go into solution faster than large particles. For a given mass of solute, as the particle size becomes smaller, the surface area per unit of mass of solid increases; Equation 2 shows that as area increases, the rate must increase proportionately. Hence, if a pharmacist wishes to increase the rate of solution of a drug, its particle size should be decreased.
2. Stirring a solution increases the rate at which a solid dissolves. This is because the thickness of the stagnant layer depends on how fast the bulk solution is stirred; as stirring rate increases, the length of the diffusional path decreases. Because the rate of solution is proportional inversely to the length of the diffusional path, the faster the solution is stirred, the faster the solute will go into solution.
3. The more soluble the solute, the faster is its rate of solution. Again, Equation 2 predicts that the larger the saturation solubility, the faster the rate.
4. With a viscous liquid, the rate of solution is decreased. This is because the diffusion coefficient is proportional inversely to the viscosity of the medium; the more viscous the solvent, the slower the rate of dissolution.

### Heat of Solution and Temperature Dependency

Turning from the kinetic aspects of dissolution, this discussion will be concerned with the situation in which there is thermodynamic equilibrium between solute in its solid phase and the solute in solution. (It is assumed that there is an amount of solid material in excess of the amount that can go into solution; hence, a solid phase is always present.) As defined earlier, the concentration of solute in solution at equilibrium is the saturation solubility of the substance.

When a solid (Solute A) dissolves in some solvent, two steps may be considered as occurring: the solid absorbs energy to become a liquid, then the liquid dissolves.

For the overall dissolution, the equilibrium existing between solute molecules in the solid and solute molecules in solution

Table 13-1. Descriptive Terms for Solubility

Descriptive Terms	Parts of Solvent for 1 Part of Solute
Very soluble	Less than 1
Freely soluble	From 1 to 10
Soluble	From 10 to 30
Sparingly soluble	From 30 to 100
Slightly soluble	From 100 to 1000
Very slightly soluble	From 1000 to 10000
Practically insoluble, or insoluble	More than 10000

may be treated as an equilibrium. Thus, for Solute A in equilibrium with its solution,

Using the Law of Mass Action, an equilibrium constant for this system can be defined, just as any equilibrium constant may be written, as

$$K_{\text{eq}} = a_{(\text{solution})}$$

$$K_{\text{eq}} = \frac{a_{(\text{solution})}}{a_{(\text{solid})}}$$

where  $a$  denotes the activity of the solute in each phase. Because the activity of a solid is defined as unity,

Because the activity of a compound in dilute solution is approximated by its concentration, and because this concentration is the saturation solubility,  $K_S$ , the van't Hoff equation (for a more complete treatment, see Sinko<sup>1</sup>) may be used, which defines the relationship between an equilibrium constant (here, solubility) and absolute temperature.

$$\frac{d \log K_s}{dT} = \frac{\Delta H}{2.3RT^2} \quad (3)$$

where  $d \log K_S/dT$  is the change of  $\log K_S$  with a unit change of absolute temperature,  $T$ ;  $\Delta H$  is a constant that, in this situation, is the heat of solution for the overall process (solid  $\rightleftharpoons$  liquid  $\rightleftharpoons$  solution); and  $R$  is the gas constant, 8.314 Joules/K/mol. Equation 3, a differential, may be solved to give:

$$\log K_s = -\frac{\Delta H}{2.3RT} + J \quad (4)$$

where  $J$  is a constant. A more useful form of this equation is:

$$\log \frac{K_{s,T_2}}{K_{s,T_1}} = \frac{\Delta H(T_2 - T_1)}{2.3RT_1T_2} \quad (5)$$

where  $K_{s,T_1}$  is the saturation solubility at absolute temperature  $T_1$  and  $K_{s,T_2}$  is the solubility at temperature  $T_2$ . Through the use of Equation 5, if  $\Delta H$  and the solubility at one temperature are known, the solubility at any other temperature can be calculated.

### Effect of Temperature

As is evident from Equation 4, the solubility of a solid in a liquid depends on the temperature. In the process of solution, if heat is absorbed (as evidenced by a reduction in temperature),  $\Delta$  is by convention positive, and the solubility of the solute will increase with increasing temperature. Such is the case for most salts, as is shown in Figure 13-2, in which the solubility of the solute is plotted as the dependent variable and the temperature as the independent variable, and the line joining the experimental points represents the solubility curve for that solute.

If a solute gives off heat during the process of solution (as evidenced by an increase in temperature), by convention  $\Delta$  is negative, and solubility decreases with an increase in temperature. This is the case with calcium hydroxide and, at higher temperatures, with calcium sulfate. (Because of the slight solubility of these substances, their solubility curves are not included.) When heat is neither absorbed nor given off, the solubility is not affected by variation of temperature, as is nearly the case with sodium chloride.

Solubility curves usually are continuous as long as the chemical composition of the solid phase in contact with the solution remains unchanged, but if there is a transition of the solid phase from one form to another, a break will be found in the curve. Such is the case with  $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ , which dissolves with absorption of heat up to a temperature of 32.4°C, at which

Figure 13-2. Effect of heat on solubility.

point there is a transition of the solid phase to anhydrous sodium sulfate,  $\text{Na}_2\text{SO}_4$ , which dissolves with evolution of heat. This change is evidenced by increased solubility of the hydrated salt up to 32.4°C, but above this temperature the solubility decreases.

These temperature effects are what would be predicted from Equation 4. When the heat of solution is negative, signifying that energy is released during dissolution, the relation between  $\log K_S$  and  $1/T$  is typified in Figure 13-3 (Curve A): as  $1/T$  increases,  $\log K_S$  increases. It can be seen that with increasing temperature ( $T$  itself actually increases proceeding left in Figure 13-3), curve A there is a decrease in solubility. On the other hand, when the heat of solution is positive—that is, when heat is absorbed in the solution process—the relation between  $\log K_S$  and  $1/T$  is typified in Figure 13-3, curve B. Hence, as temperature increases ( $1/T$  decreases), the solubility increases.

### Effect of Salts

Solubility of a nonelectrolyte in water is generally either decreased or increased by the addition of an electrolyte; it is only

Figure 13-3. Typified relationship between the logarithm of the saturation solubility and the reciprocal of the absolute temperature.

rarely that the solubility is not altered. When the solubility of a nonelectrolyte is decreased, the effect is referred to as *salting-out*; if it is increased, it is described as *salting-in*. Inorganic electrolytes commonly decrease solubility, though there are some exceptions to the generalization.

Salting-out occurs because the ions of the added electrolyte interact with water molecules, and thus, in a sense, reduce the amount of water available for dissolution of the nonelectrolyte. (See Thermodynamics of the Solution Process for another view.) The greater the degree of hydration of the ions, the more the solubility of the nonelectrolyte is decreased. If, for example, one compares the effect of equivalent amounts of lithium chloride, sodium chloride, potassium chloride, rubidium chloride, and cesium chloride (all of which belong to the family of alkali metals and are of the same valence type), lithium chloride decreases the solubility of a nonelectrolyte to the greatest extent, and the salting-out effect decreases in the order given.

This is also the order of the degree of hydration of the cations; lithium ion—being the smallest ion and, therefore, having the greatest density of positive charge per unit of surface area—is the most extensively hydrated of the cations, whereas cesium ion is hydrated the least. Salting-out is encountered frequently in pharmaceutical operations.

Salting-in commonly occurs when either the salts of various organic acids or organic-substituted ammonium salts are added to aqueous solutions of nonelectrolytes. In the first case, the solubilizing effect is associated with the anion; in the second, it is associated with the cation. In both cases the solubility increases as the concentration of added salt is increased. The solubility increase may be relatively great, sometimes amounting to several times the solubility of the nonelectrolyte in water.

### Solubility of Solutes Containing Two or More Species

In cases where the solute phase consists of two or more species (as in an ionizable inorganic salt), when the solute goes into solution, the solution phase often contains each of these species as discrete entities. For some such substance, AB, the following relationship for the solution process may be written:

As there is an equilibrium between the solute and saturated solution phases, the Law of Mass Action defines an equilibrium constant,  $K_{\text{eq}}$ :

$$K_{\text{eq}} = \frac{\alpha_{A(\text{solution})} \alpha_{B(\text{solution})}}{\alpha_{AB(\text{solid})}} \quad (6)$$

where  $\alpha_{A(\text{solution})}$ ,  $\alpha_{B(\text{solution})}$ , and  $\alpha_{AB(\text{solid})}$  are the activities of A and B in solution and of AB in the solid phase. Recall from the earlier discussion that the activity of a solid is defined as unity, and that in a very dilute solution (e.g., for a slightly soluble salt), concentrations may be substituted for activities. Equation 6 then becomes:

$$K_{\text{eq}} = C_A C_B$$

where  $C_A$  and  $C_B$  are the concentrations of A and B in solution. In this situation  $K_{\text{eq}}$  has a special name, the *solubility product*,  $K_{\text{sp}}$ . Thus:

$$K_{\text{sp}} = C_A C_B \quad (7)$$

This equation will hold true theoretically only for slightly soluble salts.

As an example of this type of solution, consider the solubility of silver chloride:

where the brackets [ ] designate molar concentrations.

At 25°C the solubility product has a value of  $1.56 \times 10^{-10}$ , the concentration of silver and chloride ions being expressed in mol/liter. The same numerical value applies also to solutions of silver chloride containing an excess of either silver or chloride ions. If the silver-ion concentration is increased by the addition of a soluble silver salt, the chloride-ion concentration must decrease until the product of the two concentrations again is equal numerically to the solubility product. To effect the decrease in chloride-ion concentration, silver chloride is precipitated, and hence its solubility is decreased. In a similar manner, an increase in chloride-ion concentration, by the addition of a soluble chloride, effects a decrease in the silver-ion concentration until the numerical value of the solubility product is attained. Again, this decrease in silver-ion concentration is brought about by the precipitation of silver chloride. This phenomenon of decrease in solubility due to the presence of one of the ions in solution is known as the *common-ion effect*.

The solubility of silver chloride in a saturated aqueous solution of the salt may be calculated by assuming that the concentration of silver ion is the same as the concentration of chloride ion, both expressed in mol/liter, and that the concentration of dissolved silver chloride is numerically the same as each silver chloride molecule gives rise to one silver ion and one chloride ion because:

$$[\text{dissolved AgCl}] = [\text{Ag}^+] = [\text{Cl}^-]$$

The solubility of AgCl is equal to  $1.56 \times 10^{-10}$ , which is  $1.25 \times 10^{-5}$  mol/liter. Multiplying this by the molecular weight of silver chloride (143), we obtain a solubility of approximately 1.8 mg/liter.

For a salt of the type  $\text{PbCl}_2$  the solubility product expression takes the form:

$$[\text{Pb}^{2+}][\text{Cl}^-]^2 = K_{\text{sp}}$$

while for  $\text{As}_2\text{S}_3$  it would be:

$$[\text{As}^{3+}]^2[\text{S}^{2-}]^3 = K_{\text{sp}}$$

because from the Law of Mass Action:

and:

For further details of methods of using solubility-product calculations, see textbooks on qualitative or quantitative analyses or physical chemistry.

Recall that the solubility-product principle is valid for aqueous solutions of slightly soluble salts, provided that the concentration of added salt is not too great. Where the concentrations are high, deviations from the theory occur, and these have been explained by assuming that in such solutions the nature of the solvent has been changed. Frequently, deviations also may occur as the result of the formation of complexes between the two salts. An example of increased solubility, by virtue of complex-ion formation, is seen in the effect of solutions of soluble iodides on mercuric iodide. According to the solubility-product principle, it might be expected that soluble iodides would decrease the solubility of mercuric iodide, but because of the formation of the more soluble complex salt  $\text{K}_2\text{HgI}_4$ , which dissociates as:

the iodide ion no longer functions as a common ion.

It is possible to formulate some general rules regarding the effect of the addition of soluble salts to slightly soluble salts in which the added salt does not have an ion common to the slightly soluble salt. If the ions of the added soluble salt are not

highly hydrated (see the previous section, Effect of Salts), the solubility product of the slightly soluble salt will increase because the ions of the added salt tend to decrease the interionic attraction between the ions of the slightly soluble salt. On the other hand, if the ions of the added soluble salt are hydrated, water molecules become less available, and the interionic attraction between the ions of the slightly soluble salt increases with a resultant decrease in solubility product. Another way of considering this effect is discussed later (see *Thermodynamics of the Solution Process*).

In general, the effect of temperature is what would be expected: increasing the temperature of the solution results in an increase of the solubility product.

### Solubility Following A Chemical Reaction

Thus far, the discussion has been concerned with solubility that comes about because of interplay of entirely physical forces. The dissolution of some substance resulted from overcoming the physical interactions between solute molecules and solvent molecules by the energy produced when a solute molecule interacted physically with a solvent molecule. The solution process, however, can be facilitated also by a chemical reaction. Almost always the chemical enhancement of solubility in aqueous systems is due to the formation of a salt following an acid–base reaction.

An alkaloidal base, or any other nitrogenous base of relatively high molecular weight, generally is slightly soluble in water, but if the pH of the medium is reduced by addition of acid, the solubility of the base is considerably increased as the pH continues to be reduced. The reason for this increase in solubility is that the base is converted to a salt, which is relatively soluble in water. Conversely, the solubility of a salt of an alkaloid or other nitrogenous base is reduced as pH is increased by addition of alkali.

The solubility of slightly soluble acid substances is, on the other hand, increased as the pH is increased by addition of alkali, the reason again being that a salt, relatively soluble in water, is formed. Examples of acid substances whose solubility is thus increased are aspirin, theophylline and the penicillins, cephalosporins, and barbiturates. Conversely, the solubility of salts of the same substances is decreased as the pH decreases.

Among some inorganic compounds a somewhat similar behavior is observed. Tribasic calcium phosphate,  $\text{Ca}_3(\text{PO}_4)_2$ , for example, is almost insoluble in water, but if an acid is added, its solubility increases rapidly with a decrease in pH. This is because hydrogen ions have such a strong affinity for phosphate ions forming nonionized phosphoric acid that the calcium phosphate is dissolved in order to release phosphate ions. Or, stated in another way, the solubilization is an example of a reaction in which a strong acid (the source of the hydrogen ions) displaces a weak acid.

In all of these examples, solubilization occurs as the result of an interaction of the solute with an acid or a base, and thus the species in solution is not the same as the undissolved solute. Compounds that do not react with either acids or bases are slightly, or not at all, influenced in their aqueous solubility by variations of pH. Such effects, if observed, are generally due to ionic *salt effects*.

It is possible to analyze quantitatively the solubility following an acid–base reaction by considering it as a two-step process. The first example is an organic acid, designated as HA, that is relatively insoluble in water. Its two-step dissolution can be represented as:

followed by:

The equilibrium constant for the first step is the solubility of HA ( $K_S = [\text{HA}]_{\text{solution}}$ ), just as was developed earlier when no

chemical reaction took place, and the equilibrium constant for the second step is the dissociation constant of the acid, which is:

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]}$$

Since the total amount of compound *in solution* is the sum of non-ionized and ionized forms of the acid, the total solubility may be designated as  $S_{\text{t(HA)}}$ , or:

$$S_{\text{t(HA)}} = [\text{HA}] + [\text{A}^-] = [\text{HA}] + K_a \frac{[\text{HA}]}{[\text{H}^+]} \quad (8)$$

and because  $K_S = [\text{HA}]$ , Equation 8 becomes:

$$S_{\text{t(HA)}} = K_S \left( 1 + \frac{K_a}{[\text{H}^+]} \right) \quad (9)$$

Equation 9 is very useful because it equates the total solubility of an acid drug with the hydrogen-ion concentration of the solvent. If the water solubility,  $K_S$ , and the dissociation constant,  $K_a$ , are known, the total solubility of the acid can be calculated at various hydrogen-ion concentrations.

Equation 9 demonstrates quantitatively how the total solubility of the acid increases as the hydrogen-ion concentration decreases (i.e., as the pH increases).

It is possible to develop an equation similar to Equation 9 for the solubility of a basic drug B, such as a relatively insoluble nitrogenous base (e.g., an alkaloid), at various hydrogen-ion concentrations. The solubility of the base in water may be represented in two steps as:

Again, if  $K_S$  is the solubility of the free base in water and  $K_b$  is its dissociation constant:

$$K_b = \frac{[\text{BH}^+][\text{OH}^-]}{[\text{B}]}$$

the total solubility of the base in water  $S_{\text{t(B)}}$  is given by:

$$S_{\text{t(B)}} = [\text{B}] + [\text{BH}^+] = [\text{B}] + \frac{K_b[\text{B}]}{[\text{OH}^-]} = K_S \left( 1 + \frac{K_b}{[\text{OH}^-]} \right) \quad (10)$$

It is convenient to rewrite Equation 10 in terms of hydrogen-ion concentration by making use of the dissociation constant for water:

$$K_w = [\text{H}^+][\text{OH}^-] = 1 \times 10^{-14}$$

Equation 10 then becomes:

$$S_{\text{t(B)}} = K_S \left( 1 + \frac{K_b}{K_w / [\text{H}^+]} \right) = K_S \left( 1 + \frac{K_b [\text{H}^+]}{K_w} \right) \quad (11)$$

Equation 11 quantitatively shows how the total solubility of the base increases as the hydrogen-ion concentration of the solvent increases. If  $K_S$  and  $K_b$  are known, it is possible to calculate the total solubility of a basic drug at various hydrogen-ion concentrations using this equation.

Equations 9 and 11 have assumed that the salt formed following a chemical reaction is infinitely soluble. This, of course, is not an acceptable assumption, as suggested and demonstrated by Kramer and Flynn.<sup>2</sup> Rather, for an acidic or basic drug, there should be a pH at which maximum solubility occurs, where this solubility remains the sum of the solution concentrations of the

free and salt forms of the drug at that pH. Using a basic drug B as the example, this would mean that a solution of B, at pH values greater than the pH of maximum solubility, would be saturated with free-base form but not with the salt form, and the use of Equation 11 would be valid for the prediction of solubility. On the other hand, at pH values less than the pH of maximum solubility, the solution would be saturated with salt form, and Equation 11 is no longer really valid. Because in this situation the total solubility of the base,  $S_{t(B)}$ , is:

$$S_{t(B)} = [B] + [BH^+]_s$$

where the subscript's 's' designates a solution saturated with salt, the correct equation to use at pH values less than the pH maximum would be:

$$S_{t(B)} = [BH^+]_s \left( 1 + \frac{[OH^-]}{K_b} \right) = [BH^+]_s \left( 1 + \frac{K_w}{K_b [H^+]} \right) \quad (12)$$

A relationship similar to Equation 12 likewise can be developed for an acidic drug at a pH greater than its pH of maximum solubility.

### Effecting Solution of Solids in the Prescription Laboratory

The method usually employed by the pharmacist when soluble compounds are to be dissolved in water in compounding a prescription requires the use of the mortar and pestle. The ordinary practice is to crush the substance into fragments in the mortar with the pestle and pour the solvent on it, meanwhile stirring with the pestle until solution is effected. If definite quantities are used and the entire volume of the solvent is required to dissolve the given weight of the salt, only a portion of the solvent should be added first, and when this is saturated, the solution is poured off and a fresh portion of solvent added. This operation is repeated until the solid is dissolved entirely and all the portions combined. Other methods of effecting solution are to shake the solid with the liquid in a bottle or flask, or to apply heat to the substances in a suitable vessel. Substances vary greatly in the rate at which they dissolve; some are capable of producing a saturated solution quickly while others require several hours to attain saturation.

With hygroscopic substances like pepsin, silver protein compounds, and some others, the best method of effecting solution in water is to place the substance directly upon the surface of the water and then stir vigorously with a glass rod. If the ordinary procedure, such as using a mortar and pestle, is employed with these substances, gummy lumps form that are exceedingly difficult to dissolve.

The *solubility* of chemicals and the *miscibility* of liquids are important physical factors for the pharmacist to know, for they often have a bearing on intelligently and properly filling prescriptions. For the information of the pharmacist, the USP provides tabular data indicating the degree of solubility or miscibility of many official substances.

### Determination of Solubility

For the pharmacist and pharmaceutical chemist, the question of solubility is of paramount importance. Not only is it necessary to know solubilities when preparing and dispensing medicines, but such information is also necessary to effect separation of substances in qualitative and quantitative analysis. Furthermore, the accurate determination of the solubility of a substance is one of the best methods for determining its purity.

The details of the determination of the solubility are affected markedly by the physical and chemical characteristics of the solute and solvent and also by the temperature at which the solubility is to be determined. Accordingly, it is not possible to describe a universally applicable method, but in general, the following rules must be observed in solubility determinations:

1. It is essential that both the dissolved substance and the solvent are pure because impurities in either affect the solubility.
2. A constant temperature must be maintained accurately during the course of the determination.
3. Complete saturation must be attained.
4. Accurate analysis of the saturated solution and correct expression of the results are imperative.

Consideration should be given also to the varying rates of dissolution of different compounds and to the marked effect of particle size on the time required for the saturation of the solution.

### The Phase Rule and Phase-Solubility Analysis

Phase-solubility analysis is a useful and accurate method for the determination of the purity of a substance. It involves the application of precise solubility methods to the principle that constancy of solubility, in the same manner as constancy of melting point, indicates that a material is pure or free from foreign admixture. It is important to recognize that the technique can be used to obtain the exact solubility of the pure substance without the necessity of the experimental material itself being pure.

The method is based on the thermodynamic principles of heterogeneous equilibria that are among the soundest of theoretical concepts of chemistry. Thus, it does not depend on any assumptions regarding kinetics or structure of matter, but is applicable to all species of molecules, and is sufficiently sensitive to distinguish between optical isomers. The requirements for an analysis are simple, for the equipment needed is basic to most laboratories and the quantities of substances required are small.

The standard solubility method consists of five steps:

1. Mixing, in separate systems, increasing amounts of a substance with measured amounts of a solvent.
2. Establishment of equilibrium for each system at identical constant temperature and pressure.
3. Separation of the solid phase from the solutions.
4. Determination of the concentration of the material dissolved in the various solutions.
5. Plotting the concentration of the dissolved material of interest per unit of solvent (y-axis, or solution concentration) against the mass of total material per unit of solvent (x-axis, or system concentration).

The solubility method has been established on the sound theoretical principles of the Gibbs phase rule:  $F = C - P + 2$ , which relates  $C$ , the number of components;  $F$ , the degrees of freedom (pressure, temperature, and concentration); and  $P$ , the number of phases for a heterogeneous equilibrium.

Solubility analyses are carried out at constant temperature and pressure, so a pure solid in solution would show only one degree of freedom because only one phase is present at concentrations below saturation. This is represented by section  $AB$  in Figure 13-4. For a pure solid in a saturated solution at equilibrium (Fig 13-4,  $BC$ ), two phases are present, solid and solution; there is no variation in concentration and, thus, at constant temperature and pressure, no degrees of freedom.

The curve  $ABC$  of Figure 13-4 represents the type of solubility diagram obtained for (1) a pure material, (2) equal amounts of two or more materials having identical solubilities, or (3) a mixture of two or more materials present in the unique ratio of their solubilities. These latter two cases are rare and often may be detected by a change in solvent system.

Line segment  $BC$  of Figure 13-4 indicates purity because it has no slope. If, however, this section does exhibit a slope, its numerical value indicates the fraction of impurity present. Line segment  $BC$ , extrapolated to the y-axis at  $D$ , is the actual solubility of the pure substance.

A representative type of solubility curve, which is obtained when a substance contains one impurity, is illustrated in

Figure 13-4. Phase-solubility diagram for a pure substance.

Figure 13-5. Here, at *B* the solution becomes saturated with one component. From *B* to *C* there are two phases present: a solution saturated with Component I (usually the major component), containing also some Component II (usually the minor component), and a solid phase of Component I. The one degree of freedom revealed by the slope of the line segment *BC* is the concentration of Component II, which is the impurity (usually the minor component). A mixture of *d* and *l* isomers could have such a curve, as would any simple mixtures in which the solubilities are independent of each other.

The section *CD* indicates that the solvent is saturated with both components of the two-component mixture. Here, three phases are present: a solution saturated with both components and the two solid phases. No variation of concentration is possible; hence, no degree of freedom is possible (indicated by the lack of slope of section *CD*). The distance *AE* on the ordinate represents the solubility of the major component, and the distance *EF* represents the solubility of the minor component.

The equilibration process is time consuming, requiring as long as 3 weeks in certain cases, but this is offset by the fact that all of the sample can be recovered after a determination. This adds to the general usefulness of the method, particularly in cases where the substance is expensive or difficult to obtain. A use for the method other than the determination of purity or of solubility is to obtain especially pure samples by recovering the solid residues at system concentration, corresponding to points on section *BC* in Figure 13-5. Thus, the method is useful not only as a quantitative analytical tool but also for purification.

Figure 13-5. Type of solubility curve obtained when a substance contains one impurity.

## SOLUTIONS OF LIQUIDS IN LIQUIDS

### Binary Systems

The following types of liquid-pairs may be recognized as binary systems:

1. Those that are soluble completely in each other in all proportions. Examples: alcohol and water, glycerin and water, alcohol and glycerin.
2. Those that are soluble in each other in definite proportions. Examples: phenol and water, ether and water, nicotine and water.
3. Those that are imperceptibly soluble in each other in any proportion. Examples: castor oil and water, liquid petrolatum and water.

The mutual solubility of liquid pairs of Type 2 has been studied extensively and found to show interesting regularities. If a series of tubes containing varying, but known, percentages of phenol and water are heated (or cooled, if necessary) just to the point of formation of a homogeneous solution, and the temperature at such points is noted, upon plotting the results a curve is obtained similar to that in Figure 13-6. On this graph the area inside the curve represents the region where mixtures of phenol and water will separate into two layers, while in the region outside of the curve, homogeneous solutions will be obtained. The maximum temperature on this curve is called the *critical solution temperature*, that is, the temperature above which a homogeneous solution occurs, regardless of the composition of the mixture. For phenol and water the critical solution temperature occurs at a composition of 34.5% phenol in water.

Temperature versus composition curves, as depicted in Figure 13-6, provide much useful information in the preparation of homogeneous mixtures of substances showing mutual-solubility behavior. At room temperature (here assumed to be 25°C), by drawing a line parallel to the abscissa at 25°C, we find that we actually can prepare two sets of homogeneous solutions, one containing from 0% to about 7.5% phenol and the other containing phenol from 72% to about 95% (its limit of solubility). At compositions between 7.5% and 72% phenol at 25°C, two liquid layers or phases will separate. In sample tubes containing

Figure 13-6. Phenol-water solubility. (From Campbell AN, Campbell AJR. *J Am Chem Soc* 1937; 59: 2481.)

a concentration of phenol in this two-layer region at 25°C, one layer always will be phenol-rich and always contain 72% phenol while the other layer will be water-rich and always contain 7.5% phenol. These values are obtained by interpolation of the two points of intersection of the line drawn at 25°C with the experimental curve.

As it may be deduced, at other temperatures, the composition of the two layers in the two-layer region is determined by the points of intersection of the curve with a line (called the *tie line*) drawn parallel to the abscissa at that temperature. The relative amounts of the two layers or phases, phenol-rich and water-rich in this example, will depend on the concentration of phenol added. As expected, the proportion of phenol-rich layer relative to the water-rich layer increases as the concentration of phenol added increases. For example, at 20% phenol in water at 25°C, there would be more of the water-rich layer than of the phenol-rich layer, whereas at 50% phenol in water, there would be more of the phenol-rich layer. The relative portion of each layer may be calculated from such tie lines at any temperature and compositions, as well as the amount of phenol present in each of the two phases. To determine how these calculations are made and for further discussion of this topic, the student should consult Sinko.<sup>1</sup>

A simple and practical advantage in the use of phase diagrams is pointed out in Martin *et al.*<sup>1</sup> Based on diagrams such as Figure 13-6, they point out that the most concentrated stock solution of phenol, which should perhaps be used by pharmacists, is one containing 76% w/w phenol in water (equivalent to 80% w/v). At room temperature this mixture is a homogeneous solution and will remain homogeneous to around 3.5°C, at which temperature freezing occurs. It should be noted that Liquefied Phenol USP contains 90% w/w phenol and freezes at 17°C. This means that if the storage area in the pharmacy falls to about 17°C (63°F), the preparation will freeze, resulting in a stock solution no longer convenient to use.

In the case of phenol and water, the mutual solubility increases with an increase in temperature, and the critical solution temperature occurs at a relatively high point. In a certain number of cases, however, the mutual solubility increases with decrease in temperature, and the critical solution temperature occurs at a relatively low value. Most of the substances that show lower critical solution temperatures are amines such as, for example, triethylamine with water.

In addition to pairs of liquids that show *either* upper or lower critical solution temperatures, there are other pairs that show *both* upper and lower critical solution temperatures, and the mutual solubility curve is of the closed type. An example of this type of liquid pair is found in the case of nicotine and water (Fig 13-7). Mixtures of nicotine and water represented by points within the curve will separate into two layers, but mixtures represented by points outside of the curve are perfectly miscible with each other.

In a discussion of solutions of liquids in liquids, it is evident that the distinction between the terms solute and solvent loses its significance. For example, in a solution of water and glycerin, which shall be considered to be the solute and which the solvent? Again, when two liquids are only partially soluble in each other, the distinction between solute and solvent might be reversed easily. In such cases, the term solvent usually is given to the constituent present in larger quantity.

### Ternary Systems

The addition of a third liquid to a binary liquid system to produce a ternary or three-component system can result in several possible combinations.

If the third liquid is soluble in only one of the two original liquids, or if its solubility in the two original liquids is markedly different, the mutual solubility of the original pair will be decreased. An upper critical solution temperature will be elevated and a lower critical solution temperature lowered. On the other hand, the addition of a liquid having roughly the same

Figure 13-7. Nicotine–water solubility.

solubility in both components of the original pair will result in an increase in their mutual solubility. An upper critical solution temperature then will be lowered and a lower critical solution temperature elevated.

An equilateral-triangle graph may be used to represent ternary systems. In this type of graph, each side of the triangle represents 0% of one of the components, and the apex opposite that side represents 100% of that component. This is illustrated using a particularly common ternary system involving two solvents that are completely miscible and a third that is miscible with only one of the two. In Figure 13-8, water and alcohol are the miscible solvents, and castor oil is the third solvent that is soluble in alcohol but not in water. Such diagrams could be applied, for example, to surfactant/oil/water systems, flavor/water/alcohol systems, drug/propellant mixture systems, drug/water/propylene glycol systems, or any other such system you might think of that would fit into this category.

The data in Figure 13-8 were obtained by determining the amount of water needed to just cloud solutions of oil in alcohol at different concentrations and at room temperature. The percentage of each solvent just clouding the system was then calculated and plotted as shown in the figure. For example, a cloudy solution developed at a mixture of about 67% alcohol, 27% oil, and 6% water. Note that the percentages of the three components must always equal 100%. In the region labeled *miscible*, any combination of the three components will result in a solution. The pharmacist can pick any combination in this region for reasons of taste, safety, stability, or cost. Figure 13-8 is constructed for room temperature; any other temperature would have its own phase diagram. Including temperature as a variable would create a three-dimensional relationship with ternary diagrams, such as Figure 13-8, stacked in the  $x$ - $y$  plane as a function of temperature on the  $z$ -axis.

Other possibilities exist in ternary liquid systems—for example, those in which two components are completely miscible and the third is partially miscible with each, and that in which all combinations of two of the three components are only partially miscible.

**Figure 13-8.** Phase diagram at constant temperature for a ternary system: two liquids completely miscible in one another with a third liquid soluble in only one of the two. (Data from Loran MR, Guth EP. *J APhA Sci Ed* 1951; 40: 465.)

### SOLUTIONS OF GASES IN LIQUIDS

Nearly all gases are more or less soluble in liquids. One has but to recall the solubility of carbon dioxide, hydrogen sulfide, or air in water as common examples.

The amount of gas dissolved in a liquid in general follows Henry's Law, which states that the weight of gas dissolved by a given amount of a liquid at a given temperature is proportional to its pressure. Thus, if the pressure is doubled, twice as much gas will dissolve as at the initial pressure. The extent to which a gas is dissolved in a liquid, at a given temperature, may be expressed in terms of the solubility coefficient, which is the volume of gas measured under the conditions of the experiment that is absorbed by one volume of the liquid. The degree of solubility also is expressed sometimes in terms of the *absorption coefficient*, which is the volume of gas, reduced to standard conditions, dissolved by one volume of liquid under a pressure of one atmosphere.

Although Henry's Law expresses fairly accurately the solubility of slightly soluble gases, it deviates considerably in the case of very soluble gases, such as hydrogen chloride and ammonia. Such deviations most frequently are due to chemical interaction of solute and solvent.

The solubility of gases in liquids decreases with a rise in temperature and, in general, also when salts are added to the solvent, the latter effect being referred to as the salting-out of the gas.

### SOLUTIONS OF SOLIDS IN SOLIDS

Various mixtures of one solid in another are being considered in the pharmaceutical sciences, primarily as a means to increase bioavailability. For example, melts of solid mixtures of drugs with excipients and eutectic mixtures are being investigated (see Chapter 11). It is possible to have a true solution of one solid in another to give rise to a continuum of one solid dispersed in another, as depicted in Figure 13-9. Such a system is referred to as a *continuous* dispersion; it is very rarely found. To achieve this would mean that two materials would have to be of similar size, structure, and interaction energy so that they might enter and occupy a mutual crystalline structure at the molecular level. Hence, such solid solutions may occur only among racemic mixtures of chiral compounds. If it were possible to form a solid

**Figure 13-9.** Phase diagram for a continuous solution of a Solid A in a Solid B (or of B in A: 1 is an ideal solution; 2 and 3, nonideal solutions. (Data from Duddu S. PhD thesis. University of Minnesota, 1993.)

solution of a drug in a water-soluble excipient, bioavailability could increase dramatically because the drug would transfer into water as individual molecules.

There are three types of continuous dispersions depicted in Figure 13-9: 1 shows an *ideal* dispersion of constant melting point, while 2 and 3 (*nonideal* solutions) show dispersions having a maximum or minimum, respectively. Each of the latter dispersions show an upper or *liquidus line* and a lower or *solidus line* that might be viewed as representing the direction (cooling or heating) used to arrive at the temperature of melting or solidification in each mixture. The composition of the liquid and solid phases in the region between the two lines can be quantified in a way that is related to the tie-line treatment for phenol-water systems, although more complicated.

More common are the *discontinuous* solid dispersions illustrated in Figure 13-10, in which two true solid solutions  $\alpha$  and  $\beta$  are separated by a eutectic phase. Such a system is found for urea/acetaminophen, which exists as solid solutions in very small regions at very high urea concentration and very high acetaminophen concentration.

At this point it is worthwhile to briefly consider solid complexes. The interaction of a drug with an excipient to form a new solid phase through strong hydrogen-bond formation can give a solid phase that is not precisely a solid solution, but nonetheless potentially important in its effects on bioavailability—both in a positive and negative sense. The phase diagram in

**Figure 13-10.** Phase diagram for a discontinuous solid solution for Solid  $\alpha$  and Solid  $\beta$ : true solid solutions  $\alpha$  and  $\beta$  are separated by a eutectic phase. (From Grant DJW, Abougela IKA. *Physicochemical interactions in pharmaceutical formulations. Anal Proc* 1982;19:545–549. DOI: 10.1039/AP9821900545. Reproduced by permission of The Royal Society of Chemistry.)

**Figure 13-11.** Temperature–concentration relationship for fused mixtures of griseofulvin (G) and phenobarbital (P). (From Grant DJW, Abougela IKA. Physicochemical interactions in pharmaceutical formulations. *Anal Proc* 1982; 19:545–549. DOI: 10.1039/AP9821900545. Reproduced by permission of The Royal Society of Chemistry.)

Figure 13-11 was obtained by fusing and cooling mixtures of griseofulvin (G) and phenobarbitone (P). When a complex is stable up to its melting point, the liquidus curve shows a peak referred to as a *congruent melting point*. Two congruently melting complexes,  $P_3G_3$  and  $P_3G$  (at  $x = 0.25$  and  $0.75$  in Fig 13-11), are found for the griseofulvin solidus-phenobarbital system.

### THERMODYNAMICS OF THE SOLUTION PROCESS

In this discussion of the thermodynamics of the solution process, the solute is assumed to be in the liquid state; hence, the heat of solution ( $\Delta H$ ) is a term different from that in Equation 3 ( $\Delta H$ ). The heat of solution for a solid solute going into solution, as defined in Equation 3, is the net heat effect for the overall dissolution:

considering only the process:

and assuming that the solute is a liquid (or a supercooled liquid in the case of a solid) at a temperature close to room temperature, at which the energy needed for melting (heat of fusion) is not being considered.

For a physical or chemical reaction to occur spontaneously at a constant temperature and pressure, the net free-energy change,  $\Delta G$ , for the reaction should be negative (see Thermodynamics, Chapter 12). Furthermore, it is known that the free-energy change depends on heat-related enthalpy ( $\Delta H'$ ) and order-related entropy ( $\Delta S$ ) factors, as seen in:

$$\Delta G = \Delta H' - T\Delta S \quad (13)$$

where  $T$  is the temperature. Recall also that the relation between free energy and the equilibrium constant,  $K$ , for a reaction is given by:

$$\Delta G = -1RT \ln K \quad (14)$$

Equations 13 and 14 certainly apply to the solution of a drug. Because the solubility is, in reality, an equilibrium constant, Equation 14 indicates that the greater the negative value of  $\Delta G$ , the greater the solubility.

The interplay of these two factors,  $\Delta H'$  and  $\Delta S$  in Equation 13, determines the free-energy change, and hence whether dissolution of a drug will occur spontaneously. Thus, if in the solution process  $\Delta H'$  is negative and  $\Delta S$  positive, dissolution is favored because  $\Delta G$  will be negative.

Because the heat of solution is quite significant in the dissolution process, one must look at its origin. (For an excellent and more complete discussion of the interactions and driving forces underlying the dissolution process, see Higuchi.<sup>6</sup>) The mechanism of solubility involves severing of the bonds that hold together the ions or molecules of a solute, the separation of molecules of solvent to create a space in the solvent into which the solute can be fitted, and the ultimate response of solute and solvent to whatever forces of interaction may exist between them. In order to sever the bonds between molecules or ions of solute in the liquid state, energy must be supplied, as is the case also when molecules of solvent are to be separated. If heat is the source of energy, it is apparent that both processes require the absorption of heat.

### Solute

Solute–solvent interaction, on the other hand, generally is accompanied by the evolution of heat as the process occurs spontaneously. In effecting solution there is, accordingly, a heat-absorbing effect and a heat-releasing effect to be considered beyond those required to melt a solid. If there is no, or very little, interaction between solute and solvent, the only effect will be that of absorption of heat to produce the necessary separations of solute and solvent molecules or ions. If there is a significant interaction between solute and solvent, the amount of heat in excess of that required to overcome the solute–solute and the solvent–solvent forces is liberated. If the opposing heat effects are equal, there will be no change of temperature.

When  $\Delta H'$  is zero, and there is no volume change, an *ideal solution* is said to exist because the solute–solute, solvent–solvent, and solute–solvent interactions are the same. For such an ideal solution, the solubility of a solid can be predicted from its heat of fusion (the energy needed to melt the solid) at temperatures below its melting point. The student is referred to Sinko<sup>1</sup> to see how this calculation is made.

When the heat of solution has a positive (energy absorbed) or negative (energy liberated) value, the solution is said to be a *nonideal solution*. A negative heat of solution favors solubility while a positive heat works against dissolution.

The magnitude of the various attractive forces involved between solute, solvent, and solute–solvent molecules may vary greatly and thus could lead to varying degrees of positive or negative enthalpy changes in the solution process. The reason for this is that the molecular structure of the various solutes and solvents determining the interactions can themselves vary greatly. For a discussion of these effects, see Sinko.<sup>1</sup>

The solute–solute interaction that must be overcome can vary from the strong ion–ion interaction (as in a salt), to the weaker dipole–dipole interaction (as in nearly all organic materials that are not salts), to the weakest induced dipole–induced dipole interaction (as with naphthalene).

The attractive forces in the solvent that must be overcome are, most frequently, the dipole–dipole interaction (as found in water or acetone) and the induced dipole–induced dipole interaction (as in liquid petrolatum).

The energy-releasing solute–solvent interactions that must be taken into account may be one of four types. In decreasing energy of interaction these are ion–dipole interactions (e.g., a sodium ion interacting with water), dipole–dipole interactions (e.g., an organic acid dissolved in water), dipole–induced dipole interaction, to be discussed later (e.g., an organic acid dissolved in carbon tetrachloride), and induced dipole–induced dipole interactions (e.g., naphthalene dissolved in benzene).

Since the energy-releasing solute–solvent interaction should approximate the energy needed to overcome the solute–solute and solvent–solvent interactions, it should be apparent why it is

not possible to dissolve a salt like sodium chloride in benzene. The interaction between the ions and benzene does not supply enough energy to overcome the interaction between the ions in the solute and therefore gives rise to a positive heat of solution. On the other hand, the interaction of sodium and chloride ions with water molecules does provide an amount of energy approximating the energy needed to separate the ions in the solute and the molecules in the solvent.

Consideration must next be given to entropy effects in dissolution processes. Entropy is an indicator of the disorder or randomness of a system. The more positive the entropy change ( $\Delta S$ ) is, the greater the degree of randomness or disorder of the reaction system and the more favorably disposed is the reaction. Unlike  $\Delta H'$ , the entropy change (an entropy of mixing) in an ideal solution, is not zero, but has some positive value, for there is an increase in the disorderliness or entropy of the system upon dissolution. Thus, in an ideal solution with  $\Delta H'$  zero and  $\Delta S$  positive,  $\Delta G$  would have a negative value, and the process would therefore be spontaneous.

In a nonideal solution, on the other hand, where  $\Delta H'$  is not zero,  $\Delta S$  can be equal to, greater than, or less than the entropy of mixing found for the ideal solution. A nonideal solution with an entropy of mixing equal to that of the ideal solution is called a *regular solution*. These solutions usually occur with non-polar or weakly polar solutes and solvents. Such solutions are accompanied by a positive enthalpy change, implying that the solute-solvent molecular interaction is less than the solute-solute and solvent-solvent molecular interactions. Regular solutions are amenable to rigorous physical chemical analysis, which will not be covered in this chapter but which can be found in outline form in Sinko.<sup>1</sup>

The possibility exists in a nonideal solution that the entropy change is greater than for an ideal solution. Such a solution occurs when there is an association among solute or solvent molecules. In essence, the dissolution process occurs when starting at a relatively ordered (low entropy) state and progressing to a disorderly (high entropy) state.

The overall entropy change is positive, greater than that of the ideal case, and favorable to dissolution. As may be expected, the enthalpy change in such a solution is positive because association in a solute or solvent must be overcome. The facilitated solubility of citric acid (an unsymmetrical molecule), as compared to inositol (a symmetrical molecule), may be explained on the basis of such a favorable entropy change.<sup>6</sup>

The solubility of citric acid is greater than that of inositol, yet on the basis of their heats of solution, inositol should be more soluble. One may regard this phenomenon in another way. The reason for the higher solubility of citric acid is that, although there is no hindrance in the transfer of a citric acid molecule as it goes from the solute to the solution phase, when the structurally unsymmetrical citric acid attempts to return to the solute phase from solution, it must assume an orientation that will allow ready interaction with polar groups already oriented. If it does not have the required orientation, it will not return readily to the solute but rather will remain in solution, thus bringing about a solubility larger than expected on the basis of heat of solution.

On the other hand, the structurally symmetrical inositol, as it leaves the solution phase, can interact with the solute phase without requiring a definite orientation; all orientations are equivalent. Hence, inositol can enter the solute phase without hindrance, and therefore, no facilitation of its solubility is observed. In general, unsymmetrical molecules tend to be more soluble than symmetrical molecules.

Another type of nonideal solution occurs when there is an entropy change less than that expected of an ideal solution.

Such nonideal behavior can occur with polar solutes and solvents. In a non-ideal solution of this type, there is significant interaction between solute and solvent. As may be expected, the enthalpy change ( $\Delta H'$ ) in such a solution is negative and favors dissolution, but this effect is tempered by the unfavorable

entropy change occurring at the same time. The reason for the lower-than-ideal entropy change can be visualized where the equilibrium system is more orderly and has a lower entropy than that expected for an ideal solution. The overall entropy change of solution thus would be less and not favorable to dissolution.

One may rationalize the lower-than-expected solubility of lithium fluoride on the basis of this phenomenon. Compared with other alkali halides, it has a solubility lower than would be expected based solely on enthalpy changes. Because of the small size of ions in this salt, there may be considerable ordering of water molecules in the solution. This effect must, of course, lead to a lowered entropy and an unfavorable effect on solubility. The effect of soluble salts on the solubility of non-electrolytes may be considered as a result of an unfavorable entropy effect (see Solubility of solutes containing two or more species, above).

## PHARMACEUTICAL SOLVENTS

The discussion will focus now on solvents available to pharmacists and on the properties of these solvents. Pharmacists must obtain an understanding of the possible differences in solubility of a given solute in various solvents because they are often called on to select a solvent that will dissolve the solute. Knowledge of the properties of solvents will allow the intelligent selection of suitable solvents.

On the basis of the forces of interaction occurring in solvents, one may broadly classify solvents as one of three types:

1. *Polar solvents*—those made up of strong dipolar molecules having hydrogen bonding (water or hydrogen peroxide).
2. *Semipolar solvents*—those also made up of strong dipolar molecules but that do not form hydrogen bonds (acetone or pentyl alcohol).
3. *Non-polar solvents*—those made up of molecules having a small or no dipolar character (benzene, vegetable oil, or mineral oil).

Naturally, there are many solvents that may fit into more than one of these broad classes; for example, chloroform is a weak dipolar compound but generally is considered non-polar in character, and glycerin could be considered a polar or semipolar solvent even though it is capable of forming hydrogen bonds.

## SOLVENT TYPES

### Water

Water is a unique solvent. Besides being a highly associated liquid, giving rise to its high boiling point, it has another very important property, a high dielectric constant. The *dielectric constant* ( $\epsilon$ ) indicates the effect that a substance has, when it acts as a medium, on the ease with which two oppositely charged ions may be separated. The ease of solubilizing salts in solvents like water and glycerin can be explained on the basis of their high dielectric constant. Also, in general, the more polar the solvent, the greater its dielectric constant.

An important concept has been introduced to pharmaceutical systems: pharmacists frequently are concerned with dissolving relatively non-polar drugs in aqueous or mixed polar aqueous solvents.<sup>11</sup> To understand what may be happening in such cases, factors concerned with the entropic effects arising from interactions originating with the non-polar solutes must be considered. Previously it had been noted that the favorable entropic effect on dissolution was due to the disruption of associations occurring among solute or solvent molecules. Now consider the effects on solubility due to solute interactions in the solution phase—because the solutes under discussion are

relatively non-polar, the interactions are of the London Force type or a hydrophobic association.

This hydrophobic association in aqueous solutions may cause significant structuring of water with a resultant ordered or low-entropy system that is unfavorable to solution. Therefore, the solution of an essentially non-polar molecular in water is not a favorable process. It should be stressed that this is due to not only an unfavorable enthalpy change but also an unfavorable entropy change generated by water structuring.

Such an unfavorable entropy change, known as the *hydrophobic effect*, is quite significant in the solution process. As an example of this effect, the aqueous solubility of a series of alkyl *p*-aminobenzoates shows a 10-million-fold decrease in solubility in going from the 1-carbon analog to the 12-carbon analog. These findings demonstrate clearly the considerable effect that hydrophobic associations can have.

## Alcohols

*Ethanol*, as a solvent, is next in importance to water. An advantage of ethanol is that growth of microorganisms does not occur in solutions containing alcohol in a reasonable concentration.

Resins, volatile oils, alkaloids, glycosides, etc., are dissolved by alcohol, but many therapeutically inert principles, such as gums, albumin, and starch, are insoluble, which makes them more useful as *selective* solvents. Mixtures of water and alcohol, in proportions varying to suit specific cases, are used extensively. They are often referred to as hydroalcoholic solvents.

*Glycerin* is an excellent solvent although its range is not as extensive as that of water or alcohol. In higher concentrations it has preservative action. It dissolves the fixed alkalis, a large number of salts, vegetable acids, pepsin, tannin, and some active principles of plants, but it also dissolves gums, soluble carbohydrates, and starch. It also is of special value as a simple solvent (as in phenol glycerite) or where the major portion of the glycerin simply is added as a preservative and stabilizer of solutions that have been prepared with other solvents (see *Glycerines*, Chapter 26).

*Propylene glycol*, which has been used widely as a substitute for glycerin, is miscible with water, acetone, or chloroform in all proportions. It is soluble in ether and will dissolve many essential oils but is immiscible with fixed oils. It is claimed to be as effective as ethyl alcohol in its power of inhibiting mold growth and fermentation.

*Isopropyl alcohol* possesses solvent properties similar to those of ethanol and is used instead of the latter in a number of pharmaceutical manufacturing operations. It has the advantage in that the commonly available product contains not over 1% of water, whereas ethyl alcohol contains about 5% water, often a disadvantage. Isopropyl alcohol is employed in some liniment and lotion formulations. It cannot be taken internally.

## General Properties

Low-molecular-weight and polyhydroxy alcohols form associated structures through hydrogen bonds just as in water. When the carbon-atom content of an alcohol rises above five, generally only monomers then are present in the pure solvent. Although alcohols have high dielectric constants compared to other types of solvents, they are small compared to water. As has been discussed, the solubility of salts in a solvent should be paralleled by its dielectric constant. That is, as the dielectric constant of a series of solvents increases, the probability of dissolving a salt in the solvent increases. This behavior is observed for the alcohols. Table 13-2, taken from Higuchi,<sup>6</sup> shows how the solubility of salts follows the dielectric constant of the alcohols.

As mentioned earlier, absolute alcohol rarely is used pharmaceutically. However, hydroalcoholic mixtures such as elixirs and spirits frequently are encountered. A very useful generalization is that the dielectric properties of a mixed solvent, such as water and alcohol, can be approximated as the weighted average of the properties of the pure components. Thus, a mixture

**Table 13-2. Solubilities of Potassium Iodide and Sodium Chloride in Several Alcohols and Acetone<sup>a</sup>**

Solvent	g KI/100 g Solvent	g NaCl/100 g Solvent
Water	148	35.9
Glycerin	...	8.3 (20°)
Propylene glycol	50	7.1 (30°)
Methanol	17	1.4
Acetone	2.9	
Ethanol	1.88	0.065
1-Propanol	0.44	0.0124
2-Propanol	0.18	0.003
1-Butanol	0.2	0.005
1-Pentanol	0.089	0.0018

<sup>a</sup> All measurements are at 25°C unless otherwise indicated. (Data from Duddu S. PhD thesis. University of Minnesota, 1993.)

of 60% alcohol (by weight) in water should have a dielectric constant approximated by:

$$\epsilon_{(\text{mixture})} = 0.6(\epsilon_{(\text{alcohol})}) + 0.4(\epsilon_{(\text{water})})$$

$$\epsilon_{(\text{mixture})} = 0.6(25) + 0.4(80) = 47$$

The dielectric constant of 60% alcohol in water is found experimentally to be 43, which is in close agreement with that just calculated. The dielectric constant of glycerin is 46, close to the 60% alcohol mixture. One would therefore expect a salt like sodium chloride to have about the same solubility in glycerin as in 60% alcohol. The solubility of sodium chloride in glycerin is 8.3 g/100 g of solvent and in 60% alcohol about 6.3 g/100 g of solvent. This agreement would be even closer if comparisons were made on a volume rather than weight basis. At least qualitatively it can be said that the solubility of a salt in a solvent or a mixed solvent closely follows the dielectric constant of the medium or, conversely, that the polarity of mixed solvents is paralleled by their dielectric constant, based on salt solubility.

Although the dielectric constant is useful in interpreting the effect of mixed solvents on salt solubility, it cannot be applied properly to the effect of mixed solvents on the solubility of nonelectrolytes. It was seen earlier that unfavorable entropic effects can occur upon dissolution of relatively non-polar nonelectrolytes in water. Such an effect due to hydrophobic association considerably affects solubility. Yalkowsky<sup>8</sup> studied the ability of cosolvent systems to increase the solubility of nonelectrolytes in polar solvents where the cosolvent system essentially brings about a reduction in structuring of solvent. Thus, by increasing, in a positive sense, the entropy of solution by using cosolvents, it was possible to increase the solubility of the non-polar molecule. Using as an example the solubility of alkyl *p*-aminobenzoates in propylene glycol–water systems, Yalkowsky reported that it is possible to increase the solubility of the nonelectrolyte by several orders of magnitude by increasing the fraction of propylene glycol in the aqueous system.<sup>8</sup> Sometimes, it is found that, as a good first approximation, the logarithm of the solubility is related linearly to the fraction of propylene glycol added by:

$$\log S_f = \log S_{f=0} + \epsilon f$$

where  $S_f$  is the solubility in the mixed aqueous system containing the volume fraction  $f$  of nonaqueous cosolvent,  $S_{f=0}$  is the solubility in water, and is a constant (not dielectric constant) characteristic of the system under study. Specifically, when a 50% solution of propylene glycol in water is used, there is a 1000-fold increase in solubility of dodecyl *p*-aminobenzoate, in comparison to pure water.

Another empirical equation sometimes used to estimate solubility of a poorly water-soluble substance in a mixed-solvent system is written as:

$$\log S_t = \log S_w f_w + \log S_1 f_1 +$$

where  $S_t$  is the total solubility,  $S_w$  and  $S_1$  are solubilities in pure water and cosolvent 1, respectively, and  $f_w$  and  $f_1$  are the fractions of water and cosolvent 1, respectively.

In a series of studies, Martin *et al.*<sup>9</sup> have made attempts to predict solubility in mixed solvent systems through an extension of the *regular solution* theory. The equations are logarithmic in nature and can reduce in form to the equations of Yalkowsky.<sup>8</sup>

### Acetone and Related Semipolar Materials

Even though acetone has a very high dipole moment ( $2.8 \times 10^{-18}$  esu), as a pure solvent it does not form associated structures. This is evidenced by its low boiling point ( $57^\circ\text{C}$ ) in comparison with the boiling point of the lower molecular weight water ( $100^\circ\text{C}$ ) and ethanol ( $79^\circ\text{C}$ ). The reason why it does not associate is that the positive charge in its dipole does not reside in a hydrogen atom, precluding the possibility of its forming a hydrogen bond. However, if some substance that is capable of forming hydrogen bonds, such as water or alcohol, is added to acetone, a very strong interaction through hydrogen bonding will occur (see Mechanism of solvent action, below). Some substances that are semipolar and similar to acetone are aldehydes, low-molecular-weight esters, other ketones, and nitro-containing compounds.

### Non-polar Solvents

Non-polar class of solvents includes fixed oils, such as vegetable oil and petroleum ether (ligroin), carbon tetrachloride, benzene, and chloroform. On a relative basis there is a wide range of polarity among these solvents; for example, benzene has no dipole moment, whereas that of chloroform is  $1.05 \times 10^{-18}$  esu.

It should be emphasized that when a solvent (such as chloroform) has highly electronegative halogen atoms attached to a carbon atom that also contains at least one hydrogen atom, such a solvent will be capable of forming strong hydrogen bonds with solutes which are polar in character. Thus, through the formation of hydrogen bonds, such solvents will dissolve polar solutes. For example, it is possible to dissolve alkaloids in chloroform.

### MECHANISM OF SOLVENT ACTION

A solvent may function in one or more ways. When an ionic salt is dissolved (e.g., by water), the process of solution involves separation of the cations and anions of the salt with attendant orientation of molecules of the solvent about the ions. Such orientation of solvent molecules about the ions of the solute—a process called *solvation* (*hydration*, if the solvent is water)—is possible only when the solvent is highly polar, whereby the dipoles of the solvent are attracted to and held by the ions of the solute. The solvent also must possess the ability to keep the solvated, charged ions apart with minimal energy.

A polar liquid such as water may exhibit solvent action, also, by virtue of its ability to break a covalent bond in the solute and bring about ionization of the latter. For example, hydrogen chloride dissolves in water and functions as an acid as a result of:

The ions formed by this preliminary reaction of breaking the covalent bond are subsequently maintained in solution by the same mechanism as ionic salts.

Still another mechanism by which a polar liquid may act as a solvent is that involved when the solvent and solute are capable of being coupled through hydrogen-bond formation.

The solubility of the low-molecular-weight alcohols in water, for example, is attributed to the ability of the alcohol molecules to become part of a water-alcohol association complex.

As the molecular weight of the alcohol increases, it becomes progressively less polar and less able to compete with water molecules for a place in the lattice-like arrangement formed through hydrogen bonding; high-molecular-weight alcohols are, therefore, poorly soluble or insoluble in water. When the number of carbon atoms in a normal alcohol reaches five, its solubility in water is reduced significantly.

When the number of hydroxyl groups in the alcohol is increased, its solubility in water generally is increased greatly; it is principally, if not entirely, for this reason that such high-molecular-weight compounds as sugars, gums, many glycosides, and synthetic compounds, such as the polyethylene glycols, are very soluble in water.

The solubility of ethers, aldehydes, ketones, acids, and anhydrides in water and in other polar solvents also is attributable largely to the formation of an association complex between solute and solvent by means of the hydrogen bond. The molecules of ethers, aldehydes, and ketones, unlike those of alcohols, are not associated themselves because of the absence of a hydrogen atom that is capable of forming the characteristic hydrogen bond. Notwithstanding, these substances are more or less polar because of the presence of a strongly electronegative oxygen atom, which is capable of association with water through hydrogen-bond formation.

Acetone, for example, dissolves in water, in all likelihood principally because of the following type of association:

The maximum number of carbon atoms that may be present per molecule possessing a hydrogen-bondable group, while still retaining water solubility, is approximately the same as for the alcohols.

Although nitrogen is less electronegative than oxygen and thus tends to form weaker hydrogen bonds, amines are at least as soluble as alcohols containing an equivalent chain length. The reason for this is that alcohols form two hydrogen bonds with a net interaction of 50,208 joules/mol. Primary amines can form three hydrogen bonds; two amine protons are shared with the oxygens of two water molecules, and the nitrogen accepts one water proton. The net interaction for the primary amine is between 50,208 and 54,392 joules/mol; hence, it shows an equal or greater solubility compared with corresponding alcohols.

The solvent action of non-polar liquids involves a somewhat different mechanism. Because they are unable to form dipoles with which to overcome the attractions between ions of an ionic salt, or to break a covalent bond to produce an ionic compound or form association complexes with a solute, non-polar liquids are incapable of dissolving polar compounds. They only can dissolve, in general, other non-polar substances in which the bonds between molecules are weak. The forces involved usually are of the induced dipole-induced dipole type. Such is the case when one hydrocarbon is dissolved in another, or an oil or a fat is dissolved in petroleum ether.

Sometimes it is observed that a polar substance, such as alcohol, will dissolve in a non-polar liquid, such as benzene. This apparent exception to the preceding generalization may be explained by the assumption that the alcohol molecule induces a temporary dipole in the benzene molecule, which forms an association complex with the solvent molecules. A binding force of this kind is referred to as a *permanent dipole-induced dipole force*.

## Some Useful Generalizations

The preceding discussion indicates that enough is known about the mechanism of solubility to be able to formulate some generalizations concerning this important physical property of substances. Because of the greater importance of organic substances in the field of medicinal chemistry, certain of the more useful generalizations about organic chemicals are presented here in summary form. However, it should be remembered that the phenomenon of solubility usually involves several variables, and there may be exceptions to general rules.

One general maxim that holds true in most instances is, the greater the structural similarity between solute and solvent, the greater the solubility. As often stated, *like dissolves like*. Thus, phenol is almost insoluble in petroleum ether but is very soluble in glycerin.

Organic compounds containing polar groups capable of forming hydrogen bonds with water are soluble in water, provided that the molecular weight of the compound is not too great. It is demonstrated easily that the polar groups OH, CHO, COH, CHOH, CH<sub>2</sub>OH, COOH, NO<sub>2</sub>, CO, NH<sub>2</sub>, and SO<sub>3</sub>H tend to increase the solubility of an organic compound in water. On the other hand, non-polar or very weak polar groups, such as the various hydrocarbon radicals, reduce solubility; the greater the number of carbon atoms in the radical, the greater the decrease in solubility. Introduction of halogen atoms into a molecule in general tends to decrease solubility because of an increased molecular weight without a proportionate increase in polarity.

The greater the number of polar groups contained per molecule, the greater the solubility of a compound, provided that the size of the rest of the molecule is not altered; thus, pyrogallol is much more soluble in water than phenol. The *relative positions* of the groups in the molecule also influence solubility; thus, in water, resorcinol (*m*-dihydroxybenzene) is more soluble than catechol (*o*-dihydroxybenzene), and the latter is more soluble than hydroquinone (*p*-dihydroxybenzene).

Polymers and compounds of high molecular weight can be poorly soluble.

High melting points frequently are indicative of low solubility for organic compounds. One reason for high melting points is the association of molecules, and this cohesive force tends to prevent dispersion of the solute in the solvent.

The *cis* form of an isomer is more soluble than the *trans* form (Table 13-3).

Solvation, which is evidence of the existence of a strong attractive force between solute and solvent, enhances the

solubility of the solute, provided there is not a marked ordering of the solvent molecules in the solution phase.

Acids, especially strong acids, usually produce water-soluble salts when reacted with nitrogen-containing organic bases.

## COLLIGATIVE PROPERTIES OF SOLUTIONS

Up to this point our concern has been with dissolving a solute in a solvent. Once the dissolution has been brought about, naturally the solution has a number of properties that are different from that of the pure solvent. Of very great importance are the colligative properties that a solution possesses.

The colligative properties of a solution are those that depend on the number of solute particles in solution, irrespective of whether these are molecules or ions, large or small. Ideally, the effect of a solute particle of one species is considered to be the same as that of an entirely different kind of particle, at least in dilute solution. Practically, there may be differences that may become substantial as the concentration of the solution is increased.

The colligative properties that will be considered are

1. Osmotic pressure.
2. Vapor-pressure lowering.
3. Boiling-point elevation.
4. Freezing-point depression.

Of these four, all of which are related, osmotic pressure has the greatest direct importance in the pharmaceutical sciences. It is the property that largely determines the physiological acceptability of a variety of solutions used for therapeutic purposes.

## OSMOTIC-PRESSURE ELEVATION

### Osmosis

The phenomenon of osmosis is based on the fact that substances tend to move or diffuse from regions of higher concentration to regions of lower concentration. When a solution is separated from the solvent by means of a membrane that is permeable to the solvent but not to the solute (such a membrane is referred to as a *semipermeable membrane*), it is possible to demonstrate visibly the diffusion of solvent into the concentrated solution, as volume changes will occur. In a similar manner, if two solutions of different concentration are separated by a membrane, the solvent will move from the solution of lower solute concentration to the solution of higher solute concentration. This diffusion of solvent through a membrane is called osmosis.

There is a difference between the activity or escaping tendency of the water molecules found in the solvent and salt solution separated by the semipermeable membrane. Because *activity*, which is related to water concentration, is higher on the pure solvent side, water moves from solvent to solution in order to equalize escaping-tendency differences. The difference in escaping-tendency gives rise to what is referred to as the osmotic pressure of the solution, which might be visualized as follows. A semipermeable membrane is placed over the end of a tube, and a small amount of salt solution placed over the membrane in the tube. The tube then is immersed in a trough of pure water so that the upper level of the salt solution initially is at the same level as the water in the trough. With time, solvent molecules will move from solvent into the tube. The height of the solution will rise until the hydrostatic pressure exerted by the column of solution is equal to the osmotic pressure.

### Osmotic Pressure of Nonelectrolytes

Quantitative studies using solutions of varying concentration of a solute that does not ionize have demonstrated that osmotic pressure is proportional to the concentration of the solute; that is, twice the concentration of a given nonelectrolyte will

**Table 13-3. Demonstration of Solubility Rules**

Chemical Compound	Solubility <sup>a</sup>
Aniline, C <sub>6</sub> H <sub>5</sub> NH <sub>2</sub>	28.6
Benzene, C <sub>6</sub> H <sub>6</sub>	1430.0
Benzoic acid, C <sub>6</sub> H <sub>5</sub> COOH	275.0

<sup>a</sup> Milliliters of mL of water required to dissolve 1 g of solute.

produce twice the osmotic pressure in a given solvent. (This is not strictly true in solutions of fairly high solute concentration but does hold quite well for dilute solutions.)

Furthermore, the osmotic pressures of solutions of different nonelectrolytes are proportional to the number of molecules in each solution. Stated in another manner, the osmotic pressures of two nonelectrolyte solutions of the same molal concentration are identical. Thus, a solution containing 34.2 g of sucrose (mol wt 342) in 1000 g of water has the same osmotic pressure as a solution containing 18.0 g of anhydrous dextrose (mol wt 180) in 1000 g of water. These solutions are said to be *isoosmotic* (*is-osmotic*) with each other because they have identical osmotic pressures.

### Osmotic Pressure of Electrolytes

In discussing the generalizations concerning the osmotic pressure of solutions of nonelectrolytes, it was stated that the osmotic pressures of two solutions of the same molal concentration are identical. This generalization, however, cannot be made for solutions of electrolytes—acids, alkalis, and salts (see Chapter 15).

For example, sodium chloride is assumed to ionize as:

It is evident that each molecule of sodium chloride that ionizes produces two ions; if sodium chloride is completely ionized, there will be twice as many particles as would be the case if it were not ionized at all. Furthermore, if each ion has the same effect on osmotic pressure as a molecule, it might be expected that the osmotic pressure of the solution would be twice that of a solution containing the same molal concentration of nonionizing substance.

For solutions that yield more than two ions—for example:

it is expected that the complete dissociation of the molecules would give rise to osmotic pressures that are three and four times, respectively, the pressure of solutions containing an equivalent quantity of a nonionized solute. Accordingly, the equation  $PV = nRT$ , which may be employed to calculate the osmotic pressure of a dilute solution of a nonelectrolyte, also may be applied to dilute solutions of electrolytes if it is changed to  $PV = i nRT$ , where the value of  $i$  approaches the number of ions produced by the ionization of the stronger electrolytes cited in the preceding examples. For weak electrolytes  $i$  represents the total number of particles, ions, and molecules together in the solution, divided by the number of molecules that would be present if the solute did not ionize. The experimental evidence indicates that, at least in dilute solutions, the osmotic pressures approach the predicted values. It should be emphasized, however, that in more concentrated solutions of electrolytes, the deviations from this simple theory are considerable, due to interionic attraction, solvation, and other factors.

### Biological Aspects of Osmotic Pressure

Osmotic pressure experiments were made as early as 1884 by the Dutch botanist Hugo de Vries in his study of plasmolysis, the term applied to the contraction of the contents of plant cells placed in solutions of comparatively high osmotic pressure. The phenomenon is caused by the osmosis of water out of the cell through the practically semipermeable membrane surrounding the protoplasm. If suitable cells (e.g., the epidermal cells of the leaf of *Tradescantia discolor*) are placed in a solution of higher osmotic pressure than that of the cell contents, water flows out of the cell, causing the contents to draw away from the cell wall. On the other hand, if the cells are placed in solutions of lower osmotic pressure, water enters the cell, producing an expansion that is limited by the rigid cell wall. By immersing cells

in a series of solutions of varying solute concentration, a solution may be found in which plasmolysis is barely detectable or absent. The osmotic pressure of such a solution is then the same, or very nearly the same, as that of the cell contents, and it is then said that the solution is *isotonic* with the cell contents. Solutions of greater concentration than this are said to be *hypertonic*, and solutions of lower concentration are called *hypotonic*.

Red blood cells, or erythrocytes, have been studied similarly by immersion into solutions of varying concentration of different solutes.<sup>10</sup> When introduced into water or into sodium chloride solutions containing less than 0.90 g of solute per 100 mL, human erythrocytes swell and often burst because of the diffusion of water into the cell and the fact that the cell wall is not sufficiently strong to resist the pressure. This phenomenon is referred to as hemolysis. If the cells are placed in solutions containing more than 0.90 g of sodium chloride per 100 mL, they lose water and shrink. By immersing the cells in a solution containing exactly 0.90 g of sodium chloride in 100 mL, no change in the size of the cells is observed; because in this solution the cells maintain their *tone*, the solution is said to be *isotonic* with human erythrocytes. For the reasons indicated it is desirable that solutions to be injected into the blood should be made isotonic with erythrocytes.

### Distinction Between Iso-smotic (isomotic) and Isotonic

The terms *isoosmotic* and *isotonic* are not to be considered as equivalent, although a solution often may be described as being both isoosmotic and isotonic. If a plant or animal cell is in contact with a solution that has the same osmotic pressure as the cell contents, there will be no net gain or loss of water by either solution, provided the cell membrane is impermeable to all the solutes present. As the volume of the cell contents remains unchanged, the *tone*, or normal state, of the cell is maintained, and the solution in contact with the cell may be described not only as being isoosmotic with the solution in the cell but also as being isotonic with it. If, however, one or more of the solutes in contact with the membrane can pass through the latter, it is evident that the volume of the cell contents will change, thus altering the *tone* of the cell; in this case the two solutions may be isoosmotic, yet not be isotonic.

### VAPOR-PRESSURE LOWERING

When a nonvolatile solute is dissolved in a liquid solvent, the vapor pressure of the solvent is lowered. This easily can be described qualitatively by visualizing solvent molecules on the surface of the solvent, which normally could escape into the vapor, being replaced by solute molecules, which have little, if any, vapor pressure of their own. For ideal solutions of nonelectrolytes, the vapor pressure of the solution follows Raoult's Law:

$$P_A = X_A P_A^0 \quad (15)$$

where  $P_A$  is the vapor pressure of the solution,  $P_A^0$  is the vapor pressure of the pure solvent, and  $X_A$  is the mole fraction of solvent. This relationship states that the vapor pressure of the solution is proportional to the number of molecules of solvent in the solution. Rearranging Equation 15 gives:

$$\frac{P_A^0 - P_A}{P_A^0} = (1 - X_A) X_B \quad (16)$$

where  $X_B$  is the mole fraction of the solute. This equation states that the lowering of vapor pressure in the solution relative to the vapor pressure of the pure solvent—called simply the relative vapor-pressure lowering—is equal to the mole fraction of the solute. The absolute lowering of vapor pressure of the solution is defined by:

$$P_A^0 - P_A = X_B P_A^0 \quad (17)$$

**Example** Calculate the lowering of vapor pressure, and the vapor pressure at 20°C, of a solution containing 50 g of anhydrous dextrose (mol wt 180.16) in 1000 g of water (mol wt 18.02). The vapor pressure of water at 20°C, in absence of air, is 2.311 kPa.

First, calculate the lowering of vapor pressure, using Equation 17, in which  $X_B$  is the mol fraction of dextrose, defined by:

$$X_B = \frac{n_B}{n_A + n_B}$$

where  $n_A$  is the number of mols of solvent and  $n_B$  is the number of mols of solute. Substituting numerical values:

$$n_B = \frac{50}{180.2} = 0.278$$

$$n_A = \frac{1000}{18.02} = 55.5$$

$$X_B = \frac{0.278}{55.5 + 0.278} = 0.00498$$

the lowering of vapor pressure is:

$$P_A^0 - P_A = 0.00498 \times 17.535$$

$$= 0.0873 \text{ mmHg}$$

The vapor pressure of the solution is:

$$P_A = 17.535 - 0.0873$$

$$= 17.448 \text{ mmHg}$$

## BOILING-POINT ELEVATION

In consequence of the fact that the vapor pressure of any solution of a nonvolatile solute is less than that of the solvent, the *boiling point* of the solution—the temperature at which the vapor pressure is equal to the applied pressure (commonly 760 mmHg)—must be higher than that of the solvent. This is clearly evident in Figure 13-12.

## FREEZING-POINT DEPRESSION

The *freezing point of a solvent* is defined as the temperature at which the solid and liquid forms of the solvent coexist in equilibrium at a fixed external pressure, commonly 1 atmosphere (1 atm = 760 mm [torr] of mercury). At this temperature the solid and liquid forms of the solvent must have the same vapor

**Figure 13-12.** Vapor-pressure-temperature diagram for water and an aqueous solution, illustrating elevation of boiling point and lowering of freezing point of the latter.

pressure, for if this were not so, the form having the higher vapor pressure would change into that having the lower vapor pressure.

The *freezing point of a solution* is the temperature at which the solid form of the pure solvent coexists in equilibrium with the solution at a fixed external pressure, again commonly 1 atm. Because the vapor pressure of a solution is lower than that of its solvent, it is obvious that solid solvent and solution cannot coexist at the same temperature as solid solvent and liquid solvent; only at some lower temperature, where solid solvent and solution do have the same vapor pressure, is equilibrium established. A schematic pressure-temperature diagram for water and an aqueous solution, not drawn to scale and exaggerated for the purpose of more effective illustration, shows the equilibrium conditions involved in both freezing-point depression and boiling-point elevation (see Fig 13-12).

The freezing-point lowering of a solution may be quantitatively predicted for ideal solutions, or dilute solutions that obey Raoult's Law, by mathematical operations similar to (though somewhat more complex than) those used in deriving the boiling-point elevation constant. The equation for the freezing-point lowering,  $\Delta T_f$ , is:

$$\Delta T_f = \frac{RT_0^2 M_A m}{1000 \Delta H_{\text{fus}}} = K_f m \quad (18)$$

where:

$$K_f = \frac{RT_0^2 M_A}{1000 \Delta H_{\text{fus}}} \quad (19)$$

The value of  $K_f$  for water, which freezes at 273.1° K and has a heat of fusion of 79.7 cal/g, is:

$$K_f = \frac{8.314}{1000} \frac{273.1^2}{18.02} \frac{18.02}{333.46} = 0.0068^\circ \quad (20)$$

The molal freezing-point depression constant is not intended to represent the freezing-point depression for a 1-molal solution, which is too concentrated for the premise of ideal behavior to be applicable. In dilute solutions the freezing-point depression, calculated to a 1-molal basis, approaches the theoretical value—the more dilute the solution, the better the agreement between experiment and theory.

To calculate the molecular weight of the solute, the freezing point of a dilute solution of a nonelectrolyte solute may be used (as was the boiling point). The applicable equation is:

$$M_B = \frac{(K_f \times 1000 \times W_B)}{(W_A \times \Delta T_f)} \quad (21)$$

The molecular weight of organic substances soluble in molten camphor may be determined by observing the freezing point of a mixture of the substance with camphor. This procedure, called the *Rast method*, uses camphor because it has a very large molal freezing-point-depression constant, about 40. Because the *constant* may vary with different lots of camphor and with variations of technique, the method should be standardized using a solute of known molecular weight.

Freezing-point determinations of molecular weights have the advantage over boiling-point determinations of greater accuracy and precision by virtue of the larger magnitude of the freezing-point depression compared to boiling-point elevation. Thus, in the case of water the molal freezing-point depression is approximately 3.5 times greater than the molal boiling-point elevation.

## IDEAL BEHAVIOR AND DEVIATIONS

In setting out to derive mathematical expressions for colligative properties, such phrases as for *ideal solutions* or for *dilute solutions* were used to indicate the limitations of the expressions.

Samuel Glasstone defines an ideal solution as “one which obeys Raoult’s Law over the whole range of concentration and at all temperatures” and gives as specific characteristics of such solutions their formation only from constituents that mix in the liquid state without heat change and without volume change. These characteristics reflect the fact that addition of a solute to a solvent produces no change in the forces between molecules of the solvent. Thus, the molecules have the same escaping-tendency in the solution as in the pure solvent, and the vapor pressure above the solution is proportional to the ratio of the number of solvent molecules in the surface of the solution to the number of the molecules in the surface of the solvent—which is the basis for Raoult’s Law.

Any change in intermolecular forces produced by mixing the components of a solution may result in deviation from ideality; such a deviation may be expected particularly in solutions containing both a polar and a non-polar substance. Solutions of electrolytes, except at high dilution, are especially prone to depart from ideal behavior, even though allowance is made for the additional particles that result from ionization. When solute and solvent combine to form solvates, the escaping-tendency of the solvent may be reduced in consequence of the reduction in the number of free molecules of solvent; thus, a negative deviation from Raoult’s Law is introduced. On the other hand, the escaping-tendency of the solvent in a solution of nonvolatile solute may be increased because the cohesive forces between molecules of solvent are reduced by the solute; this results in a positive deviation from Raoult’s Law.

Although few solutions exhibit ideal behavior over a wide range of concentration, most solutions behave ideally at least in high dilution, where deviations from Raoult’s Law are negligible.

### Colligative Properties of Electrolyte Solution

Earlier in this chapter, attention was directed to the increased osmotic pressure observed in solutions of electrolytes, the enhanced effect being attributed to the presence of ions, each of which acts, in general, in the same way as a molecule in developing osmotic pressure. Similar magnification of vapor-pressure lowering, boiling-point elevation, and freezing-point depression occurs in solutions of electrolytes. Thus, at a given constant temperature, the abnormal effect of an electrolyte on osmotic pressure is paralleled by abnormal lowering of vapor pressure; the other colligative properties are (subject to variation of effect with temperature) comparably intensified. In general, the magnitude of each colligative property is proportional to the total number of particles (molecules and/or ions) in solution.

While in very dilute solutions, the osmotic pressure, vapor-pressure lowering, boiling-point increase, and freezing-point depression of solutions of electrolytes would approach values two, three, and four times greater for NaCl, Na<sub>2</sub>SO<sub>4</sub>, and Na<sub>3</sub>PO<sub>4</sub> than in solutions of the same molality of a nonelectrolyte, two other effects are observed as the concentration of electrolyte is increased. The first effect results in less than two-, three-, or four-fold intensification of a colligative property. This reduction is ascribed to interionic attraction between the positively and negatively charged ions. Consequently, the ions are not completely dissociated from each other and do not exert their full effect in lowering vapor pressure, etc. This deviation generally increases with increasing concentration of electrolyte. The second effect intensifies the colligative properties and is attributed to the attraction of ions for solvent molecules, which holds the solvent in solution and reduces its escaping-tendency, with consequent enhancement of the vapor-pressure lowering. Solvation also may reduce interionic attraction and thereby further lower the vapor pressure.

These factors (and possibly others) combine to effect a progressive reduction in the molal values of colligative properties as the concentration of electrolyte is increased from 0.5 to 1.0 molal, beyond which the molal quantities either increase (sometimes quite abruptly) or remain almost constant.

### ACTIVITY AND ACTIVITY COEFFICIENT

Various mathematical expressions are employed to relate properties of chemical systems (equilibrium constants, colligative properties, pH, etc.) to the stoichiometric concentration of one or more molecular, atomic, or ionic species. In deriving such expressions it is either stated or implied that they are valid only so long as intermolecular, interatomic, and/or interionic forces may be ignored or remain constant, under which restriction the system may be expected to behave ideally. But intermolecular, interatomic and/or interionic forces do exist, and not only do they change as a result of chemical reaction, but they also change with variation in the concentration or pressure of the molecules, atoms, or ions under observation. In consequence, mathematical expressions involving stoichiometric concentrations or pressures generally have limited applicability. The conventional concentration terms provide a count of molecules, atoms, or ions per unit volume but afford no indication of the physical or chemical activity of the species measured, and it is this activity that determines the physical and chemical properties of the system.

In recognition of this, G. N. Lewis introduced both the quantitative concept and methods for evaluation of activity as a true measure of the physical or chemical activity of molecular, atomic, or ionic species, whether in the state of gas, liquid, or solid, or whether present as a single species or in a mixture. Activity may be considered loosely as a corrected concentration or pressure that takes into account not only the stoichiometric concentration or pressure but also any intermolecular attractions, repulsions, or interactions between solute and solvent in solution, association, and ionization. Thus, activity measures the net effectiveness of a chemical species.

Because only relative values of activity may be determined, a *standard state* must be chosen for quantitative comparisons to be made. Indeed, because activity measurements are needed for many different types of systems, several standard states must be selected. Because this discussion is concerned mainly with solutions, the standard state for the solvent is pure solvent, while for the solute it is a hypothetical solution with free energy corresponding to unit molality under conditions of ideal behavior of the solution. The relationship of activity to concentration is measured in terms of an activity coefficient, which is discussed in Chapter 15.

### PRACTICAL APPLICATIONS OF COLLIGATIVE PROPERTIES

One of the most important pharmaceutical applications of colligative properties is in the preparation of isotonic intravenous and isotonic lacrimal solutions, the details of which are discussed in Chapter 16.

Other applications of the colligative properties are found in experimental physiology. One such application is in the immersion of tissues in salt solutions, which are isotonic with the fluids of the tissue, in order to prevent changes or injuries that may arise from osmosis.

The colligative properties of solutions also may be used in determining the molecular weight of solutes, or in the case of electrolytes, the extent of ionization. The method of determining molecular weight depends on the fact that each of the colligative properties is altered by a constant value when a definite number of molecules of solute is added to a solvent (see Chapter 15). For example, in dilute solutions the freezing point of water is lowered at the rate of 1.855 for each mole of a nonelectrolyte dissolved in 1000 g of water.

The boiling-point elevation may be used similarly for determining molecular weights. The boiling point of water is raised at the rate of 0.52°C for each mole of solute dissolved in 1000 g of water; the corresponding values for benzene, carbon tetrachloride, and phenol are 2.57°C, 4.88°C, and 3.60°C, respectively. The observed vapor-pressure lowering and osmotic pressure likewise may be used to calculate molecular weights.

To determine the extent to which an electrolyte is ionized, it is necessary to know its molecular weight, as determined by some other method, and then to measure one of the four colligative properties. The deviation of the results from similar values for nonelectrolytes then is used in calculating the extent of ionization.

### QUANTITATIVE TREATMENT OF SOLUBILITY

The focus of discussion so far has been on the qualitative aspects of solubility. It is, however, important to understand some quantitative relationships that can help pharmaceutical scientists predict the solubility of new-drug entities in various solvents and allow them to choose the best solvent system for a given drug. The observation that structurally similar chemical entities have better solubility in each other is based on the fact that cohesive forces operating in such molecules are of the same order of magnitude. One measure of these cohesive forces is a quantity known as internal pressure ( $P_i$ ). It is given by<sup>1</sup>:

$$P_i = \frac{(\Delta H_v - RT)}{V} \quad (22)$$

where  $\Delta H_v$  is the heat of vaporization of a substance and  $V$  is its molar volume at temperature  $T$ . Since Equation 22 contains  $\Delta H_v$  which depends on the amount of energy required to break intermolecular (cohesive) bonds,  $P_i$  is a measure of cohesive forces among the molecules. This value is high in polar substances; for example, water has a  $P_i$  value of 2301.2 joules/mL. Therefore, drugs with high internal pressure show higher solubility in water. The term  $P_i$  usually is reserved for solubility of liquids in liquids.

For a quantitative estimate of solubility of solids in liquids, it is assumed that in an ideal solution the heat of solution is equal to the heat of fusion (heat required to melt one mole of solid to liquid without changing its temperature). Because ideal solubility does not depend on the nature of solvent, it can be expressed by equation 23:

$$-\log X_2^i = \frac{\Delta H_f}{2.303R} \left( \frac{T_0 - T}{T_0 T} \right) \quad (23)$$

where  $X_2^i$  is the mol fraction solubility in an ideal solution,  $\Delta H_f$  is the molar heat of fusion of solute,  $T_0$  is the melting point of solute, and  $T$  is the solution temperature such that  $T < T_0$ .

In a nonideal solution, the mol fraction solubility ( $X$ ) has to be replaced by thermodynamic activity ( $\alpha$ ) of the solute. This activity can be expressed in terms of mol fraction solubility as:

$$a_2 = X_2 \gamma_2 \quad (24)$$

in which  $a_2$  is a proportionality constant called the *activity coefficient*. The value of  $a_2$  in ideal solution is equal to its maximum value of unity. By taking the log of the above equation and substituting in Equation 23, one obtains the equation of non-ideal solubility as:

$$-\log X_2 = \frac{\Delta H_f}{2.303R} \left( \frac{T_0 - T}{T_0 T} \right) + \log a_2 \quad (25)$$

It can be seen that when  $a_2 = 1$ ,  $\log a_2$  is zero, and the equation reduces to the ideal solubility equation.

In general, ideal solutions are rare. Solutions of non-polar solutes in non-polar solvents usually come close to being ideal. However, solutions involving polar solutes or solvents almost always show significant deviation from ideality. The value of  $a_2$  is hard to determine and varies with concentration of solution. It can be, however, estimated by:

$$\log a_2 = \left[ (\omega_{11})^{1/2} - (\omega_{22})^{1/2} \right]^2 \frac{V_2 \Phi_1^2}{2.303RT} \quad (26)$$

where  $\omega_{11}$  is the amount of work involved in separating solvent molecules to create space for a solute molecule,  $\omega_{22}$  is the work involved in breaking a solute molecule from its bulk,  $V_2$  is the molar volume of solute at temperature  $T$ ,  $\Phi_1$  is the volume fraction of the solvent, and  $R$  is the gas constant. The terms  $\omega_{11}$  and  $\omega_{22}$  are a measure of the internal energy or cohesive forces of the solvent and solute, respectively. It can be seen from Equation 26 that deviation from ideality is high if values of  $\omega_{11}$  and  $\omega_{22}$  are different from each other or if the molar volume of the solute is high. The  $\omega$  terms are also known as the *solubility parameters*, denoted as  $\delta$ . Thus the equation of nonideal solubility can be written as:

$$-\log X_2 = \frac{\Delta H_f}{2.303R} \left( \frac{T_0 - T}{T_0 T} \right) + \frac{V_2 \Phi_1^2}{2.303RT} (\delta_1 - \delta_2)^2 \quad (27)$$

The following observations can be made from Equation 27.

1. For dilute solutions  $\Phi_1$  is approximately equal to unity and thus may be disregarded in estimating solubility in dilute solutions
2. The closer the values of  $\Delta_1$  and  $\Delta_2$ , the greater the solubility for a given pair of solute and solvent. In fact, when  $\Delta_1 = \Delta_2$ , the equation reduces to the equation for ideal solution, in which case the solubility is at its maximum value and depends only on the molar heat of fusion of the solute.
3. Solutions of larger solute molecules (high value of  $V_2$ ) show higher deviation from ideality. It is not surprising, therefore, that solutions of polymers and other high-molecular-weight compounds show a very different behavior than ideal solution (see Solutions of polymers, below).

The solubility parameters can be measured using property of the material that involves molecular or cohesive interactions. These include the molar heat of vaporization, surface tension, internal pressure, and several others. One method suggested by Hilderbrand *et al.*<sup>12</sup> is to use the expression for internal pressure to estimate the value of solubility parameter as follows:

$$\delta = \left( \frac{\Delta H_v - RT}{V} \right)^{1/2} \quad (28)$$

The meanings of the symbols are the same as defined earlier. The values of solubility parameters are available in several references for many commonly used drugs. As intermolecular forces are composed of many kinds of forces, including polar and non-polar forces, the individual contribution of these forces can be included in quantitative estimate of solubility parameter. Hilderbrand and Scott<sup>13</sup> suggested Equation 29 for this purpose:

$$\delta^2 = \delta_D^2 + \delta_P^2 + \delta_H^2 \quad (29)$$

where  $\Delta_D^2$  is the partial solubility parameter arising from non-polar interactions,  $\Delta_P^2$  is the partial solubility parameter from polar interactions, and  $\Delta_H^2$  is the partial solubility parameter from the hydrogen-bonding tendency among the molecules. The value of  $\Delta_D^2$  is fairly constant for all types of molecules, polar as well as non-polar, because non-polar forces operate in all of these molecules. This value ranges from 29.288 to 41.84 joules/mL. Because  $\Delta_P^2$  is due to polar forces, which are essentially absent in non-polar compounds, its value range is broader, 0 to 54.392 joules/mL. The value of  $\Delta_H^2$ , on the other hand, has the highest contribution where present and has a range of 0 to 104.6 joules/mL. Therefore, for non-polar compounds, such as linear hydrocarbons, the total value of is composed entirely of  $\Delta_D^2$  and is close to about 7. For this reason, most hydrocarbons show a similar behavior of solubility. In the nonhydrogen-bonding compounds that are relatively polar,  $\Delta_P^2$  has significant contribution.

## SOLUTIONS OF POLYMERS

The solubility behavior of polymers is usually significantly different from that of small molecules. Although there is no well-defined value of molecular weight cutoff point between polymers and regular molecules, polymer solutions included in the discussion here will focus on molecules whose size approaches the colloidal range.

Depending upon the manner in which the monomers are connected to each other, polymers can be of several types. From the solubility standpoint, however, the nature of the monomers is of great significance. In general, the solubility behavior of homopolymers (consisting of monomers repeated  $n$  times) mimics the solubility behavior of the monomers. This implies that the homopolymers consisting of relatively hydrophobic monomers will be poorly soluble in water. Examples of such polymers include polystyrene and polyamines.

However, if the hydrophobic monomers form parts of the block polymers (consisting of blocks of one repeating monomer unit followed by a block of different monomer) or heteropolymers (several monomers attached in random manner), their contribution to solubility may not be as negative as one would expect from their structure. This is because polymers are long molecules and generally have the flexibility to fold themselves in a manner that allows their hydrophobic areas to be folded away from water, much in the way that amphiphiles aggregate to form a hydrophobic core. This arrangement allows the hydrophilic monomers to stay in contact with water, thereby allowing substantial solubility. Examples of such polymers include proteins (which may contain hydrophobic amino acid residues).

Many of the so-called *biological polymers* consist of monomers that carry a net negative or positive charge at near neutral pH. These are known as *polyelectrolytes*, and they are generally very soluble in water. Their solubility is driven by the electrostatic interactions between water and the charged monomers. Examples of such polymers include DNA, proteins, certain derivatized cellulose polymers, and carrageenans. Such polymers are of significant importance in pharmaceutical dosage forms as thickeners, additives, stabilizers, and controlled-release matrices.

Many biological polymers exist as random coil structures in aqueous solution. If the structure is treated as an approximate sphere, then its radius, known as the *radius of gyration* ( $R_g$ ), is a function of its molecular weight. In polymers of very high molecular weight (typically 100 kDa or higher) this radius may be so large that the polymer in solution behaves like a particle, approaching the size of the colloidal range. The volume of this particle is given by<sup>14</sup>:

$$V_{\text{coil}} = \frac{4}{3} \pi R_g^3 \quad (30)$$

where  $V_{\text{coil}}$  is the volume of a single polymer chain and  $R_g$  is the radius of gyration. When the value of this volume is large, the system no longer behaves as a dilute solution, even when the molar concentration is small and polymer-polymer interactions are significant. Depending on the polymer molecular weight, significant overlapping between the polymer chains may occur at concentration as low as 0.1%.<sup>14</sup> At higher concentration the swollen polymer and free solvent may occupy comparable volumes in the solution.

Unlike in regular solutions, the solubility of polymers is driven primarily by entropic changes. Upon mixing a polymer with a solvent, which is generally water in pharmaceutical solutions, two different kinds of entropic effects occur. One is the increase in entropy due to mixing of two molecular species. This effect is small in a dilute solution. The second effect is that the entropy of the polymer configuration increases, due to swelling of the molecules and also to greater flexibility in solution. Based on these entropic changes, Flory<sup>15,16</sup> derived Equation 31 to describe the overall entropic change ( $\Delta S_{\text{mix}}$ ) in a polymer solution:

$$\Delta S_{\text{mix}} = -R(n_s \ln \Phi_s + n_p \ln \Phi_p) \quad (31)$$

where  $n_s$  and  $n_p$  are the number of molecules of solvent and polymer, respectively, and  $\Phi_s$  and  $\Phi_p$  represent their volume fraction, respectively. The free-energy change ( $\Delta G_{\text{mix}}$ ) in the process of solubility can be written as:

$$\Delta G_{\text{mix}} = RT(n_s \ln \Phi_s + n_p \ln \Phi_p) + (n_s + N_p n_p) \varpi \Phi_p \Phi_s \quad (32)$$

The first term on the right side of Equation 32 is the entropy of mixing, and the second term is the enthalpy of mixing.  $n_p$  in the second term is the degree of polymerization, and  $\varpi$  is the effective molar interaction parameter (effectively,  $\varpi$  is the square of the difference between solubility parameters of the polymer and solvent, multiplied by Avogadro's number). It is clear from the above equation that the value of  $\Delta G_{\text{mix}}$  and, therefore, the polymer solubility are driven primarily by the volume fraction of the polymer in solution.

## METHODS TO INCREASE SOLUBILITY OF POORLY SOLUBLE DRUGS

A large number of promising drug candidates do not make it to the market because of poor bioavailability, due primarily to their poor solubility in aqueous medium. Recently, several strategies have been used to improve solubility profile of these drugs and include the following:

1. Use of buffers
2. Use of cosolvents
3. Use of surfactants
4. Complexation
5. Solid dispersions.

### Use of Buffers

The idea behind the use of buffers to improve solubility is to create and maintain pH conditions in a system that causes the drug to be in its ionized state. As discussed previously in this chapter, the ionized fraction of a drug is much more soluble in water, due to its increased polarity relative to the unionized fraction. Buffers can also help in reducing the likelihood of drug precipitation when drug solution is diluted in an aqueous medium. Consistent with the principles of solubility changes with pH, acidic drugs are formulated under relatively basic conditions while the opposite is true for the basic drugs. Some examples of drugs that are formulated with buffer systems are Amikacin sulfate (pH 3.5–5.5, citrate buffer) and Midazolam hydrochloride (pH 3).<sup>17–19</sup> The drugs that make good candidates for use of pH variation or buffers are the ones that have the ability to ionize within a pH range of 2–8.

### Use of Cosolvents

A common way to increase drug solubility is through the use of a water-miscible organic solvent. This strategy is based on the fact that poor solubility of drugs in water results from the great difference in polarity of the two components, water being of very high polarity and the drug having low polarity. Addition of a cosolvent with a polarity value of less than that of water reduces the difference between polarity of the drug and water cosolvent system, thereby improving solubility. Commonly used cosolvents for this purpose are the hydrogen bonding organic solvents such as ethyl alcohol, propylene glycol, and glycerin.

The polarity scale of solvents is defined by a property known as the dielectric constant. This value for water is 80, and for ethyl alcohol, propylene glycol, and glycerin, it is 24, 32, and 42, respectively. Most poorly soluble drugs have dielectric constant values of less than 20. Examples of some parenteral solution that contain cosolvents include chlordiazepoxide (25% propylene glycol), diazepam (10% ethyl alcohol and 40% propylene glycol), and digoxin (10% ethyl alcohol and 40% propylene

glycol). Non-polar and nonionizable drugs are good candidates for cosolvent systems.<sup>17–19</sup>

### Use of Surfactants

Surfactants are molecules with well defined polar and non-polar regions that allow them to aggregate in solution to form micelles. Non-polar drugs can partition into these micelles and be solubilized. Depending on the nature of the polar area, surfactants can be nonionic (e.g., polyethylene glycol), anionic (e.g., sodium dodecyl sulfate), cationic (e.g., trialkylammonium), and zwitterionic (e.g., glycine and proteins). Among these, the most commonly used ones are the anionic and non-ionic surfactants. Since the process of solubilization occurs due to presence of micelles, generally high concentrations of surfactants are needed to significantly improve drug solubility. One example of surfactant based solution is Taxol (paclitaxel), an anti-cancer drug that is solubilized in 50% solution of Cremophor. Other examples include valrubicin in 50% Cremophor, and cyclosporin in 65% Cremophor.<sup>17–19</sup>

### Complexation

Complexation is the association between two or more molecules to form a noncovalent-based complex that has higher solubility than the drug itself. From the solubility standpoint, complexes can be put into two categories the stacking complexes and inclusion complexes. Stacking complexation is driven by association of non-polar areas of the drug and complexing agent. This results in exclusion of the non-polar areas from contact with water, thereby reducing the total energy of the system. This aggregation is favored by large, planar, non-polar regions on the molecules. Stacking can be homogeneous or mixed but results in a clear solution.

Inclusion complexes are formed by insertion of drug molecule into a cavity formed by the complexing agent. In this arrangement the non-polar area of the drug molecule is excluded from water, due to its insertion in the complexing agent. One requirement for the complexing agent in such systems is that it has a non-polar core and a polar exterior. The most commonly used inclusion complexing molecules are cyclodextrins. The cyclic oligomers of glucose are relatively soluble in water and have cavities large enough to accept non-polar portions of many drug molecules. Cyclodextrins can consist of six, seven, or eight sugar residues and are classified as  $\alpha$ ,  $\beta$  and  $\gamma$ , respectively. Due to geometric considerations, steroid molecules are very suitable for inclusion into cyclodextrin complexes.

### Solid Dispersions

Solid dispersion refers to the dispersion of one or more active ingredients in an inert carrier or matrix at solid state, prepared by the melting (fusion), solvent, or the melting-solvent method. It has also been defined as the product formed by converting a fluid drug-carrier combination to the solid state. The term coprecipitate or co-evaporate has also been used frequently when a solid dispersion is prepared by the solvent method.

#### CLASSIFICATION OF SOLID DISPERSIONS

Solid dispersions can be classified as follows:

- Simple eutectic mixtures
- Solid solutions
- Glass solutions of suspensions
- Compound or complex formation between the drug and the carriers
- Amorphous precipitations of drug in crystalline carrier.

#### SIMPLE EUTECTIC MIXTURES

A simple eutectic mixture consists of two compounds that are completely miscible in the liquid state but only to a very limited extent in the solid state. A eutectic mixture of a sparingly water-soluble drug and a highly water-soluble carrier may be regarded

thermodynamically as an intimately blended physical mixture of its two crystalline components. These components are assumed to crystallize simultaneously in very small particulate sizes. The increase in specific surface area, therefore, is mainly responsible for the increased rate of dissolution of a poorly water-soluble drug.

Differential thermal analysis (DTA) of binary mixtures normally exhibits two endotherms, but a binary mixture of eutectic composition usually exhibits a single major endotherm. In the case of a simple eutectic system, the thaw points of binary mixtures of varying compositions are equal to the eutectic temperature of the system.

#### SOLID SOLUTIONS

A solid solution consists of a solid solute dissolved in a solid solvent. The particle size in solid solution is reduced to molecular level. Successful solubilization of itraconazole has been achieved using solid solution techniques. Solid solutions of lower drug concentrations generally give faster dissolution rate, and drug dissolution improves considerably with an increase in molecular weight of a water-soluble polymer, such as polyethylene glycol.

#### GLASS SOLUTIONS OF SUSPENSIONS

A glass solution is a homogeneous system in which a glassy or a vitreous form of the carrier solubilizes drug molecules. PVP has been used as a carrier in several formulations. In its matrix form, PVP dissolved in an organic solvent, undergoes a transition to a glassy state upon evaporation of the solvent.

#### COMPOUND OR COMPLEX FORMATION BETWEEN DRUG AND CARRIERS

This system is characterized by complexation of two components in a binary system during solid dispersion preparation. The availability of a drug from the complex is dependent on the solubility, dissociation constant, and intrinsic absorption rate of the complex.  $\alpha$ ,  $\beta$  and  $\gamma$  Cyclodextrins in combination with polyethylene glycol (PEG) 6000, have been used to formulate such systems.

#### AMORPHOUS PRECIPITATION

Amorphous precipitation occurs when the drug precipitates as an amorphous form in the inert carrier. The high-energy state of the drug in this system generally produces much greater dissolution rates than the corresponding crystalline forms of the drug.

OTHER SEPARATION TECHNIQUES 252

Separation may be defined as an operation that brings about isolation and/or purification of a single chemical constituent or a group of chemically related substances. Most medicinal agents require some degree of purification before being incorporated into desirable dosage forms. Many times the analysis of pharmaceutical preparations requires separation of the chief constituent from other formulation constituents before quantitative measurement can be made.

Although the problems of separation are the concern chiefly of pharmaceutical manufacturers, at times they may be encountered by the pharmacist in the prescription laboratory; hence, all pharmacy practitioners should have knowledge of the underlying principles and the techniques employed in the basic processes of separation.

The processes of separation may be divided into two general categories—simple and complex—depending on the complexity of the method used.

*Simple processes* bring about separation of constituents through a single mechanical manipulation. Processes in this category are limited usually to separations of relatively simple mixtures or solutions. Some examples of this type are the use of:

- a separatory funnel or pipette to separate two immiscible liquids such as water and ether
- a distillation process to separate two miscible liquids such as benzene and chloroform
- a garbling process to separate solids
- centrifugation, filtration, and expression processes to separate solids from liquids.

*Complex processes* usually require formation of a second phase by the addition of either a solid, liquid, or gas plus mechanical manipulation to bring about effective separation. One example is the separation of aspirin (acetylsalicylic acid) from salicylic acid. In this mixture, salicylic acid is considered to be an impurity, and to separate the impurity from the desired constituent, a suitable solvent is added to the mixture for the purpose of recrystallizing only the acetylsalicylic acid. The contaminant remains in solution and is removed in the filtrate during the filtration process.

Only selected processes involving separations will be covered in this chapter. Other methods are discussed in such chapters as *Complex Formation* (Chapter 18), *Colloidal Dispersions* (Chapter 20), and *Coarse Dispersions* (Chapter 21).

### FILTRATION

Filtration is the process of clarifying, harvesting, or separating particulate matter from a liquid or gas. Filtration is used to separate solid impurities from liquids and gases and to prepare a filtrate free of unwanted suspended substances. The desired

component may be the retained particulates on the filter or the liquid passing through the filter, as shown in Figure 14-1. Molecular filtration involves a process of ultrafiltration.

This is accomplished by the intervention of a porous substance, called the *filter* or the *filtering medium*. The liquid that has passed through the filter is called the *filtrate*. The *retentate* or *residue* is the portion of the sample that does not pass through the filter.

Filters are available in many different pore sizes, physical configurations and chemical compositions. Commonly, filters are divided into two broad classes: Depth and Membrane.

*Depth filters* consist of a random fiber matrix, bonded together to form a maze of flow channels. Particulate removal results from entrapment by, or adsorption to, the filter matrix. Generally, 95% of the particles larger than the manufacturers stated pore size will be retained by depth filters when gravity or vacuum is used. Examples of depth filters include glass fiber, paper (cellulose) fiber and fritted glass.

*Membrane (screen, surface) filters* remove all particles larger than the specified pore size, thus removing 100% of these materials from the filtrate. They are sometimes called “absolute filters.” Their major limitation is the low particle holding capacity. Membrane filters are composed of either natural or synthetic materials such as various cellulose derivatives and polymers.

Figure 14-1. The process of filtration.

## MATHEMATICS OF FILTRATION

In 1842, Poiseuille proposed a relationship for streamlined flow of liquids under pressure through capillaries. This equation in its simplified form is represented by

$$V = \frac{\pi \Delta p r^4}{8L\eta}$$

where  $V$  = flow velocity,  $r$  = flow capillary radius,  $L$  = capillary length,  $\eta$  = viscosity of the fluid, and  $\Delta p$  = pressure differential at the two ends of the capillary.

The modified Poiseuille equation has been shown to be valid for liquid flow through sand, glass beads, and various porous media. It represents the foundation for all mathematical models of filtration that were developed subsequently. Of critical importance in this equation is the powerful effect of capillary radius; i.e., by reducing it to 1/8 its original size, the pressure differential must be increased more than 4000 times in order to obtain the same flow velocity, all other factors remaining constant.

On the basis of the Poiseuille formula, the Kozeny-Carman relationship was established. This may be expressed as

$$V = \left[ \frac{e^3}{KS^2(1-e)^2} \right] \left[ \frac{A\Delta p g}{\eta L} \right] \quad (1)$$

where  $A$  = cross-sectional area of porous bed (filter medium),  $e$  = porosity of bed,  $S$  = surface area of medium,  $K$  = constant, and the remaining symbols are the same as in the Poiseuille equation.

The Kozeny-Carman relationship, like Poiseuille's law states that the rate of flow is directly proportional to the pressure drop across the medium and to the area of the bed, and inversely proportional to the viscosity of the liquid and the thickness of the bed. To characterize the material composing the bed, two new quantities,  $e$  and  $S$ , are introduced, replacing capillary radius.

The use of a non-definite constant  $K$ , rather than the definite constant in Poiseuille's equation,  $\pi/8$ , offers greater utility in the use of this equation in accounting for the geometry of the medium. The constant,  $K$ , generally ranges in value from 3 to 6. The Kozeny-Carman equation finds its greatest limitation in complex systems such as filter paper, but provides excellent correlation in filter beds composed of porous material.

In applying Poiseuille's law to filtration processes, one must recognize the capillaries found in the filter bed are highly irregular and non-uniform. Therefore, if the length of a capillary is taken as the thickness of the bed or medium and the correction factor for the radius is applied, the flow rate is more closely approximated. These factors have been taken into account in the formulation of the Darcy equation

$$V = (k\Delta p) / (L\eta) \quad (2)$$

where  $k$  is the permeability coefficient and depends on the nature of the precipitate to be filtered and the filter medium itself.

## FILTERING MEDIA

The filtering medium, whether a filter paper, synthetic fiber, or porous bed of glass, sand, or stone, is composed of countless channels that impart porosity to the medium. Almost without exception these channels or pores are nonuniform and possess a rather tortuous nature.

The mechanism of filtration basically involves a two-step process:

1. The filter medium itself resists the flow of solid material while permitting the passage of liquid.
2. During the course of the filtration the suspended, solid material builds up on the filter medium and thereby forms a filter bed, which acts as a second, and often more efficient, filter medium.

The ability of a filter medium to eliminate solid matter from a liquid is termed *retention*. It must be borne in mind that the filtration process must compromise retention with filtration rate, the speed at which the purified liquid (the filtrate) is recovered. To illustrate this point, it will be noted that a slab of marble will most effectively retain the solid material contained in a suspension; unfortunately, it would require a few centuries to collect the purified filtrate.

Both the retentive ability of a filter medium and filtration rate of a liquid through the medium depend on the porosity of the medium. Each factor, however, is influenced significantly by the viscosity and nature of the liquid, the proportion of solid matter in the liquid, and the size, shape, and physical nature of the suspended solids.

The flow of a liquid through a filter bed follows the same basic rules that govern the flow of any liquid through a medium offering resistance. The *flow rate* through the medium will vary directly with the area of the medium, as well as the pressure drop or driving force across the bed.

$$\text{Rate of flow} \propto \frac{(\text{driving force})(\text{cross-sectional area})}{\text{resistance}} \quad (3)$$

The flow rate is retarded by the viscosity of the liquid being filtered and by any obstruction to flow. These obstructions include the resistance of the filter medium itself and the second filter bed or *filter cake* that builds up on the medium at a rate dependent on the solids content of the liquid. In considering the nature of the precipitate, it is known that large particles are easier to filter than are small particles because of the tendency of the latter to enter into and occlude the pores of the bed, thus hindering the passage of the filtrate. In addition, the buildup of small particles on the filter tends to form a nonporous, densely packed bed that also resists passage of the filtrate. The resistance offered by the medium itself will not vary significantly during the filtration process. It depends on the thickness of the medium as well as its porosity. The resistance of the filter cake, on the other hand, is not constant and generally increases continuously during the operation. The resistance offered by the cake depends both on its thickness and physical nature. The thickness of the cake is dictated by the amount of filtrate passing through the filter and on the solids content of the liquid. The physical nature of the cake—whether it is loose, compacted, coarse, fine, granular, or gelatinous—determines whether or not it will readily allow the flow of liquid.

Considerations in selecting a filter include (1) chemical composition, (2) surface area, (3) filter holder, (4) extractables, and (5) sterility requirements. After considering these factors, the selection of the proper filter should be greatly narrowed and the final selection may need to be experimentally determined with respect to resolution, capacity, speed, and recovery.

The key factor in choosing a separation method is its ability to discriminate on the basis of one or more molecular properties of the sample components. When choosing a separation method, give primary consideration to those processes that emphasize molecular properties in which the components differ to the greatest extent.

There are four common driving mechanisms used in filtration.

1. gravity (atmospheric pressure)
2. low pressure vacuum (1–15 psi)
3. high pressure syringe or pump (15–100 psi)
4. centrifugation.

## TYPES OF FILTRATION MEDIA

### Filter Paper

Filter paper most frequently is employed in clarification processes required of the pharmacy practitioner. Only high-quality filter paper should be used to ensure maximum filtering efficiency (See Figure 14-2). When possible the first few milliliters

**Figure 14-2.** Example of filter paper used in laboratory filtrations. (Courtesy of PCCA-Professional Compounding Centers of America.)

of filtrate should be discarded to eliminate (insofar as possible) contamination of the pharmaceutical product by free fibers associated with most filter paper.

### Membrane Filters

Membrane filter media are produced from pure cellulose, cellulose derivatives, and polymeric materials. All have an extremely uniform micropore structure as well as an exceptionally smooth surface. The integral structure contains no fibers or particles that can work loose and contaminate a filtrate. This is a particular advantage in the filtration of ophthalmic solutions. The presence of these fibers is difficult to prevent when using many other filter media, including paper filters.

The efficiency of membrane filters is due to the uniform pore system that functions like a highly effective sieve. The pore size, of different types of these filters, ranges from 10 nm to 100 microns. All particles in liquids or gases that are larger than the pore of a given filter are retained on the surface. The thickness of these membrane filters ranges from 50 to 200 microns.

The pores that penetrate these filters pass directly through the entire thickness of the membrane, with a minimum of cross-linkage. Porosity or pore volume is estimated as 80% of the total fiber volume. The high porosity of these filters, coupled with the *straight-through* configuration of the pores, results in flow rates through the membrane filters that are at least 40 times faster than flow rates through conventional filter media that possess the same particle size retention capabilities.

Membrane (surface, screen) filters remove all particles larger than its specified pore size. It is not true that all particles smaller than the pore size go through the filter. Since particles larger than the pore size deposit on the filter surface, this new layer can act as a depth filter trapping particles smaller than the rated pore size. Agitation can reduce this problem for pore sizes down to 0.1 micron; but with smaller pore sizes, the adhesion forces between particles are too strong to dislodge them from the filter surface or each other.

Since the pore size of membrane filters can be closely controlled, it is possible to assign an absolute pore size rating. The major limitation of these filters is their low particle holding capacity. Prefilters (depth filters) may be used in series with membrane filters to increase the total particle capacity.

Membrane manufacturers have standardized certain diameters which range from 13 to 293 mm. Some common diameter sizes include the 25, 47, 90, 142, and 293 mm filters. Different types are available for use in the filtration of either aqueous or nonaqueous liquids. The discs generally are used in conjunction with specialized holders of either plastic, metal or glass composition. With small volumes (i.e., less than 500 mL), solutions usually are filtered using vacuum techniques. Larger volumes require filtration under pressure provided by an inert gas such as nitrogen. An example of a membrane filter is shown in Figure 14-3.

In addition to their obvious utility in routine filtration processes on both a laboratory and industrial scale, these filters have been used for a wide range of purposes, including chemical analysis, microbiological analysis, and bacterial filtration. The latter process provides an economical and rapid method for sterilizing heat-labile material (see Chapter 25).

Handling guidelines with membrane filters:

1. Never handle the filter with fingers. Always use a blunt, curve-typed, nonserrated forcep.
2. Always remove the “separator papers” (blue or yellow usually) before using.

### Other Filtering Media

Many devices have been advanced to replace filter paper, which has many disadvantages, particularly for large-scale operations. A great many variations of filtering processes, each designed to fit the needs of special cases, are found in the modern pharmaceutical laboratory. The filter press, the centrifugal filter, the vacuum filter, sand-bed filter, charcoal filter, paper-pulp filter, and porous porcelain filter are all examples of specialized filtration methods. Each one of these possesses some advantageous quality, and it is the experience of the laboratory operators that guides them in their selection of appropriate filtering devices. Reference is made later in the text to many of these special-scale filters.

However, it would not be inappropriate to refer briefly to special filtering devices that may be useful in the prescription or research laboratory.

**Cotton Filters**—A small pledget of absorbent cotton, loosely inserted in the neck of a funnel, adequately serves to remove large particles of extraneous material from a clear liquid. Although this properly might be termed colation, the cotton also can be used to serve as a fairly efficient filter. It is sometimes necessary to return the liquid a number of times to secure perfect transparency.

**Figure 14-3.** Example of a filter membranand holder (Luer lock syringe membrane filter). (Courtesy of PCCA-Professional Compounding Centers of America.)

**Glass-Wool Filters**—When solutions of highly reactive chemicals, such as strong acids, are to be filtered, filter paper cannot be used. In its place glass wool may be used just as one uses absorbent cotton for filtering. This material is resistant to ordinary chemical action, and when properly packed into the neck of a funnel it constitutes a very effective filtering medium.

**Sintered-Glass Filters**—These filters have as the filtering medium a flat or convex plate consisting of particles of Jena glass powdered and sifted to produce granules of uniform size that are molded together. The plates can be fused into a glass apparatus of any required shape (Figure 14-4). These filters vary in porosity, depending on the size of the granules used in the plate. They were formerly used in the filtration of solutions such as those intended for parenteral injection but have been replaced by 0.22 micron membrane filters. A vacuum attachment is necessary to facilitate the passage of the liquid through the filter plate (see Chapter 25).

**Fritted glass filter**—designations are Extra Coarse (170–222 microns), Coarse (40–60 microns), Medium (10–15 microns), Fine (4–5.5 microns), Very fine (2–2.5 microns), and Ultrafine (0.9–1.4 microns).

**Fiber glass filters** are made with borosilicate glass and they possess the highest retention capacity of all depth filters. They also have a wider chemical compatibility than paper (cellulose) filters. An important precaution is “Do Not Fold” since folding may jeopardize the filter integrity. These filters are suitable for use in Gooch, Buchner, or membrane filtering apparatus.

## Funnels

Funnels are conical-shaped utensils intended to facilitate the pouring of liquids into narrow-mouthed vessels. They also are used widely in pharmacy for supporting filter media. Funnels may be made of glass, polyethylene, metal, or any other material that serves a specific purpose. The community pharmacist will find the glass funnel to be quite adequate for all processes of clarification in prescription practice. Most funnels used by the pharmacy practitioner are conical in shape and may be fluted, grooved, or ribbed for the purpose of facilitating the downward flow of the filtrate, as shown in Figure 14-5.

The *Büchner* type of funnel is used today largely in pharmaceutical laboratories. A piece of round filter paper is laid on the perforated porcelain diaphragm and the filtration conducted. This funnel is especially applicable to vacuum filtration, as shown in Figure 14-6 (see the discussion, *Vacuum Filtration*).

## Filtration of Volatile Liquids

It is evident that the ordinary methods of filtering liquids will not be practical for very volatile liquids because of the loss through evaporation, and the liability to explosion in the case of flammable volatile liquids. Funnels must be covered, the receiving vessel closed, and provision made for the escape of the confined air in the receiving vessel. The following method is quite useful. A rubber cover, perforated to admit a tube, is placed on

Figure 14-4. Sintered-glass filters.

Figure 14-5. Typical funnel apparatus.

top of the funnel; connection between the bottle and funnel is effected as shown in Figure 14-7.

## FILTRATION AIDS

It has long been known that addition of an insoluble adsorbent powder to a liquid prior to its filtration greatly increases the efficiency of the process. Purified talc, siliceous earth (kieselguhr), clays, charcoal, paper pulp, chalk, magnesium carbonate, bentonite, silica gel, and others have been used for this purpose. It must not be overlooked, however, that powdered substances employed for such purposes must be insoluble and inert, so not all of those in the foregoing list are applicable for general filtration.

*Talc* is nonadsorbent to materials in solution and is a chemically inert medium for filtering any liquid, provided it has been purified for this purpose and it is not the impalpably fine variety that will pass through the filter paper.

*Kieselguhr* is almost pure silica ( $\text{SiO}_2$ ). It is as applicable as talc for general filtration purposes, with no danger of removing active constituents by adsorption.

*Siliceous earths or clays*, such as fuller's earth or kaolin in the hydrated form which is produced when they are brought into contact with aqueous liquids, are safe for general use only in filtering fixed oils. Liquids containing coloring matter or

Figure 14-6. Gooch crucible and Büchner funnel apparatus. (Courtesy of Thomas.)

Figure 14-7. Filtration of volatile liquids.

alkaloidal principles must not be filtered through these media, for adsorption of both color and alkaloids occurs and the filtrate is altered in comparison.

*Charcoals*, as a rule, possess adsorptive properties not only toward color but for many active constituents of medicinal preparations, such as alkaloids and glycosides. Consequently, charcoal should never be used as a filtering medium unless the removal of such constituents is desirable.

*Chalk* and *magnesium carbonate* readily react with acids and possess a finite solubility in water and aqueous fluids, with the production of alkalinity in the filtrate. This is particularly true of magnesium carbonate; the degree of alkalinity imparted to the filtrate is sufficiently great to cause precipitation of alkaloids. Either of these media, when added to an alkaloidal preparation prior to filtration, will precipitate and remove all of the alkaloidal constituents. Neither is suitable for general use.

A *prefilter* (a depth filter) is used prior to a membrane filter to prevent premature clogging and blocking of the membrane filter. In some cases, a pure and inert powder-like material can be used to form a porous film or cake on the surface of depth filters. Filter aids include diatomaceous earth, silica or activated charcoal. Filter aids will reduce filter pore clogging and thus maintain an adequate filtration speed.

## RAPID FILTRATION APPARATUS

Much attention has been given to methods for increasing the rapidity of filtration. This may be accomplished by applying pressure on the filter or by creating a vacuum in the receiving vessel.

## VACUUM FILTRATION

One of the first practical efforts made to create a vacuum to aid filtration was by means of the Bunsen pump. Its action depends on the principle that a column of water descending through a tube from a height is capable of carrying with it the air contained in a lateral tube, if the latter is placed properly. This form of aspirator is practicable where water pressure is available.

*Pumps Acting by Water Pressure*—The various aspirator or vacuum pumps that operate under the influence of water pressure are all based on the same principle. The following are selected for illustration from the great variety in use. Figure 14-8 shows Chapman's vacuum pump. Valve *a* prevents the water from flowing into the bottle which carries the filter when the pressure of water ceases or is reduced and *b* is an inline restrictor.

Figure 14-8. Chapman's Vacuum Pump.

On a larger scale, the vacuum for filtration is produced by one of the many types of vacuum pumps now available. The pump should be protected from vapors by placing a suitable vapor trap between the filter unit and the pump. The trap usually is cooled to very low temperatures by means of dry ice and acetone when very high vacuum is needed.

In assembling a filtering apparatus using the vacuum principle, it is necessary that there be no leaks in the connections from the filter to the aspirator. If filter paper is used in connection therewith, a plainly folded paper must be used and its tip must be protected against breakage by reinforcing it with a filter paper support or some other device. A Büchner filter also may be used, employing a specially strong filter paper.

In analytical work it is customary to use the Gooch crucible and flask (Figure 14-6) for rapid filtration. The flask, of especially thick glass, is provided with a side tube that is connected to a water aspirator pump. The perforated crucible bottom is converted into a filter bed of the required thickness by means of a filter mat placed over the perforations in the porcelain base.

## PRESSURE FILTRATION

Figure 14-9 illustrates a sectional drawing of a plate-and-frame filter press. The material to be filtered enters the apparatus under pressure through a pipe at the bottom and is forced into one of the many chambers. A filter cloth is positioned on both sides of each chamber. As the material passes through the filtering cloth, solids remain behind in the chamber and the clear filtrate passes through and out of an opening located on top of the apparatus.

Rotary-drum vacuum filters are used widely in the pharmaceutical industry, especially in the preparation of antibiotics by the fermentation process. In this type of filtration a perforated drum, wrapped with a cloth or other suitable substance holding a filter medium, is immersed partially in a tank holding the material to be filtered (Figure 14-10).

The drum is rotated through the slurry of material and a vacuum within the drum draws the material into and through the filter medium. During this step of the process, the filtrate is taken into the drum and collected, while the solid material remains deposited on the outer surface of the drum. This material is then removed by a scraper in the last step of the operating cycle, just before the rotating drum repeats another cycle.

## CENTRIFUGATION

Centrifugation is useful particularly when separation by ordinary filtration is difficult, as in separating a highly viscous mixture. A diagram is shown in Figure 14-11. Separations may be accomplished more rapidly in a centrifuge than under the action of gravity. In addition, the degree of separation that is attainable may be greater because the forces available are of a far higher order of magnitude.

The apparatus consists essentially of a container in which a mixture of solid and liquid, or of two liquids, is rotated at high speeds so that the mixture is separated into its constituent parts by the action of centrifugal force. A solid or liquid, mixed with a liquid of lesser density, may be separated because the substance of higher specific gravity is thrown outward with greater force—it will be impelled to the bottom of the container, leaving a clear supernatant layer of pure liquid.

Figure 14-11. Example of the before and after centrifugation process.

Two basic types of centrifuges are available: *sedimentation* and *filtration*. The *sedimentation* type of centrifuge depends on differences in the densities of the two or more phases comprising the mixture. This instrument is capable of separating both solid–liquid and liquid–liquid mixtures. *Filtration centrifuges*, however, are limited to the separation of solid–liquid mixtures.

## DIFFERENTIAL CENTRIFUGATION

Separation is achieved primarily based on the size of the particles in differential centrifugation. This type of separation is commonly used in simple pelleting and in obtaining partially-pure preparation of subcellular organelles and macromolecules. For the study of subcellular organelles, tissue or cells are first disrupted to release their internal contents. This crude disrupted cell mixture is referred to as a homogenate. During centrifugation of a cell homogenate, larger particles sediment faster than smaller ones and this provides the basis for obtaining crude organelle fractions by differential centrifugation. A cell homogenate can be centrifuged at a series of progressively higher *g*-forces and times to generate pellets of partially-purified organelles.

When a cell homogenate is centrifuged at  $1000 \times g$  for 10 minutes, unbroken cells and heavy nuclei pellet to the bottom of the tube. The supernatant can be further centrifuged at  $10,000 \times g$  for 20 minutes to pellet subcellular organelles of intermediate velocities such as mitochondria, lysosomes, and microbodies. Some of these sedimenting organelles can be obtained in partial purity and are typically contaminated with other particles. Repeated washing of the pellets by resuspending in isotonic solvents and repelleting may result in removal of contaminants that are smaller in size. Obtaining partially-purified organelles by differential centrifugation serves as the preliminary step for further purification using other types of centrifugal separation (density gradient separation).

### DENSITY GRADIENT CENTRIFUGATION

Density gradient centrifugation is the preferred method to purify subcellular organelles and macromolecules. Density gradients can be generated by placing layer after layer of gradient media such as sucrose in a tube with the heaviest layer at the bottom and the lightest at the top in either a discontinuous or continuous mode. The cell fraction to be separated is placed on top of the layer and centrifuged. Density gradient separation can be classified into two categories, rate-zonal (size) separation and isopycnic (density) separation.

#### Rate-zonal (size) separation

Rate-zonal separation takes advantage of particle size and mass instead of particle density for sedimentation. Figure 14-12 illustrates a rate-zonal separation process and the criteria for successful rate-zonal separation. Examples of common applications include separation of cellular organelles such as endosomes or separation of proteins, such as antibodies. For instance, Antibody classes all have very similar densities, but different masses. Thus, separation based on mass will separate the different classes, whereas separation based on density will not be able to resolve these antibody classes.

Certain types of rotors are more applicable for this type of separation than others. The criteria for successful rate-zonal

**Figure 14-12.** Example of size separation by centrifugation. (From Cole-Parmer Technical Library, Basics of Centrifugation. ©Thermo Fisher Scientific. <http://www.coleparmer.com/techinfo/techinfo.asp?htmlfile=basic-centrifugation.htm&ID=30>, accessed 30 November, 2011)

centrifugation include the following factors: (1) the density of the sample solution must be less than that of the lowest density portion of the gradient, (2) the density of the sample particle must be greater than that of the highest density portion of the gradient, (3) the pathlength of the gradient must be sufficient for the separation to occur, and (4) the time is important. If you perform too long runs, particles may all pellet at the bottom of the tube.

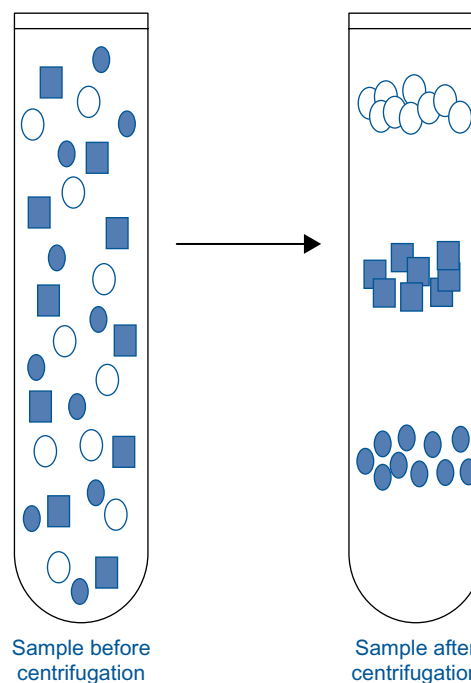

#### Isopycnic (density) separation

In this type of separation, a particle of a particular density will sink during centrifugation until a position is reached where the density of the surrounding solution is exactly the same as the density of the particle. Once this quasi-equilibrium is reached, the length of centrifugation does not have any influence on the migration of the particle. A common example for this method is separation of nucleic acids in a CsCl gradient. Figure 14-13 illustrates the isopycnic separation and criteria for successful separation. The criteria for successful isopycnic separations include the following factors: (1) the density of the sample particle must fall within the limits of the gradient densities, (2) any gradient length is acceptable, and (3) the run time must be sufficient for the particles to band at their isopycnic point. Excessive run times have no adverse effect.

### SEDIMENTATION CENTRIFUGES

#### Bottle Centrifuge

The design of the bottle centrifuge and the disc centrifuge are based on the sedimentation principle (i.e., separation by density difference). The bottle centrifuge, which consists of a vertical spindle that rotates the containers in a horizontal plane, commonly is used to separate materials of different densities. Separation in a centrifugal field is brought about because denser particles in a mixture require greater forces to hold them in a circular path of a given radius than do lighter particles. Thus, the lighter particles are displaced toward the axis of the centrifuge by the heavier particles. During the centrifugation of

**Figure 14-13.** Example of density separation by centrifugation. (From Cole-Parmer Technical Library, Basics of Centrifugation. ©Thermo Fisher Scientific. <http://www.coleparmer.com/techinfo/techinfo.asp?htmlfile=basic-centrifugation.htm&ID=30>, accessed 30 November, 2011)

blood, for example, a speed of 3000 rpm is required to separate blood corpuscles from serum. If the radius of the centrifuge is assumed to be 10 cm, the acceleration,  $a$ , acting on a particle can be approximated to be  $10^6 \text{ cm/sec}^2$ ; or about 1000 times the acceleration due to gravity,  $g$

$$\alpha = 4\pi^2 N^2 r = \frac{4(3.14)^2 (3000)^2 (10)}{3600} = 10^6 \text{ cm/sec}^2$$

$$N = \text{revolution/sec}; r = \text{radius in cm} \quad (4)$$

$$\frac{10^6 \text{ cm/sec}^2}{10^3 \text{ cm/sec}^2} = 1000(g)$$

$10^3 \text{ cm/sec}^2 = \text{approximate acceleration due to gravity}$

Under these conditions, the blood corpuscles eventually migrate under the influence of centrifugal force to the tip of the centrifuge tube.

The separation of particles in a liquid medium also depends on the nature of the medium. A solid particle settling under the influence of acceleration due to gravity in a liquid phase accelerates until a constant terminal velocity is reached. The terminal velocity is known as the settling velocity of the particle and is described mathematically by Stokes' Law. It can be shown that Stokes' Law can be extended to those cases where settling takes place in a centrifugal field,

$$v_s = v_g \frac{\omega^2 r}{g} \quad (5)$$

where  $v_s$  is the settling velocity of a particle in a centrifugal field,  $v_g$  is the settling velocity of a particle in a gravitational field (Stokes' Law),  $\omega$  is the angular velocity of the particle in the settling zone, and  $r$  is the radius at which the settling velocity is determined.

Consider a solid particle at an initial position in a liquid medium and a distance  $r$  from the axis of rotation. Under these conditions,

$$v_s = dr/dt \quad (6)$$

Substituting Equation 6 into Equation 5 gives

$$dr/dt = v_g \frac{\omega^2 r}{g} \quad (7)$$

Rearranging and integrating between limits gives

$$\int_r^{r_c} \frac{dr}{r} = \int_0^t v_g \frac{\omega^2 r}{g} dt \quad (8)$$

$$\ln \frac{r_c}{r} = v_g \frac{\omega^2 t}{g} \quad (9)$$

where  $r_c$  is the distance between the surface of the sedimented cake in the tip of the tube and the axis of rotation, and  $t$  is the time during which the particle is subjected to centrifugal acceleration while the particle travels the distance from  $r$  to  $r_c$ . Equation 9 shows that if centrifuging conditions for a given suspension are to be compared in different centrifuges, the speed, bottle size, centrifuge dimensions, and centrifuging time must be taken into consideration.

### Filtration Centrifuge

The filtration centrifuge is restricted to the separation of solid-liquid mixtures. It is similar in principle to the sedimentation type, but rather than containers it possesses a porous wall through which the liquid phase may pass but upon which the solid phase is retained. Analogous to filtration, this process requires consideration of the flow of liquid through the solid bed that accumulates on the porous plate. The plate may be either solid or semisolid (gel).

### Ultracentrifuge

When extremely fine solid matter must be separated from a liquid, such as in colloid or biological research, the ultracentrifuge is employed. In this instrument a relatively small rotor is operated at speeds exceeding 100,000 rpm and forces up to one million times gravity are exerted. High speeds are attained with air or oil turbines and bearings lubricated with a film of compressed air. Friction heat may be minimized by the use of high vacuum.

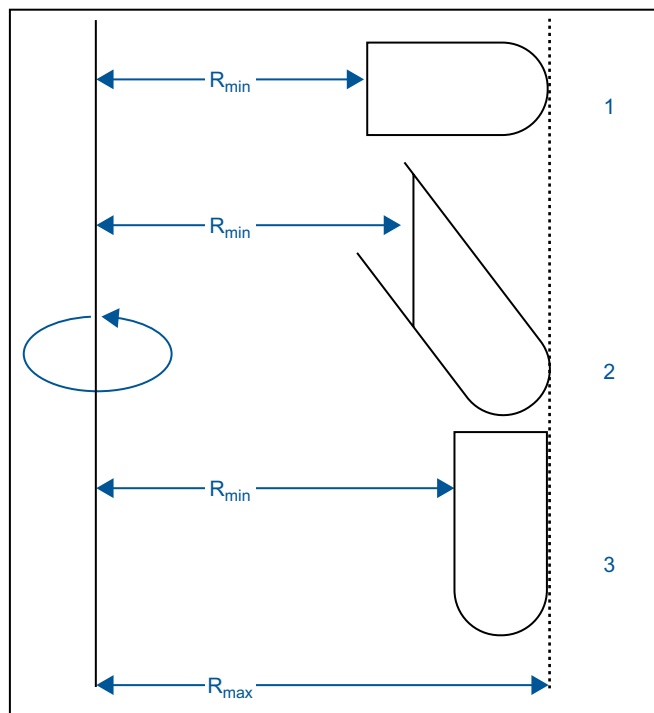

By placing the samples in specially constructed cells and spinning them in the ultracentrifuge, it is possible to separate the dispersed phase from the continuous phase rather rapidly. To aid the investigator, optical attachments may be employed to photograph the settling while the centrifuge is in operation.

Only small batches of material can be handled in these instruments during a single run. Ultracentrifuges are employed in the determination of particle size and molecular weight of polymeric and other high-molecular-weight materials such as proteins and nucleic acids by direct or indirect observation of the rate of separation of particles in solution or suspension.

### Rotors

Rotors can be broadly classified into three common categories namely swinging-bucket rotors, fixed-angle rotors, and vertical rotors (Figure 14-14, Table 14-1). Note that each type of rotor has strengths and limitations depending on the type of separation. Other rotors include continuous flow and elutriation rotors.

In swinging bucket rotors, the sample tubes are loaded into individual buckets that hang vertically while the rotor is at rest. When the rotor begins to rotate the buckets swing out to a horizontal position (Figure 14-14). This rotor is particularly useful when samples are to be resolved in density gradients. The longer pathlength permits better separation of individual particle types from a mixture. However, this rotor is relatively inefficient for pelleting. Also, care must be taken to avoid

**Figure 14-14.** Rotor types used in centrifugation. (From Cole-Parmer Technical Library, Basics of Centrifugation. ©Thermo Fisher Scientific. <http://www.coleparmer.com/techinfo/techinfo.asp?htmlfile=basic-centrifugation.htm&ID=30>, accessed 30 November, 2011)

**Table 14-1. Types and Characteristics of Centrifuge Rotors**

Type of rotor	Pelleting	Rate-zonal sedimentation	Isopycnic
Fixed-angle	Excellent	Limited	Variable*
Swinging-Bucket	Inefficient	Good	Good**
Vertical	NS	Good	Excellent
Zonal	NS	Excellent	Good

NS= not suitable

\* Good for macromolecules, poor for cells, and organelles

\*\* Good for cells and organelles, caution needed if used with CsCl  
(Data from Cole-Parmer Technical Library, Basics of Centrifugation.  
<http://www.coleparmer.com/techinfo/techinfo.asp?htmlfile=basic-centrifugation.htm&ID=3> accessed 28 July, 2011)

“point loads” caused by spinning CsCl or other dense gradient materials that can precipitate.

In fixed-angle rotors, the sample tubes are held fixed at the angle of the rotor cavity. When the rotor begins to rotate, the solution in the tubes reorients. This rotor type is most commonly used for pelleting applications. Examples include pelleting bacteria, yeast, and other mammalian cells. It is also useful for isopycnic separations of macromolecules such as nucleic acids.

In vertical rotors, sample tubes are held in vertical position during rotation. This type of rotor is not suitable for pelleting applications but is most efficient for isopycnic (density) separations due to the short pathlength. Applications include plasmid DNA, RNA, and lipoprotein isolations.

### Selection of Centrifuge Tubes

The selection of the appropriate centrifuge tube is one that prevents sample leakage or loss, ensures chemical compatibility, and allows easy sample recovery. The selection should also consider factors such as clarity, chemical resistance, and the sealing mechanism (if needed).

One should check the product guide pages or tube packaging for notes on recommended sample volume and maximum speed. If using thin-walled sealed tubes, they should be run in a fixed angle or vertical rotor. If necessary to autoclave the tubes, it should be only at 121°C for 15 minutes. One should avoid cleaning plastic tubes in automated dishwashers or glassware washers, which may produce excessively hot temperatures. Also, only a mild laboratory detergent in warm water should be used, followed by a rinse and air dry.

## PRECIPITATION

Precipitation is the process of separating solid particles from a previously clear liquid—a solution—by physical or chemical changes. The separated solid is termed a *precipitate*; the cause of precipitation is the *precipitant*; and the liquid that remains in the vessel above the precipitate is called the supernatant liquid.

In pharmacy, precipitation may be useful for many purposes. It provides a convenient method of obtaining solid substances in the form of fine particles, such as the precipitation of calcium carbonate (precipitated chalk). White Lotion is an example of a preparation prepared by precipitation, in this case by mixing aqueous solutions of zinc sulfate and sulfurated potash to form an insoluble, finely divided zinc sulfide, free sulfur, and various polysulfides.

One of the most important uses of precipitation is in the purification of solids. The process as applied to purification is termed *recrystallization*. The impure solid usually is dissolved in a suitable solvent at elevated temperatures. On cooling, the bulk of the impurities remain solubilized while the purified solid product precipitates. This procedure is repeated as many times as necessary, using a number of solvents if required.

## SEPARATION OF IMMISCIBLE LIQUIDS

The separation of liquids that are mutually soluble usually is effected by distillation, if one or both of the liquids are volatile. The separation of liquids that are immiscible is generally a simpler process. Separations of this kind are necessary in analytical procedures, manufacturing operations, distillation of volatile oils, and accidental contaminations and admixtures, and are usually best made using a separatory funnel. When very small amounts of liquids are floating on the surface of another liquid, separation is accomplished most easily by using a pipet, medicine dropper, or glass syringe with an attached needle.

The Florentine Receiver can be used for the separation of volatile oils from the water that accompanies them during steam distillation. Where the volatile oil is lighter than water, the principle shown in Figure 14-15 may be used. The oil and water collect in the glass receiver during distillation, the oil floating on the top, while the water ascends the bent tube from the bottom; further addition of distillate causes the water to overflow from the side tube. The reverse action is produced in the receiver for light or heavy oils (Figure 14-16), in which either a lighter or a heavier fraction may be collected continuously.

## EXPRESSION

Expression is a process of *forcibly* separating liquids from solids. A number of mechanical principles have been recognized in the operation of expression, namely the use of the spiral twist press, the screw press, the roller press, the filter press, and the hydraulic press.

### SPIRAL TWIST PRESS

The principle of this press is best and most practically illustrated in the usual process of manually expressing a substance contained in a cloth.

**Figure 14-15.** Florentine Receiver apparatus.

**Figure 14-16.** Receiver for light or heavy oils.

## ROLLER PRESS

This is used for large-scale pressing of oily seeds, fatty substances, and so on. Care must be taken to apply the force gradually to the bag containing the material to be pressed, and not to use it on substances that will be corrosive to the rubber rollers.

## HYDROSTATIC OR HYDRAULIC PRESS

Of the presses heretofore mentioned, each has some special advantage of use, but each also has some objectionable feature. The spiral twist is not powerful and its action is limited. The screw presses have friction with which to contend; the friction of a screw increases with the intensity of the pressure applied, and when a certain limit is reached all further force applied is wasted, and if continued may result in destruction of the press. The roller press is very limited in its action. Although the hydraulic press is expensive, after the first coat it is the most economical because the greatest power is obtained at the expense of the least labor. The principle of a hydraulic press is based on the fact that pressure exerted upon an enclosed liquid is transmitted equally in all directions. Tremendous pressures can be developed with hydraulic presses. An example is shown in Figure 14-9.

## COUNTERCURRENT DISTRIBUTION

Countercurrent Distribution (CCD) may be defined as a series of liquid-liquid extractions (immiscible solvents) conducted in a multiple-tube apparatus in which one phase is permitted to advance to the next tube in the series independently of the other phase.<sup>1</sup> The separation of the components in the mixture depends on the distribution coefficient of each of the components, the volume of the solvents used, and the number of transfers taken.

Some important applications of CCD in the pharmaceutical sciences are:

- the isolation and purification of chemicals and biochemicals that might otherwise be damaged by the extremes of temperature or pH that occur during the separation processes
- the separation of a crude plant extract into its various chemically related fractions as a preparative step
- the determination of purity and homogeneity of chemicals and medicinal agents
- the characterization of substances extracted from biochemical systems in studies determining the metabolic or biologic disposition of drugs.

Separation using CCD is based on Nernst Law. According to this law, when two practically immiscible solvents are in contact with each other and a substance that is soluble in each is added, the substance distributes itself in such a way that at equilibrium and at a given temperature the ratio of the concentrations of the two solutions is a constant. Strictly speaking, it is the activity ratio rather than the concentration ratio that remains constant. For most purposes, however, concentration values give satisfactory approximations.

When the ratio of concentrations expresses a distribution value for a single chemical species, the constant is designated as a partition coefficient or distribution coefficient,  $K$ , and may be expressed mathematically as

$$K = C_u / C_l \quad (10)$$

In this expression  $C_u$  and  $C_l$  represent concentrations in the upper and lower phases, respectively. There is no accepted convention to date, and the distribution coefficient could just as well be expressed as the reciprocal:  $C_l/C_u$ . In actual practice one deals with and measures total analytical concentrations; thus, more than one chemical species usually is present in each phase. An example would be the distribution of benzoic acid between benzene and water. In the aqueous phase, benzoic

acid would be present both in the ionized ( $A^-$ ) and un-ionized form (HA). In benzene, benzoic acid would be present in the un-ionized form (HA) and in the dimerized form  $(HA)_2$ . The ratio expressing total benzoic acid in the organic phase and total benzoic acid in the aqueous phase is the partition ratio or the apparent distribution coefficient,  $K$ .

Although the purpose of using CCD is to bring about the separation of two or more substances, the basic principles of operation are best introduced by first considering the distribution pattern of a single solute in the two immiscible solvents.

1. Assume that the solute under consideration has a distribution coefficient of unity when distributed between chloroform and buffer solution and that there are no deviations from Nernst's law of distribution due to molecular association, dissociation, ionization, or chemical reactions.
2. Consider six containers such as 250-mL glass-stoppered Erlenmeyer flasks, each holding 50 mL of chloroform (lower phase) as diagrammed in Figure 14-17 (Row A). Add to container No 0, 100 mg of solute under consideration dissolved in 50 mL of buffer solution, and shake until equilibrium has been established. Because equal volumes of solvent are used and the distribution coefficient of solute in these two solvents is unity, the solute at equilibrium will distribute itself in such a way that one-half is found in each of the upper and lower phases (Row B). Because 100 mg was originally present, 50 mg will be found in both layers of Container 0 (Row B).
3. Transfer the upper phase of Container 0 holding 50 mg of solute to Container 1 (Row B) and add fresh buffer solution to Container 0 (Row B). Shake both containers until equilibrium has been established. At equilibrium the quantity of solute in each phase of Containers 0 and 1 (Row C) will be 25 mg.
4. Transfer the upper phase of Container 1 (Row C) to Container 2 (Row C), and the upper phase of Container 0 (Row C) to Container 1. Add fresh buffer solution to Container 0 (Row C) and shake all three containers until equilibrium has been established. At equilibrium the quantity of solute (25 mg) in Container 2 (Row D) will have distributed itself so that one-half (12.5 mg) is in the upper phase and one-half (12.5 mg) is in the lower phase. Because 25 mg of solute was transferred to Container 1 from Container 0, 25 mg of solute will be present in each phase of Container 1 (Row D). The quantity (25 mg) of solute in Container 0 will distribute itself between the chloroform layer and freshly added buffer solution so that one-half (12.5 mg) will be present in each layer (Row D).

Continue this general procedure of transferring the upper phases of Containers 0, 1, and 2 to Containers 1, 2, and 3, respectively; then add fresh buffer to Container 0. Shake the four flasks until equilibrium is established. A distribution is obtained as shown in Row E. Continuing in a like manner will give a distribution as shown in Row F.

A plot of the fraction of solute in each container versus container number is shown in Figure 14-18. The significance of this curve is that the distribution of the solute shows a peak in which the maximum is located in a specific container and the location of the peak container is a function of the partition coefficient. Hence, it can be seen that two or more solutes with different  $K$  values can be separated effectively after the passage of a mixture through many tubes (usually 25 or more, depending upon  $K$  values) in a CCD apparatus.

Figure 14-18 illustrates the distribution of a solute after only four transfers. In actual practice between 8 and 2000 containers or tubes usually are used in multiple extractions of this kind. The tubes are connected in series in a train and are rocked simultaneously rather than individually to bring about distribution of solutes between the two phases. The device also permits

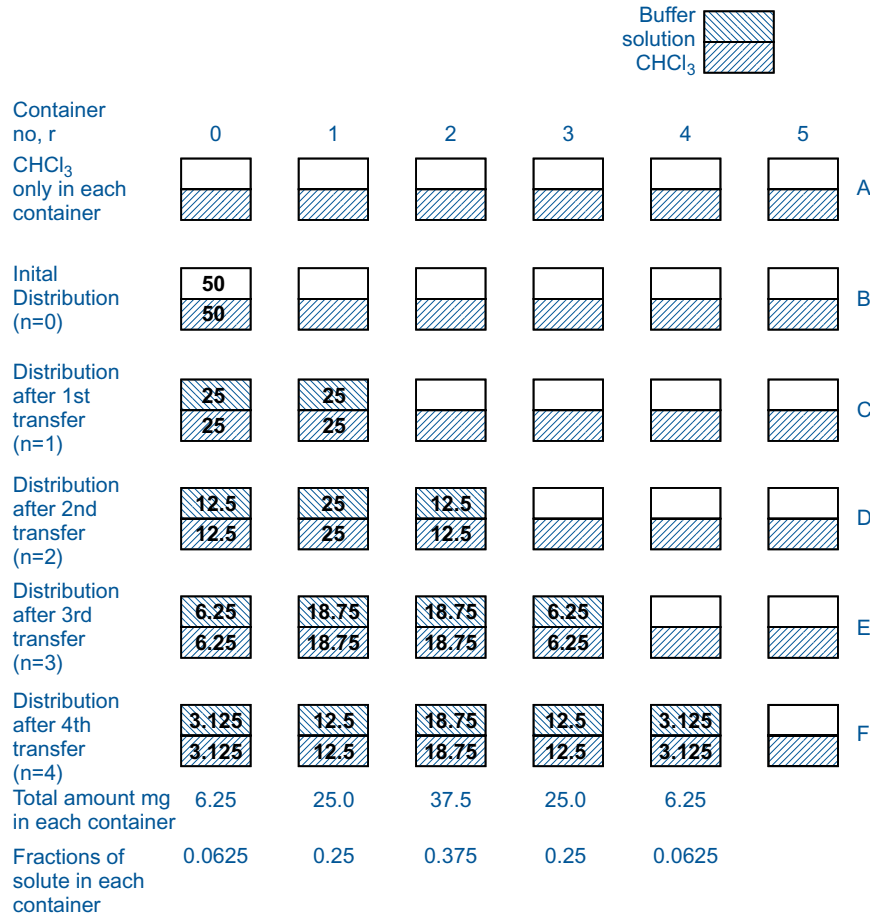

Figure 14-17. Theoretical distribution of solute after varying numbers of transfer.

Figure 14-18. Distribution of solute after four transfers.

the transfer of upper phases to the next tube in series, in one operation. A device of this type is called a countercurrent distribution apparatus.

To study the fraction of a given solute present in each tube  $r$ , after  $n$  number of transfers, it is convenient to use:

$$f_{n,r} = \frac{n!}{r!(n-r)!} \left( \frac{1}{1+KR} \right)^n (KR)^r \quad (11)$$

where  $K$  is defined as the partition coefficient and  $R$  is defined as the ratio of the volume of the upper phase to the volume of the lower phase, ( $V_u/V_l$ ).

This equation can be illustrated as follows: Calculate the fraction of solute in tubes 0, 1, 2, 3, and 4 after four transfers are made in a CCD apparatus using equal volumes of upper and

lower phases. The  $K$  value for the solute in the solvent system is assumed to be 1.0 in this example.

For Tube 3,

$$f_{4,3} = \frac{4!}{3!(4-3)!} \left( \frac{1}{1+1} \right)^4 (1)^3 = 0.25 \quad (12)$$

By similar calculations the fraction of solutes in Tube 0, 1, 2, and 4 is found to equal

$$f_{4,0} = 0.0625; f_{4,1} = 0.25; f_{4,2} = 0.375; f_{4,4} = 0.0625$$

The distribution of solute using Equation 2 is shown in Figure 14-18.

When a large number of transfers (50) are made and  $K$  is near unity it is more convenient to use a Gaussian treatment to calculate the fraction of solute in a particular tube. The appropriate equations are

$$y_x = \frac{1.00}{\sqrt{2\pi nKR/(KR+1)^2}} \exp \left\{ - \left( \frac{x^2}{2nKR/(KR+1)^2} \right) \right\} \quad (13)$$

$$T_{\max} = \frac{nKR}{KR+1}$$

where  $y_x$  represents the fraction of solute with distribution coefficient  $K$  in the tube that is  $x$  distant from the peak tube;  $\exp$  is the exponent of the base  $e$ ,  $\exp 2 = e^2$ ;  $\pi = 3.14$ ;  $K$ ,  $R$ , and  $n$  are terms that have been defined previously and  $r_{\max}$  represents the number of the tube containing the maximum amount of solute.

Distribution curves may be prepared from the hypothetical data or from a computer program using these equations. Figure 14-19 illustrates a series of curves for a solute in which  $K = 1.0$

**Figure 14-19.** Distribution of solute after varying number of transfers.

and  $R = 1.0$  following 8, 32, and 128 transfers. It is interesting to observe that as the number of transfers increases, the amplitude of the curve decreases and the solute spreads through more and more tubes. At first thought, this would seem undesirable, but the significant point is that the fraction of vessels containing solute after 128 transfers is now much less than after 10 transfers.

Therefore, two solutes with different but similar  $K$  values can be separated in 128 transfers because each solute occupies a smaller fraction of total tubes. If this separation were attempted with 10 to 20 transfers, both solutes would occupy nearly all of the tubes and no separation would be obtained.

Figure 14-20 illustrates the distribution patterns obtained in a 16-transfer experiment for solutes having distribution coefficients that differ by one order of magnitude. Under no circumstances can a separation be obtained if the distribution coefficients of the solutes are equal.

The procedure of operation that has been considered thus far is known as the *fundamental procedure*. Here, the solute is distributed through a specified number of tubes and nothing is withdrawn from the system until the entire operation is completed. Then the tube contents are withdrawn and analyzed for the purpose of determining solute concentrations, or the solutes are withdrawn simply for the purpose of isolating them from a mixture.

Another procedure of operation that is of interest primarily due to its analogy to elution chromatography is known as *end withdrawal*. In this operation the fundamental procedure is

**Figure 14-20.** Distribution of two solutes with different  $K$  values.

followed for a predetermined number of transfers as previously described. Then the upper phase only of the last tube in the train is collected. All other upper phases are advanced to the next tube in succession and after equilibration the upper phase of the last tube,  $n$ , is again collected.

This process is continued until all upper phases have passed through  $n$  tubes containing lower phase. In elution chromatography the analogy is similar. However, fresh upper phase is added continuously to the first *tube* (called a *plate* in elution chromatography) until only upper phase is eluted from the column.

In summary, the degree of separation of two or more solutes using CCD depends upon the distribution coefficients of the solutes, nature and volume of the solvents used, and number of transfers taken.

## OTHER SEPARATION TECHNIQUES

### CLARIFICATION

Clarification is the process by which finely divided solids and colloidal materials are separated from liquids without the use of filters. The process is employed to remove suspended oil from aqueous solutions, such as aromatic waters, and for the removal of undesirable solids that interfere with the transparency of such natural products as honey and fruit juices.

Clarification generally is resorted to when the contaminating material is finely subdivided, amorphous, or colloidal in nature and tends to plug a filtration medium rapidly. A number of methods are available to handle this difficult problem.

This may involve varying the temperature or pH of the medium. When a viscid liquid is heated, its viscosity and specific gravity are decreased and particles that are suspended in it will separate. Those particles that are more dense than the liquid will fall to the bottom, while those that are less dense will rise to the surface. In the latter case the minute bubbles of steam formed in the heating process become enveloped in the viscid particles, rise through their buoyancy, and a scum is formed that may be separated readily.

The dewaxing of oils at a reduced temperature offers a further example of the possibilities of contaminant modification. Oil that is chilled rapidly often produces an amorphous wax that will plug a straining medium. Slow chilling, on the other hand, produces a wax with a more crystalline nature, which has good filtration characteristics.

The simplest method of clarification, although not always feasible, is gravitational sedimentation. This method involves the least amount of labor and expense and is used frequently, particularly on a large scale, when haste is unnecessary. The deposit formed is called a *sediment* or *sludge*. These terms are not synonymous with *precipitate*. A sediment is solid matter separated merely by the action of gravity from a liquid in which it has been suspended. A precipitate, on the other hand, is solid matter separated from a previously clear solution by physical or chemical change. Fixed oils usually are clarified by gravitational sedimentation. In vegetable oils the sediment consists principally of albuminous and gummy substances, cellular tissue, and water, all of which have been separated with the oil during the expression process.

The clarification process generally is carried out by adding a clarifying agent such as paper, pulp, tale, infusorial earth, as well as a number of other materials to the turbid liquid. These agents usually act to reduce turbidity by physical adsorption of the contaminating material, although a large number of specific, physicochemical coagulants also are in use. After the addition of the clarifying agent, the mixture is agitated and the agents, along with the adsorbed impurities, are removed by filtration or any other suitable means. Albumin and gelatin are examples of clarifying agents obtained from natural sources. Substances of a synthetic nature, such as polyamines, also are used for this purpose.

## COLATION

Colation or straining (from Latin *colare*, to strain) is the process of separating a solid from a fluid by pouring the mixture on a cloth or porous substance that will permit the fluid to pass through, but will retain the solid. This operation frequently is used for separating sediment or mechanical impurities of various kinds from liquids. Colation should not be considered as a separate process but simply as a crude form of filtration, with larger pores in the straining medium than usually are employed for filtration.

The essential apparatus is a straining medium and a strainer support or frame. The straining medium is usually a cloth material such as flannel, muslin, wool, or cheesecloth. The material should be colorless and washed before use. Fabrics, particularly those of cotton, usually are treated or impregnated with a material called *sizing* to improve their appearance and quality for certain purposes; however, for use as a strainer, the fabric must be free of sizing because it causes contamination. Many different substances are used for sizing, some being soluble in cold water, others only in hot water. Thus, the proper method for their removal is to soak the fabric for a few hours in cold distilled water, rinse thoroughly; then cover with distilled water, boil for a few minutes, and rinse well in distilled water to remove the last traces of the gelatin, albumin, glue, or starch that may have been present in the sizing.

## CONTINUOUS WASHING

The use of the wash bottle is limited to small operations. A simple method of automatically supplying the wash liquid in larger quantities is shown in Figure 14-21. This requires attention from the operator only at the beginning of the operation. The inverted bottle containing the washing solvent is furnished with a perforated stopper and a short glass tube. All that is necessary is to fill the bottle and adjust it over the funnel so that the end of the tube is at the height at which the level of liquid in the funnel is to be maintained. When the bottle is tilted slightly (if the tube selected is not too narrow in diameter), the liquid runs into the funnel until it rises to the orifice of the tube, whereupon the flow ceases. As the liquid gradually passes through the solid substance in the funnel, the level falls below the orifice, bubbles of air pass through the tube into the bottle, the liquid once more flows, and the operation continues until the upper bottle is empty. Many elaborate methods of continuous washing have been suggested, but the simple apparatus just described is quite satisfactory if a tube of proper diameter has been selected,

Figure 14-21. Continuous washing apparatus.

one of such size that the force of capillary attraction will not be strong enough to prevent the passage of air.

## DECANTATION

The simplest method available for the separation of a solid from its soluble impurities is the technique of decantation. This method involves washing and subsequent agitation of the solid with an appropriate solvent, allowing the solid to settle and removing the supernatant solvent. These three steps are repeated as often as required to attain the desired purity of the solid. This method also is applicable to the simple separation of solids and liquids, such as after precipitation of a material from a mother liquor. Decantation provides an effective method for washing magmas and other gelatinous products.

Some degree of skill is required to decant liquids effectively. It is most convenient to decant from a lipped vessel that is not filled to capacity. In addition, the use of a stirring rod over the lip and rim of the vessel is suggested as a guide to steady the hand of the operator. Also, very low vacuum with a glass micro-pipette can be used to remove small quantities of supernatant close to the interface boundary.

## DECOLORATION

Decoloration, or decolorization as it sometimes is called, is the process of depriving solutions of color by use of an appropriate adsorptive medium. In many respects it is closely related to the clarification process. Decoloration is used for removal of coloring matter from a number of raw materials, both natural and synthetic, and from many finished products. Animal charcoal (also called bone black), wood charcoal, or activated charcoal frequently are used as decolorizing agents. Clays such as bentonite, kaolin, and fuller's earth also are used for this purpose.

## DIFFUSION AND DIALYSIS

Diffusion is the spontaneous penetration of one substance into another under the potential of a concentration gradient. Simply stated, material will tend to move from a region of higher concentration to one of lower concentration. The driving force or potential of such a process may be enhanced by the application of an electric field.

If the two regions of concentration noted are separated by a selective membrane, certain species will diffuse through the membrane, while other molecular species will be held back. When this selectivity is dictated by the porosity of the membrane, the process is termed *dialysis*. Dialysis is used principally for the separation of small molecules and ions contained in a mixture with colloidal material. The latter substances diffuse with difficulty or not at all. Materials such as gums, starch, albumin, and proteins fall into this colloidal, nondiffusible category.

The rate of diffusion across a semipermeable membrane is directly proportional to the concentration gradient between the two surfaces of the membrane and to the area of the membrane, but is inversely proportional to the membrane thickness. These factors are expressed in Fick's law of diffusion

$$ds/dt = [kA(C_i - C_o)]/h$$

where  $S$  is the amount of substance diffused at time  $t$ ,  $k$  is a permeability constant,  $A$  is the membrane area,  $h$  is the membrane thickness,  $ds/dt$  is the diffusion rate,  $C_i$  is concentration on one side, and  $C_o$  is concentration on the other side of the membrane.

## GEL FILTRATION

Gel filtration is a chromatographic method, also called size-exclusion chromatography (SEC), where molecules in solution are separated by their size, not by their molecular weight. SEC is usually applied to large molecules or macromolecular complexes such as proteins. When an aqueous solution is used to transport the sample through the column, the technique is known as gel-filtration chromatography, versus gel permeation

chromatography, which is used when an organic solvent is used as a mobile phase. The technique of SEC is widely used for polymer characterization.

One primary application of SEC is fractionation of proteins and other water-soluble polymers, while gel permeation chromatography is used to analyze the molecular weight distribution of organic-soluble polymers. SEC typically uses a gel medium, such as polyacrylamide, dextran or agarose, and filtration under low pressure.

Changyin *et al.* used different types of Sephadex gels for separation. Their study investigated various reagents necessary to perform the separation in an ultimate purification of the compound. The results indicated that optimization was capable of being done to separate the impurities from the active compound. The nature of the mobile phase, the ionic type, pH value, and molarity were important for the optimization. Cephalosporin gel chromatography was shown to be important in the separation of high-molecular-weight impurities which frequently are associated with allergic responses in patients. This method has been demonstrated to serve as an excellent quality-control procedure for the impurities in cephalosporin preparations.<sup>2</sup>

A feasibility study of liposome separation that was undertaken to explore the use of size-exclusion chromatography, such as gel filtration of a large-scale process, demonstrated that it could separate liposomes from freeze-dried material in a chromosome preparation.<sup>3</sup> The chromatographic step was intended to improve the drug encapsulation by removing free (unencapsulated) drugs from external media. The selected stationary phase was G-50 Sephadex. The model drug used in the study was orciprenaline sulfate. The technique was able to produce a suitable size exclusion that efficiently removed the free drug from the liposome preparation.

In a study of liposomes loaded with calcitonin, it was necessary to observe the location of the protein to protect it from enzymatic digestion.<sup>4</sup> The analysis of the liposome produced from this protein was extracted using suitable gel separation of the liposome mixture to ensure the location of the protein within the system. It established the stability and the ultimate formation of the liposome product. This ensured the appropriate loading of the protein within the liposome product.

A process for purifying bovine pancreatic glucagon as a by-product of insulin production has been described.<sup>5</sup> The glucagon-containing supernatant from the alkaline crystalline crystallization of insulin was precipitated using ammonium sulfate and isoelectric precipitation. The precipitate was then purified by ion-exchange chromatography on Q-Sepharose FF gel filtration on Sephadex G-25 and ion-exchange chromatography on S-Sepharose FF. Successful yields were obtained using this technique, which was successful because of the gel filtration procedure.

A report was presented on the characterization of adenosine receptors in porcine striatal membranes and their solubilization by detergent digitonin.<sup>6</sup> Once the drug was solubilized, the material was bound to sites after the removal of receptors from the lipid environment. Gel filtration on Superdex 200 accomplished the separation into appropriate molecular weights. Suitable purification was achieved by this means.

In another report of the use of gel filtration, the expression and purification of human gamma-glutamylcysteine synthetase were studied.<sup>7</sup> Specific proteins and polypeptides were isolated and their amounts characterized by the use of Superdex 200 along with ATP-affinity resins. Cyclosporin A has potential for wide clinical use, limited only by the very narrow therapeutic index.<sup>8</sup> Potentiation of its clinical efficacy is thus very desirable. Preliminary data had indicated that the mixture of cyclosporin A, with hyaluronate, could increase its efficiency. In this study, it was found that cyclosporin A could reduce the hypersensitivity in test animals when administered along with hyaluronate. To demonstrate the association of this mixture, gel filtration was required, which showed the protection of the molecule from being

bound to red blood cells. This association would improve the clinical response and was proven only by the use of gel filtration.

## Lotion

Lotion (displacement washing) is the process by which soluble impurities are removed from insoluble material by the addition of a suitable washing solvent. The wash liquid usually is separated from the purified solid by decantation or filtration. An expedient method of adding the washing solvent to the solid in a fine, controlled spray is by the use of wash bottles or spray bottles and a Buchner funnel apparatus.

## RECRYSTALLIZATION

Recrystallization is a process in which the crystal structure of the sample is completely disrupted by dissolution and then crystals are allowed to regrow leaving impurities in the solution. The mechanism involved is that impurities can seldom fit into the crystal structure of another compound. The chosen solvent generally is one where the impurities are more soluble than the substance being purified.

Soluton recrystallization as a technique involves several steps: (1) selection of solvent, (2) dissolution of the solid to be purified in the solvent at or near its boiling point, (3) filtration of the hot solution to remove impurities, (4) cooling of the solution to form crystals, (5) separation of the crystals from the supernatant solution, (6) washing of the crystals to remove adhering solution, and (7) drying the crystals.

## REVERSE OSMOSIS

Reverse osmosis is the separation, concentration and fractionation of inorganic or organic substances in aqueous or non-aqueous solutions in the liquid or the gaseous phase; it involves a semipermeable membrane and a driving force or pressure. As reverse osmosis (Figure 14-22) is used it is necessary to evaluate new composite reverse osmosis membranes that have been developed with significant improved performance over older commercially available conventional composite membranes. The Energy Saving Polyamide (ESPA) membrane chemistry provides a high flux at low operating pressure while maintaining a very good salt and organic rejection. The membranes have been demonstrated to operate for several years. Appropriate transmission and field emission electron micrographs of the membrane demonstrated the structure of the membrane skin layer is the reason for the improved performance. This surface charge of the various membranes was demonstrated qualitatively using zeta-potential measurements. Newer membranes have a low surface charge and operate at a lower pressure. In an effort to further improve the available reverse osmosis water-treatment membranes, other studies have been conducted to evaluate specific ultra-low-pressure membranes. Newer membranes have been designed with a 30% increase in productivity over conventional membranes. These improvements are particularly important to multistage systems for water purification.

\* semipermeable membrane

Figure 14-22. Principles of reverse osmosis.

Recommendations have been made by many to improve the systems by using ultra-low-pressure membranes.

### TANGENTIAL FLOW FILTRATION

Tangential flow filtration permits rapid flow of the small molecules and solvent to pass through the filter. The “sweeping” action of the liquid moving over the membrane decreases the concentration of retentate on the filter surface preventing concentration polarization. This method permits high filtration flow rates without shearing fragile molecules or cells. A variable restrictor is used to provide pressure drop across the filter.

### ULTRAFILTRATION

Ultrafiltration (UF), also termed molecular filtration, is a technique for separating dissolved molecules on the basis of effective Stoke's Radius (size) under applied pressures. The molecular filter is a thin, selectively permeable membrane that retains most macro-molecules above a certain size while permitting smaller molecules to pass into the filtrate. It is difficult to assign a molecular weight cutoff (MWCO) of an UF membrane since many factors affect it, including the pore size distribution of the membrane and the size, shape and electrical charge of the dissolved analytes to be filtered. At best the MWCO of an UF can be regarded as a “general” guide to the molecular weight or size (Stoke's radius) in which each type of filter is most efficient. MWCO should not be interpreted as a sharp cut-off point but rather a range. UF is not a high resolution technique but is useful for certain types of fractionation.

## Ionic Solutions and Electrolytic Equilibria

Barbara R. Conway, PhD

ELECTROLYTES 257

CHEMICAL EQUILIBRIA 260

PHARMACEUTICAL SIGNIFICANCE 274

### ELECTROLYTES

**Electrolytes** are substances containing free ions, thus rendering the substance electrically conductive. The most typical electrolyte is an **ionic solution** typified by solutions of acids, bases, or salts. As most drugs are weak acids or bases, it is essential to understand the properties of ionic solutions. **Colligative properties** are properties of solutions that depend on the number of molecules in a given volume of solvent rather than the weight concentration of the molecules. The colligative properties of solutions of electrolytes depend on the total number of entities in solution, including ions. In order to determine which species are present in ionic solutions, it is imperative to understand **ionic equilibria** and their impact on subsequent drug activity. An understanding of these fundamental concepts and an ability to manipulate and predict the subsequent drug properties is crucial in pharmaceutical disciplines.

### COLLIGATIVE PROPERTIES

In general, for nonelectrolytes, a given colligative property of two equimolar solutions will be identical. This generalization, however, cannot be made for solutions of electrolytes.

Van't Hoff pointed out that the osmotic pressure of a solution of an electrolyte is considerably greater than the osmotic pressure of a solution of a nonelectrolyte of the same molal concentration. This anomaly remained unexplained until 1887 when Arrhenius proposed a hypothesis that forms the basis for our modern theories of electrolyte solutions.

This theory postulated that when electrolytes are dissolved in water they split up into charged particles known as **ions**. Each of these ions carries one or more electrical charges, with the total charge on the positive ions (**cations**) being equal to the total charge on the negative ions (**anions**). Such solutions conduct electricity by virtue of the movement of these ions under application of an electrical charge; cations move to the negative terminal and anions to the positive terminal. Thus, although these solutions may contain charged particles, it remains neutral. The increased osmotic pressure of such solutions is due to the increased number of particles formed in the process of ionization. For example, sodium chloride is assumed to dissociate as

It is evident that each molecule of sodium chloride that is dissociated produces two ions, and if dissociation is complete, there will be twice as many particles as would be the case if it were not dissociated at all. Furthermore, if each ion has the same effect on osmotic pressure as a molecule, it might be expected that the osmotic pressure of the solution would be twice that of a solution containing the same molal concentration of a nonionizing solute.

Osmotic-pressure data indicate that, in very dilute solutions of salts that yield two ions, the pressure is very nearly double that of solutions of equimolar concentrations of nonelectrolytes. Similar magnification of vapor-pressure lowering, boiling-point elevation and freezing-point depression occurs in dilute solutions of electrolytes.

The Van't Hoff factor,  $i$ , is the ratio of the colligative effect produced by a concentration,  $m$ , of electrolyte, divided by the effect observed for the same concentration of nonelectrolyte, or

$$i = \frac{\pi}{(\pi)_0} = \frac{\Delta P}{(\Delta P)_0} = \frac{\Delta T_b}{(\Delta T_b)_0} = \frac{\Delta T_f}{(\Delta T_f)_0} \quad (1)$$

in which  $\pi$ ,  $\Delta P$ ,  $\Delta T_b$ ,  $\Delta T_f$  refer to the osmotic pressure, vapor-pressure lowering, boiling-point elevation and freezing-point depression, respectively, of the electrolyte. The terms  $(\pi)_0$  and so on refer to the nonelectrolyte of the same concentration. In general, with strong electrolytes (those assumed to be 100% ionized), the van't Hoff factor is equal to the number of ions produced when the electrolyte goes into solution (2 for NaCl and MgSO<sub>4</sub>, 3 for CaCl<sub>2</sub> and Na<sub>2</sub>SO<sub>4</sub>, 4 for FeCl<sub>3</sub> and Na<sub>3</sub>PO<sub>4</sub>, etc.).

In very dilute solutions the osmotic pressure, vapor-pressure lowering, boiling-point elevation and freezing-point depression of solutions of electrolytes approach values two, three, four, or more times greater (depending on the type of strong electrolyte) than in solutions of the same molality of nonelectrolyte, thus confirming the hypothesis that an ion has the same primary effect as a molecule on colligative properties. Interionic attraction and solvation effects can lead to deviations from this:

Interionic attraction between the positive and negatively charged ions, in consequence of which the ions are not dissociated completely from each other and thus do not exert their full effect on vapor pressure and other colligative properties. This results in less than 2-, 3-, or 4-fold intensification of a colligative property and this deviation generally increases with increasing concentration of electrolyte.

The second effect intensifies the colligative properties and is attributed to the attraction of ions for solvent molecules (called **solvation**, or, if water is the solvent, **hydration**), which holds the solvent in solution and reduces its escaping tendency, with a consequent enhancement of the vapor-pressure lowering. Solvation also reduces interionic attraction and, thereby, further lowers the vapor pressure.

### CONDUCTIVITY

The ability of metals to conduct an electric current results from the mobility of electrons in the metals. This type of conductivity is called **metallic conductance**. On the other hand, various chemical compounds—notably acids, bases, and salts—conduct electricity by virtue of ions present or formed, rather than by electrons. This is called **electrolytic conductance**, and the conducting compounds are electrolytes. Although the fact that certain electrolytes conduct electricity in the molten state is important, their behavior when dissolved in a solvent, particularly in water, is of greater concern in pharmaceutical science.

The electrical conductivity (or conductance) of a solution of an electrolyte is merely the reciprocal of the resistance of the solution. Therefore, to measure conductivity is actually to measure electrical resistance, commonly with a **Wheatstone bridge apparatus**, and then to *calculate* the conductivity. Figure 15-1 is a representation of the component parts of the apparatus.

**Figure 15-1.** Alternating current Wheatstone bridge for measuring conductivity.

The solution to be measured is placed in a glass or quartz cell having two inert electrodes, commonly made of platinum or gold and coated with spongy platinum to absorb gases, across which passes an alternating current generated by an oscillator at a frequency of about 1000 Hz. The reason for using alternating current is to reverse the electrolysis that occurs during flow of current that would cause polarization of the electrodes and lead to abnormal results. The size of the electrodes and their distance apart may be varied to reduce very high resistance or increase very low resistance to increase the accuracy and precision of measurement. Thus, solutions of high conductance (low resistance) are measured in cells having small electrodes relatively far apart, whereas solutions of low conductance (high resistance) are measured in cells with large electrodes placed close to each other.

Electrolytic resistance, like metallic resistance, varies directly with the length of the conducting medium and inversely with its cross-sectional area. The known resistance required for the circuit is provided by a resistance box containing calibrated coils. Balancing of the bridge may be achieved by sliding a contact over a wire of uniform resistance until no (or minimum) current flows through the circuit, as detected either visually with a cathode-ray oscilloscope or audibly with earphones.

The resistance, in ohms, is calculated by the simple procedure used in the Wheatstone bridge method. The reciprocal of the resistance is the conductivity, the units of which are **reciprocal ohms** (also called *mho*). As the numerical value of the conductivity will vary with the dimensions of the conductance cell, the value must be calculated as **specific conductance**,  $L$ ,

which is the conductance in a cell having electrodes of 1 cm<sup>2</sup> cross-sectional area and 1 cm apart. If the dimensions of the cell used in the experiment were known, calculating the specific conductance would be possible. Nevertheless, this information actually is not required, because calibrating a cell by measuring in it the conductivity of a standard solution of known specific conductance is possible—and much more convenient—and then calculating a **cell constant**. Because this constant is a function only of the dimensions of the cell, it can be used to convert all measurements in that cell to specific conductivity. Solutions of known concentration of pure potassium chloride are used as standard solutions for this purpose.

### Equivalent conductance

In studying the variation of conductance of electrolytes with dilution it is essential to make allowance for dilution so that the comparison of conductances may be made for identical amounts of solute. This may be achieved by expressing conductance measurements in terms of **equivalent conductance**,  $\Lambda$ , which is obtained by multiplying the specific conductance,  $L$ , by the volume in milliliters,  $V_e$ , of a solution containing 1 g-eq of solute. Thus,

$$\Lambda = LV_e = \frac{1000L}{C} \quad (2)$$

where  $C$  is the concentration of electrolyte in the solution in g-eq/L, that is, the normality of the solution. For example, the equivalent conductance of 0.01 N potassium chloride solution, which has a specific conductance of 0.001413 mho/cm, may be calculated in either of the following ways:

$$\begin{aligned} \Lambda &= 0.001413 \times 100,000 \times 141.3 \text{ mho cm}^2/\text{eq} \\ \text{or} \quad \Lambda &= \frac{1000 \times 0.001413}{0.01} = 141.3 \end{aligned}$$

### Strong and weak electrolytes

Electrolytes are classified broadly as strong electrolytes and **weak electrolytes**. The usual criterion for distinguishing between strong and weak electrolytes is the extent of **ionization**. The former category includes solutions of strong acids, strong bases, and most salts; the latter includes weak acids and bases, primarily organic acids, amines, and a few salts. Such strong electrolytes completely, or almost completely, dissociate into their ions in solution, and as such, it is difficult to determine an ionization constant for these. Weak electrolytes, which exist both in the molecular and ionized state in solution, can be categorized by the extent of this dissociation by an equilibrium constant. For the purposes of this discussion, classification of electrolytes as strong or weak will be based on certain conductance characteristics exhibited in aqueous solution. The equivalent conductances of some electrolytes, at different concentrations, are given in Table 15-1 and for certain of these electrolytes again in Figure 15-2, where the equivalent conductance is plotted against the square root of concentration. By plotting the

**Table 15-1. Equivalent Conductances<sup>a</sup>, at 25°C**

GEQ/L	HCl	HOAc	NaCl	KCl	NaI	KI	NaOAc
Inf dil	426.1	390.6 <sup>a</sup>	126.5	149.9	126.9	150.3	91.0

<sup>a</sup>The equivalent conductance at infinite dilution for acetic acid, a weak electrolyte, is obtained by adding the equivalent conductances of hydrochloric acid and sodium acetate and subtracting that of sodium chloride.

**Figure 15-2.** Variation of equivalent conductance with square root of concentration.

data in this manner a linear relationship is observed for strong electrolytes, whereas a steeply rising curve is noted for weak electrolytes; this difference is a characteristic that distinguishes strong and weak electrolytes. The interpretation of the steep rise in the equivalent conductance of weak electrolytes is that the degree of ionization increases with dilution, becoming complete at infinite dilution.

Interionic interference effects generally have a minor role in the conductivity of weak electrolytes. With strong electrolytes, which are usually completely ionized, the increase in equivalent conductance results not from increased ionization but from diminished ionic interference as the solution is diluted, in consequence of which ions have greater freedom of mobility (i.e., increased conductance).

The value of the equivalent conductance extrapolated to infinite dilution (i.e., zero concentration), designated by the symbol  $\Lambda_0$ , has special significance. It represents the equivalent conductance of the completely ionized electrolyte when the ions are so far apart that there is no interference with their migration due to interionic interactions. It has been shown, by Kohlrausch, that the equivalent conductance of an electrolyte at infinite dilution is the sum of the equivalent conductances of its component ions at infinite dilution, expressed symbolically as

$$\Lambda_0 = l_0(\text{cation}) + l_0(\text{anion}) \quad (3)$$

The significance of Kohlrausch's law is that each ion, at infinite dilution, has a characteristic value of conductance that is independent of the conductance of the oppositely charged ion with which it is associated. Thus, if the equivalent conductances of various ions are known, the conductance of any electrolyte may be calculated simply by adding the appropriate ionic conductances.

As the fraction of current carried by cations (**transference number** of the cations) and by anions (**transference number**

of anions) in an electrolyte may be determined readily by experiment, ionic conductances are known. Table 15-2 gives the equivalent ionic conductances at infinite dilution of some cations and anions. It is not necessary to have this information to calculate the equivalent conductance of an electrolyte, for Kohlrausch's law permits the latter to be calculated by adding and subtracting values of  $\Lambda_0$  for appropriate electrolytes. For example, the value of  $\Lambda_0$  for acetic acid may be calculated as

$$\Lambda_0(\text{CH}_3\text{COOH}) = \Lambda_0(\text{HCl}) + \Lambda_0(\text{CH}_3\text{COONa}) + \Lambda_0(\text{NaCl})$$

which is equivalent to

$$l_0(\text{H}^+) + l_0(\text{CH}_3\text{COO}^-) + l_0(\text{H}^+) + l_0(\text{Cl}^-) + l_0(\text{Na}^+) + l_0(\text{CH}_3\text{COO}^-) + l_0(\text{Na}^+) + l_0(\text{Cl}^-)$$

This method is especially useful for calculating conductance for weak electrolytes such as acetic acid. As evident from Figure 15-2, the  $\Lambda_0$  value for acetic acid cannot be determined accurately by extrapolation because of the steep rise of conductance in dilute solutions. For strong electrolytes, on the other hand, the extrapolation can be made very accurately. Thus, in the example above, the values of for HCl,  $\text{CH}_3\text{COONa}$ , and NaCl are determined easily by extrapolation as the substances are strong electrolytes. Substitution of these extrapolated values, as given in Table 15-2, yields a value of 390.6 for the value of  $\Lambda_0$  for  $\text{CH}_3\text{COOH}$ .

### Ionization of weak electrolytes

When Arrhenius introduced his theory of ionization he proposed that the degree of ionization,  $\alpha$ , of an electrolyte is measured by the ratio

$$\alpha = \frac{\Lambda}{\Lambda_0} \quad (4)$$

where  $\Lambda$  is the equivalent conductance of the electrolyte at any specified concentration of solution and  $\Lambda_0$  is the equivalent conductance at infinite dilution. As strong electrolytes were not yet recognized as being 100% ionized, and interionic interference effects had not been evaluated, he believed the equation to be applicable to both strong and weak electrolytes. It now is known that the apparent variation of ionization of strong electrolytes arises from a change in the mobility of ions at different concentrations, rather than from varying ionization, so the equation is not applicable to strong electrolytes. It does provide, however, a generally acceptable approximation of the degree of ionization of weak electrolytes, for which deviations resulting from neglect of activity coefficients and of some change of ionic mobilities with concentration are, for most purposes, negligible. The following example in Box 15-1 illustrates the use of the equation to calculate the degree of ionization of a typical weak electrolyte.

The degree of dissociation also can be calculated using the van't Hoff factor,  $i$ , and

$$\alpha = \frac{i-1}{v-1} \quad (5)$$

where  $v$  is the number of ions into which the electrolyte dissociates.

**Table 15-2. Equivalent Ionic Conductivities at Infinite Dilution, at 25°C**

CATIONS	$l_0$	ANIONS	$l_0$
H <sup>+</sup>	349.8	OH <sup>-</sup>	198.0
Li <sup>+</sup>	38.7	Cl <sup>-</sup>	76.3
Na <sup>+</sup>	50.1	Br <sup>-</sup>	78.4
K <sup>+</sup>	73.5	I <sup>-</sup>	76.8
NH <sub>4</sub> <sup>+</sup>	61.9	AcO <sup>-</sup>	40.9
½ Ca <sup>2+</sup>	59.5	½ SO <sub>4</sub> <sup>2-</sup>	79.8
½ Mg <sup>2+</sup>	53.0		

**Box 15-1**

1. Calculate the degree of ionization of  $1 \times 10^{-3}$  N acetic acid, the equivalent conductance of which is 48.15 mho  $\text{cm}^2/\text{eq}$ . The equivalent conductance at infinite dilution is 390.6 mho  $\text{cm}^2/\text{eq}$ .

$$\alpha = \frac{48.15}{390.6} = 0.12$$

The percentage ionization is therefore 12%.

2. A  $1.0 \times 10^{-3}$  N solution of acetic acid has a van't Hoff factor equal to 1.12. Calculate the degree of dissociation of the acid at this concentration.

$$\alpha = \frac{i - 1}{v - 1} = \frac{1.12 - 1}{2 - 1} = 0.12$$

This result agrees with that obtained using equivalent conductance and Equation 4.

**Ionic strength**

Ionic strength is a measure of the intensity of the electrical field in a solution and may be expressed as

$$\mu = \frac{1}{2} \sum C_i z_i^2$$

where  $z_i$  is the valence of ion  $i$ . The **mean ionic activity coefficient** is a function of ionic strength as are such diverse phenomena as solubilities of sparingly soluble substances, rates of ionic reactions, effects of salts on pH of buffers, electrophoresis of proteins, and so on.

The greater effectiveness of ions of higher charge on a specific property, compared with the effectiveness of the same number of singly charged ions, generally coincides with the ionic strength calculated by Equation 6. The variation of ionic strength with the valence (charge) of the ions comprising a strong electrolyte should be noted.

For univalent cations and univalent anions (called **uniunivalent** or 1-1) electrolytes, the ionic strength is identical with molarity. For bivalent cation and univalent anion (**biunivalent** or 2-1) electrolytes, or univalent cation and bivalent anion (**unibivalent** or 1-2) electrolytes, the ionic strength is three times the molarity. For bivalent cation and bivalent anion (**bibivalent** or 2-2) electrolytes, the ionic strength is four times the molarity. These relationships are evident from the following example in Box 15-2.

The ionic strength of a solution containing more than one electrolyte is the sum of the ionic strengths of the individual salts comprising the solution. For example, the ionic strength of a solution containing NaCl,  $\text{Na}_2\text{SO}_4$ ,  $\text{MgCl}_2$ , and  $\text{MgSO}_4$ , each at a concentration of 0.1 M, is 1.1.

**Debye-Huckel theory**

The **Debye-Huckel equations**, which are applicable only to very dilute solutions (about 0.02  $\mu$ ), may be extended to some-

**Box 15-2**

Calculate the ionic strength of 0.1 M solutions of NaCl,  $\text{Na}_2\text{SO}_4$ ,  $\text{MgCl}_2$ , and  $\text{MgSO}_4$ , respectively, for

$$\text{NaCl } \mu = \frac{1}{2}(0.1 \times 1^2 + 0.1 \times 1^2) = 0.1$$

$$\text{Na}_2\text{SO}_4 \mu = \frac{1}{2}(0.2 \times 1^2 + 0.1 \times 2^2) = 0.3$$

$$\text{MgCl}_2 \mu = \frac{1}{2}(0.1 \times 2^2 + 0.2 \times 1^2) = 0.3$$

$$\text{MgSO}_4 \mu = \frac{1}{2}(0.1 \times 2^2 + 0.1 \times 2^2) = 0.4$$

what more concentrated solutions (about 0.1  $\mu$ ) in the simplified form

$$\log f_i = \frac{-0.51 z_i^2 \sqrt{\mu}}{1 + \sqrt{\mu}} \quad (7)$$

The mean ionic activity coefficient for aqueous solutions of electrolytes at 25° can be expressed as

$$\log f_{\pm} = \frac{-0.51 z_+ z_- \sqrt{\mu}}{1 + \sqrt{\mu}} \quad (8)$$

in which  $z_+$  is the valence of the cation and  $z_-$  is the valence of the anion. When the ionic strength of the solution becomes high (approximately 0.3 to 0.5), these equations become inadequate and a linear term in 0 is added. This is illustrated for the mean ionic activity coefficient,

$$\log f_{\pm} = \frac{-0.51 z_+ z_- \sqrt{\mu}}{1 + \sqrt{\mu}} + k_s \mu \quad (9)$$

in which  $K_s$  is a **salting-out constant** chosen empirically for each salt. This equation is valid for solutions with ionic strength up to approximately 1.

**CHEMICAL EQUILIBRIA**

**Equilibrium** is the balance between two opposing reactions or forces. Most chemical reactions proceed in both forward and reverse directions. Chemical equilibrium maintains constant concentration of reactants and products as both processes are occurring at the same rate. Thus the concentration of the reactants and the products may not necessarily be equal but the rate of the forward reaction equals the rate of the reverse reaction. In practice some reactions can proceed almost to completion and thus can be considered as irreversible. The ionization of weak electrolytes, however, is a reversible reaction and if the overall system remains static, that is, the products are not removed, then an equilibrium expression can be written.

For the generalised reaction

the **equilibrium constant (K)** for the reaction can be written as the product of the concentration of the reactants divided by the product of the concentration of the products, i.e.

$$K = \frac{[C]x[D]}{[A]x[B]} \quad (10)$$

For reactions where the concentration of the products is high, the equilibrium will be driven to the right hand side of the equation. Thus the numerator will exceed the denominator and K will have a large value. Conversely, if the reaction only proceeds to a very limited extent, the equilibrium will lie mainly to the left and K will be less than unity. Le Chatelier's Principle states that if a dynamic equilibrium is disturbed by changing the conditions, then the position of equilibrium will move to counteract the change. The equilibrium constant, K, will therefore remain constant under fixed conditions.

**BRØNSTED-LOWRY ACID-BASE THEORY**

Due to shortcomings in the Arrhenius theory, it was recognised that a broader definition was needed and this led to parallel theories being proposed in 1923 by Brønsted and Lowry. It defines an acid as a substance that can ionise in solution to give a solvated hydrogen ion (i.e., a proton stabilised by interaction with either the solvent or a substance in solution). Conversely a base is a substance that will accept a hydrogen atom. This led to the simplified concept that an acid is a **proton donor** and a base is a **proton acceptor**. This led to the concept of a complementary relationship between acids and bases (similar to that between oxidants and reductants). This ionization process will always involve both species and they are known as **conjugate acid-base pairs**.

This conjugate acid-base relationship may be expressed by

The pair of substances is thus related through their mutual ability to gain or lose a proton. Specific examples of such pairs are

However, these examples of acid-base pairs represent reactions that are possible in principle only. Protons, (and electrons), can be transferred only from one substance (an ion, atom, or molecule) to another. Thus an acid will not release a proton unless a base capable of accepting it is present simultaneously. This means that any actual manifestation of acid-base behavior must involve interaction between two sets of conjugate acid-base pairs, represented as

In such a reaction, which is called **protolysis** or a **protolytic reaction**, A<sub>1</sub> and B<sub>1</sub> constitute one conjugate acid-base pair, and A<sub>2</sub> and B<sub>2</sub> the other; the proton given up by A<sub>1</sub> (which thereby becomes B<sub>1</sub>) is transferred to B<sub>2</sub> (which becomes A<sub>2</sub>).

The complementary nature of the acid-base pairs listed is reminiscent of the complementary relationship of pairs of oxidants and reductants where, however, the ability to gain or lose one or more electrons—rather than protons—is the distinguishing characteristic.

When an acid, such as hydrochloric, is dissolved in water, a protolytic reaction occurs.

The ionic species H<sub>3</sub>O<sup>+</sup>, called **hydronium** or **oxonium** ion, always is formed when an acid is dissolved in water. Often, for convenience, this is written simply as H<sup>+</sup> and is called the hydrogen ion, although the “bare” ion practically is nonexistent in solution.

When a base (e.g., ammonia) is dissolved in water, the reaction of protolysis is

It is apparent that not only molecules, but also cations and anions, may function as acids or bases. The conjugate acid, NH<sub>4</sub><sup>+</sup> is also capable of protolysis in water, thus when ammonium chloride is dissolved in water the following reactions occurs

The proton theory of acid-base function makes the concept of hydrolysis superfluous. In the preceding examples water sometimes behaves as an acid and at other times as a base. Such an amphoteric substance is called, in Brønsted's terminology, an **amphiprotic** substance.

## LEWIS ACID-BASE THEORY

The proton concept of acids and bases provides a more general definition for these substances, but it does not indicate the basic reason for proton transfer, nor does it explain how such substances as sulfur trioxide, which is not capable of donating a proton—can behave as acids. A number of theories have been proposed to counteract this deficiency, and a more inclusive definition of acids and bases, the electronic theory, was proposed by Lewis in 1923. In 1916 he proposed that sharing of a pair of electrons by two atoms established a bond (covalent) between the atoms; therefore, an acid is a molecule or ion capable of accepting a pair of electrons made available by another substance called a base, thereby forming a **coordinate covalent bond**. The base is the substance that donates a share in its electron pair to the acid. Thus substances such as boron trichloride, stannic chloride and carbon dioxide can be classified as acids whereas amines, ethers and carboxylic acid anhydrides, which do not contain any hydroxyl group, can be act as bases.

The following equation illustrates how Lewis' definitions explain the transfer of a proton (hydrogen ion) to ammonia to form ammonium ion.

The reaction of boron trichloride, which according to the Lewis theory is an acid, with ammonia is similar, for the boron lacks an electron pair if it is to attain a stable octet configuration, whereas ammonia has a pair of electrons that may be shared, thus,

For acid-base and ionic equilibria, it is the Brønsted-Lowry theory that is most useful and is the definition generally quoted with respect to pharmaceuticals.

## Dissociation of strong acids and bases

When the strong acids such as HClO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HCl, or HNO<sub>3</sub> are dissolved in water, the solutions—if they are of identical normality and are not too concentrated—all have about the same hydrogen-ion concentration, indicating the acids to be of about the same strength. The reason for this is that each one of these acids undergoes practically complete protolysis in water.

This phenomenon, called the **leveling effect of water**, occurs whenever the added acid is stronger than the hydronium ion. Such a reaction manifests the tendency of proton-transfer reactions to proceed spontaneously in the direction of forming a weaker acid or weaker base.

Because the strongest acid that can exist in an amphiprotic solvent is the conjugate acid form of the solvent, any stronger acid will undergo protolysis to the weaker solvent acid. HClO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HCl, or HNO<sub>3</sub> are all stronger acids than the hydronium ion, so they are converted in water to the hydronium ion.

When the strong bases sodium hydride, sodium amide, or sodium ethoxide are dissolved in water, each reacts with water to form sodium hydroxide. These reactions illustrate the leveling effect of water on bases. Because the hydroxide ion is the strongest base that can exist in water, any base stronger than the hydroxide ion undergoes protolysis to hydroxide.

Intrinsic differences in the acidity of acids become evident if they are dissolved in a relatively poor proton acceptor such as anhydrous acetic acid. Perchloric acid (HClO<sub>4</sub>), a strong acid, undergoes practically complete reaction with acetic acid to produce the **acetonium** ion (acid<sub>2</sub>):

but sulfuric acid and hydrochloric acid behave as weak acids. It is because perchloric acid is a very strong acid when dissolved in glacial acetic acid that it has found many important applications in analytical chemistry as a titrant for a variety of substances that behave as bases in acetic acid. Because of its ability to differentiate the acidity of various acids, it is called a **differentiating solvent for acids**; this property results from its relatively weak proton-acceptor tendency. A solvent that differentiates basicity of different bases must have a weak proton-donor tendency; it is called a **differentiating solvent for bases**. Liquid ammonia is typical of solvents in this category.

Solvents that have both weak proton-donor and proton-acceptor tendencies are called **aprotic solvents** and may serve as differentiating solvents for both acids and bases; they have little if any action on solutes and serve mainly as inert dispersion media for the solutes. Useful aprotic solvents are benzene, toluene, or hexane.

## IONIZATION OF ACIDS AND BASES

### Ionization of acids

Acids and bases commonly are classified as strong or weak acids and strong or weak bases depending on whether they are ionized extensively or slightly in aqueous solutions. If, for example, 1 N aqueous solutions of hydrochloric acid and acetic acid are compared, it is found that the former is a better conductor of electricity, reacts much more readily with metals, catalyzes certain reactions more efficiently, and possesses a more acid taste than the latter. Both solutions, however, will neutralize identical amounts of alkali. A similar comparison of 1 N solutions of sodium hydroxide and ammonia reveals the former to be more active than the latter, although both solutions will neutralize identical quantities of acid.

The differences in the properties of the two acids are attributed to differences in the concentration of hydrogen (more accurately hydronium) ion, the hydrochloric acid being ionized to a greater extent and thus containing a higher concentration of hydrogen ion than acetic acid. Similarly, most of the differences between the sodium hydroxide and ammonia solutions are attributed to the higher hydroxyl-ion concentration in the former.

The ionization of incompletely ionized acids may be considered a reversible reaction of the type

where HA is the molecular acid and A<sup>-</sup> is its anion. An equilibrium expression based on the law of mass action may be applied to the reaction

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} \quad (11)$$

where  $K_a$  is the **ionization constant** or **dissociation constant**, and the brackets signify the concentration of each species. It should be borne in mind, that in some pharmaceutical preparations, especially when formulating poorly soluble drugs, it can be common to add a cosolvent such as ethanol or propylene glycol. The resulting change in dielectric constant causes a shift in the equilibrium and thus the  $pK_a$  is altered, decreasing acid and basic strength.

Although the strength of an acid commonly is measured in terms of the ionization or dissociation constant defined in Equation 11, the process of ionization is not that simple given that the proton will not detach itself from one molecule unless it is accepted simultaneously by another molecule. When an acid is dissolved in water, the latter acts as a base, accepting a proton (Brønsted's definition of a base) by donating a share in a pair of electrons (Lewis' definition of a base). This reaction may be written as

Application of the law of mass action gives

$$K = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}][\text{H}_2\text{O}]} \quad (12)$$

For ionizations in dilute solutions, it is acceptable to neglect the role of water as it can be considered as remaining constant (at approximately 55.3 moles/liter at 25 °C). The constant  $K$  can be rewritten to include the concentration of water and the equation becomes

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}]} \quad (13)$$

where  $K_a$  is the ionization or dissociation constant (or the **acidity constant**). This is numerically identical to equation 11 as  $[\text{H}_3\text{O}^+]$  is numerically equal to  $[\text{H}^+]$ . For exact work, the **thermodynamic activity** should be used in place of concentration, especially for more concentrated solutions.  $K_a$  remains relatively constant for any given weakly ionized acid in any given solvent and at any given temperature. With increasingly stronger acids, some deviation may occur but in simple terms, the ionization constant increased with increasing acid strength (due to a shift in the equilibrium to the right-hand side of the equation).

### Ionization of bases

The ionization of a base may be written

The equilibrium expression for this reaction is

$$K = \frac{[\text{BH}^+][\text{OH}^-]}{[\text{H}_2\text{O}][\text{B}]} \quad (14)$$

With  $[\text{H}_2\text{O}]$  constant, as before, the expression becomes

$$K_b = \frac{[\text{BH}^+][\text{OH}^-]}{[\text{B}]} \quad (15)$$

Ionization of a base is often exemplified by ammonia,  $\text{NH}_3$ . Thus for ammonia, the expression can be written

$$K_b = \frac{[\text{NH}_4^+][\text{OH}^-]}{[\text{NH}_3]} \quad (16)$$

and  $K_b$  for ammonia is  $1.8 \times 10^{-5}$ .  $K_b$  is not used extensively in modern terminology as it is more useful to relate both acids and bases on the same terms, i.e. their affinity for the hydrogen ion.

### Ionization of water

Although it is a poor conductor of electricity, pure water does ionize through a process known as **autoprotolysis**, in the following manner:

Application of the law of mass action to this reaction gives

$$K = \frac{[\text{H}_3\text{O}^+][\text{OH}^-]}{[\text{H}_2\text{O}]^2} \quad (17)$$

where  $K$  is the equilibrium constant for the reaction. Because the concentration of  $\text{H}_2\text{O}$  (molecular water) is much higher the hydronium ion or hydroxyl ion concentrations, it can be considered to be constant and  $[\text{H}_2\text{O}]^2$  can be combined with  $K$  to give a new constant,  $K_w$ , known as the **ion product of water**, the **dissociation constant of water** or **autoprotolysis constant**.  $K_w$  is approximately equal to  $1 \times 10^{-14}$  at 25°, however, it does vary with temperature. For example it is  $2.57 \times 10^{-14}$  at 37°C, and this should be considered in any calculations pertaining to deviations from the standard.

$$K_w = [\text{H}_3\text{O}^+][\text{OH}^-] = K[\text{H}_2\text{O}]^2 \quad (18)$$

Because the autoprotolysis of pure water yields one hydronium ion for each hydroxyl ion produced,  $[\text{H}_3\text{O}^+]$  equal to  $[\text{OH}^-]$ . At

25°C each has a value of  $1 \times 10^{-7}$  mol/L ( $1 \times 10^{-7} \times 1 \times 10^{-7}$  so  $K_w = 1 \times 10^{-14}$ ). A solution in which  $[H_3O^+]$  is equal to  $[OH^-]$  is termed a **neutral solution**.

If an acid is added to water, the hydronium ion concentration will be increased and the equilibrium between hydronium and hydroxyl ions will be disturbed momentarily. To restore equilibrium, some of the hydroxyl ions, originally present in the water, will combine with a part of the added hydronium ions to form nonionized water molecules, until the product of the concentrations of the two ions has been reduced to  $10^{-14}$ . When equilibrium again is restored, the concentrations of the two ions no longer will be equal. If, for example, the hydronium-ion concentration is  $1 \times 10^{-3}$  N when equilibrium is established, the concentration of hydroxyl ion will be  $1 \times 10^{-11}$  (the product of the two concentrations being equal to  $10^{-14}$ ). As  $[H_3O^+]$  is much greater than  $[OH^-]$  the solution is said to be an **acid** or **acidic**.

In a similar manner, the addition of an alkali to pure water momentarily disturbs the equilibrium between hydronium and hydroxyl ions. To restore equilibrium, some of the hydronium ions originally present in the water will combine with part of the added hydroxyl ions to form nonionized water molecules. The process continues until the product of the hydronium and hydroxyl ion concentrations again is equal to  $10^{-14}$ . Assuming that the final hydroxyl-ion concentration is  $1 \times 10^{-4}$  N, the concentration of hydronium ion in the solution will be  $1 \times 10^{-10}$ . Because  $[OH^-]$  is much greater than  $[H_3O^+]$ , the solution is said to be **basic** or **alkaline**.

### Relationship of $K_a$ and $K_b$

A particularly interesting and useful relationship between the strength of an acid and its conjugate base, or a base and its conjugate acid, exists. For illustration, consider the strength of the base  $NH_3$  and its conjugate acid  $NH_4^+$  in water. The behavior of  $NH_3$  as a base is expressed by

The equilibrium expression (as stated in Equation 16) is

$$K_b = \frac{[NH_4^+][OH^-]}{[NH_3]} \quad (19)$$

If we consider the behavior of the conjugate acid,  $NH_4^+$ , in water,

then the equilibrium expression is

$$K_a = \frac{[NH_3][H_3O^+]}{[NH_4^+]} \quad (20)$$

Multiplying Equations 19 and 20

$$K_a K_b = \frac{[NH_3][H_3O^+][NH_4^+][OH^-]}{[NH_4^+][NH_3]} \quad (21)$$

It is obvious that

$$K_a K_b = [H_3O^+][OH^-] = K_w \quad (22)$$

where  $K_w$  is the ion product of water as defined in Equation 18. The utility of this relationship, which is a general one for any conjugate acid/base pair, is evident from the following deductions: (1) The strength of an acid may be expressed in terms either of the  $K_a$  or the  $K_b$  of its conjugate base, or vice versa; (2) the  $K_a$  of an acid may be calculated if the  $K_b$  of its conjugate base is known, or vice versa; and (3) the stronger an acid is, the weaker its conjugate base, or vice versa.

The pH of the purest water obtainable, so-called **conductivity water**, is 7 when the measurement is made carefully under conditions to exclude carbon dioxide and prevent errors inherent in the measuring technique (such as acidity or alkalinity of the indicator). Upon agitating this water in the presence of carbon dioxide in the atmosphere (equilibrium water), the value drops rapidly to 5.7. This is the pH of nearly all distilled water that has been exposed to the atmosphere for even a short time and often is called **equilibrium water**.

It should be emphasized strongly that the generalizations stated concerning neutrality, acidity, and alkalinity hold exactly only when (1) the solvent is water, (2) the temperature is 25°C, and (3) there are no other factors to cause deviation from the simply formulated equilibria underlying the definition of pH given in the preceding discussion.

### Ionization of polyprotic electrolytes

Acids that are capable of donating more than one proton and bases capable of accepting more than one proton are termed **polyprotic**. The ionization of a polyprotic acid occurs in stages, two stages to diprotic (or dibasic) acids, three stages for triprotic acids, and can be illustrated by considering the equilibria involved in the ionization of phosphoric acid, a tribasic acid. In general for a polyprotic substance (e.g.,  $H_nA$ ), there are  $n+1$  possible species in solution. The three ionization processes are considered separately and the equilibrium expressions are:

$$K_1 = \frac{[H_3O^+][H_2PO_4^-]}{[H_3PO_4]} \quad (23)$$

$$K_2 = \frac{[H_3O^+][HPO_4^{2-}]}{[H_2PO_4^-]} \quad (24)$$

$$K_3 = \frac{[H_3O^+][PO_4^{3-}]}{[HPO_4^{2-}]} \quad (25)$$

If the three expressions for the ionization constants are multiplied together, an overall ionization,  $K$ , can be obtained

$$K = K_1 K_2 K_3 = \frac{[H_3O^+]^3 [PO_4^{3-}]}{[H_3PO_4]} \quad (26)$$

Each of the successive ionizations is suppressed by the hydronium ion formed from preceding stages according to Le Chatelier's principle. The successive dissociation constants always decrease in value, as successive protons must be removed from species that always are charged more negatively and this are more difficult. The third and final ionization of phosphoric acid is very weak and the amount of  $PO_4^{3-}$  is very low. This can be seen from the data in Table 15-3, in which  $K_1$  for phosphoric acid is approximately 100,000 times greater than  $K_2$ , which is in turn approximately 100,000 times greater than  $K_3$ . Although successive dissociation constants are always smaller, the difference is not always as great as it is for phosphoric acid. Tartaric acid, for example, has  $K_1 = 9.12 \times 10^{-4}$  and  $K_2 = 4.27 \times 10^{-5}$ .

Applying the law of mass action to this series of reactions, and using the concepts outlined in Equations 14–16, the relationship between the various  $K_a$  and  $K_b$  values for phosphoric acid are

$$K_w = K_{a1} \times K_{b3} = K_{a2} \times K_{b2} \times K_{a3} \times K_{b1} \quad (27)$$

where  $K_{a1}$ ,  $K_{a2}$ , and  $K_{a3}$  refer to the equilibria given by Equations, respectively;  $K_{b1}$ ,  $K_{b2}$ , and  $K_{b3}$  refer to the reaction of  $PO_4^{3-}$ ,  $HPO_4^{2-}$ , and  $H_2PO_4^-$ , respectively, with water.

### Electronegativity and dissociation constants

Table 15-3 gives the dissociation constants of several weak acids and weak bases, in water, at 25°C. Strong acids and strong bases do not obey the law of mass action, so dissociation constants cannot be formulated for these strong electrolytes. Table 15-3 shows that great variations occur in the strength of weak

**Table 15-3. Dissociation Constants in Water at 25°C**

Substance		K
Weak acids		
Acetic		$1.75 \times 10^{-3}$
Acetylsalicylic		$3.27 \times 10^{-4}$
Barbital		$1.23 \times 10^{-8}$
Barbituric		$1.05 \times 10^{-4}$
Benzoic		$6.30 \times 10^{-5}$
Benzyl penicillin		$1.74 \times 10^{-3}$
Boric	$K_1$	$5.8 \times 10^{-10}$
Caffeine		$1 \times 10^{-14}$
Carbonic	$K_1$	$4.31 \times 10^{-7}$
	$K_2$	$4.7 \times 10^{-11}$
Citric (1H <sub>2</sub> O)	$K_1$	$7.0 \times 10^{-4}$
	$K_2$	$1.8 \times 10^{-5}$
	$K_3$	$4.0 \times 10^{-7}$
Dichloroacetic		$5 \times 10^{-2}$
Ethylenediaminetetraacetic acid (EDTA)	$K_1$	$1 \times 10^{-2}$
	$K_2$	$2.14 \times 10^{-3}$
	$K_3$	$6.92 \times 10^{-7}$
	$K_4$	$5.5 \times 10^{-11}$
Formic		$1.77 \times 10^{-4}$
Glycerophosphoric	$K_1$	$3.4 \times 10^{-2}$
	$K_2$	$6.4 \times 10^{-7}$
Glycine	$K_1$	$4.5 \times 10^{-3}$
	$K_2$	$1.7 \times 10^{-10}$
Lactic		$1.39 \times 10^{-4}$
Mandelic		$4.29 \times 10^{-4}$
Monochloroacetic		$1.4 \times 10^{-3}$
Oxalic (2H <sub>2</sub> O)	$K_1$	$5.5 \times 10^{-2}$
	$K_2$	$5.3 \times 10^{-5}$
Phenobarbital		$3.9 \times 10^{-8}$
Phenol		$1 \times 10^{-10}$
Phosphoric	$K_1$	$7.5 \times 10^{-3}$
	$K_2$	$6.2 \times 10^{-8}$
	$K_3$	$2.1 \times 10^{-13}$
Picric		$4.2 \times 10^{-1}$
Propionic		$1.34 \times 10^{-5}$
Saccharin		$2.5 \times 10^{-2}$
Salicylic		$1.06 \times 10^{-3}$
Succinic	$K_1$	$6.4 \times 10^{-5}$
	$K_2$	$2.3 \times 10^{-6}$
Sulfadiazine		$3.3 \times 10^{-7}$
Sulfamerazine		$8.7 \times 10^{-8}$
Sulfapyridine		$3.6 \times 10^{-9}$
Sulfathiazole		$7.6 \times 10^{-8}$
Tartaric	$K_1$	$9.6 \times 10^{-4}$
	$K_2$	$4.4 \times 10^{-5}$
Trichloroacetic		$1.3 \times 10^{-1}$
Weak bases		
Acetanilide		$4.1 \times 10^{-14}$ (40°)
Ammonia		$1.74 \times 10^{-5}$
Apomorphine		$1.0 \times 10^{-7}$
Atropine		$4.5 \times 10^{-5}$
Benzocaine		$6.0 \times 10^{-12}$
Caffeine		$4.1 \times 10^{-14}$ (40°)
Cocaine		$2.6 \times 10^{-6}$
Codeine		$9 \times 10^{-7}$

Substance		K
Ephedrine		$2.3 \times 10^{-5}$
Morphine		$7.4 \times 10^{-7}$
Papaverine		$8 \times 10^{-9}$
Physostigmine	$K_1$	$7.6 \times 10^{-7}$
	$K_2$	$5.7 \times 10^{-13}$
Pilocarpine	$K_1$	$7 \times 10^{-8}$
	$K_2$	$2 \times 10^{-13}$
Procaine		$7 \times 10^{-6}$
Pyridine		$1.4 \times 10^{-9}$
Quinine	$K_1$	$1.0 \times 10^{-6}$
	$K_2$	$1.3 \times 10^{-10}$
Reserpine		$4 \times 10^{-8}$
Strychnine	$K_1$	$1 \times 10^{-6}$
	$K_2$	$2 \times 10^{-12}$
Theobromine		$4.8 \times 10^{-14}$ (40°)
Thiourea		$1.1 \times 10^{-15}$
Urea		$1.5 \times 10^{-14}$

acids and weak bases. Dissociation constants for pharmaceuticals are often found in the appropriate monographs, published literature or some useful lists.<sup>1</sup> The effect of various substituents on the strength of acids and bases depends on the electronegativity of the substituent atom or radical. For example, the substitution of one chlorine atom into the molecule of acetic acid increases the degree of ionization of the acid. Substitution of two chlorine atoms further increases the degree of ionization, and introduction of three chlorine atoms produces a still stronger acid. Acetic acid ionizes primarily because the oxygen atom adjacent to the hydrogen atom of the carboxyl group has a stronger affinity for electrons than the hydrogen atom. Thus, when acetic acid is dissolved in water, the polar molecules of the water have a stronger affinity for the hydrogen of acetic acid than the hydrogen atoms of water. The acetic acid ionizes as a consequence of this difference in affinities.

When an atom of chlorine is introduced into the acetic acid molecule, forming ClCH<sub>2</sub>COOH, the electrons in the molecule are attracted very strongly to the chlorine because of its relatively high electronegativity; the bond between the hydrogen and the oxygen in the carboxyl group is thereby weakened, and the degree of ionization increased. Introduction of two or three chlorine atoms weakens the bond further and increases the strength of the acid. On the other hand, substitution of chlorine into the molecule of ammonia reduces the strength of the base because of its decreased affinity for the hydrogen ion.

### Ionic strength and dissociation constants

Most solutions of pharmaceutical interest are in a concentration range such that the ionic strength of the solution may have a marked effect on ionic equilibria and observed dissociation constants. One method of correcting dissociation constants for solutions with an ionic strength up to about 0.3 is to calculate an **apparent dissociation constant**,  $pK'_a$  as

$$pK'_a = pK_a + \frac{0.51 (2Z - 1) \sqrt{\mu}}{1 + \sqrt{\mu}} \quad (28)$$

in which  $pK_a$  is the tabulated thermodynamic dissociation constant,  $Z$  is the charge on the acid, and  $\mu$  is the ionic strength. See Box 15-3.

### DETERMINATION OF PH AND PKA

The numerical values of hydronium ion concentration may vary enormously; for a normal solution of a strong acid the value is nearly 1, whereas for a normal solution of a strong base it is approximately  $1 \times 10^{-14}$ ; there is a variation of 100,000,000,000,000

**Box 15-3**

Calculate  $pK'_\alpha$ , for succinic acid at an ionic strength of 0.1. Assume that  $pK_2$  is 5.63. The charge on the acid species is  $-1$ .

$$\begin{aligned} pK'_2 &= 5.63 \frac{0.51(-2-1)\sqrt{0.1}}{1 + \sqrt{0.1}} \\ &= 5.63 - 0.37 = 5.26 \end{aligned}$$

between these two limits. Because of the inconvenience of dealing with such large numbers, in 1909 Sørensen proposed that hydronium ion concentration be expressed in terms of the logarithm (log) of its reciprocal. To this value he assigned the symbol pH. Mathematically this is written as

$$pH = \log \frac{1}{[H_3O^+]} \quad (29)$$

This equation can also be displayed as

$$pH = \log 1 - \log[H_3O^+] \quad (30)$$

$$pH = -\log[H_3O^+] \quad (31)$$

as the logarithm of 1 is zero.

Thus the pH also may be defined as the negative logarithm of the hydronium ion concentration. In general, this type of notation is used to indicate the negative logarithm of the term that is preceded by the p, which gives rise to the following

$$pOH = \text{plog}[OH^-] \quad (32)$$

and similarly

$$pK_a = -\log K_a \quad (33)$$

and

$$pK_b = -\log K_b \quad (34)$$

This enables the pH of a solution to be considered on a numerical scale from 0–14 and is more convenient in terms of speech, writing and data manipulation. Acidic solutions having a predominance of  $[H_3O^+]$  have pH values between 0 and 7. The hydronium concentration of pure water, at 25°C, is  $1 \times 10^{-7} N$ , corresponding to a pH of 7. This figure, therefore, is designated as the neutral point, and all values below a pH of 7 represent acidity—the smaller the number, the greater the acidity. Values above 7 represent alkalinity—the larger the number, the greater the alkalinity. Mathematically there is no reason why negative numbers or numbers above 14 should not be used. In practice, however, such values are never encountered because solutions that might be expected to have such values are too concentrated to be ionized extensively or the interionic attraction is so great as to materially reduce ionic activity.

Ionization constants are small, often inconvenient figures whereas the  $pK_a$  is convenient in speech and notation. This, the  $K_a$  of acetic acid is  $1.75 \times 10^{-5}$ , which can be converted to the more convenient 4.76.

The relationship of pH to hydronium ion and hydroxyl ion concentrations may be seen in Table 15-4. A calculation of  $pK_a$  is given in Box 15-4.

When bases are expressed as  $K_b$ , it is often convenient to convert them to  $K_a$ . The ionic product of water can be used to facilitate this and the “p” notation is useful.  $K_a$  and  $K_b$  are related to  $K_w$

$$K_a \times K_b = K_w = [H_3O^+][OH^-] = 1 \times 10^{-14} \quad (\text{at } 25^\circ\text{C}) \quad (35)$$

Taking negative logarithms

$$pK_a + pK_b = pK_w = 14.00 \quad (\text{at } 25^\circ\text{C}) \quad (36)$$

The  $pK_b$  value for ammonia is 4.74 at 25°C but it is more common and convenient to use the  $pK_a$  value of 9.26. See Box 15-5 for a calculation.

**Box 15-4**

The following examples illustrate the conversion from exponential to p notation.

1. Calculate the pH corresponding to a hydronium ion concentration of  $1 \times 10^{-4}$  g-ion/L.

Solution:

$$\begin{aligned} pH &= \log \frac{1}{1 \times 10^{-4}} \\ &= \log 10,000 \text{ or } \log (1 \times 10^4) \\ (1 \times 10^{-4}) &= +4 \\ pH &= 4 \end{aligned}$$

2. Calculate the pH corresponding to a hydronium ion-concentration of 0.000036 N (or g-ion/L). (Note: This more frequently is written as a number multiplied by a power of 10, thus,  $3.6 \times 10^{-5}$  for 0.000036.)

$$\begin{aligned} pH &= \log \frac{1}{3.6 \times 10^{-5}} \\ &= \log 28,000 \text{ or } \log (2.8 \times 10^4) \\ \log (1 \times 10^4) &= \log 2.8 + 10^4 \\ \log 2.8 &= +0.44 \\ \log 10^4 &= +4.00 \\ pH &= 4.44 \end{aligned}$$

This problem also may be solved as follows:

$$\begin{aligned} pH &= -\log (3.6 \times 10^{-5}) \\ \log 3.6 &= +0.56 \\ \log 10^{-5} &= -5.00 \\ &= -4.00 = \log (3.6 \times 10^{-5}) \\ pH &= -(-4.44) = +4.44 = 4.44 \end{aligned}$$

The procedure should be reversed to convert pH to hydronium ion-concentration.

Thus:

$$\begin{aligned} pH &= \log \frac{1}{[H_3O^+]} \\ 4.44 &= \log \frac{1}{[H_3O^+]} \\ \frac{1}{[H_3O^+]} &= \text{antilog of } 4.44 = 28,000 \text{ (rounded off)} \\ [H_3O^+] &= \frac{1}{28,000} = 0.000036 \text{ or } 3.6 \times 10^{-5} \end{aligned}$$

Tip:

In finding the antilog of  $-4.44$  it should be kept in mind that the mantissa (the number to the right of the decimal point) of a log to the base 10 (the common or Briggsian logarithm base) is **always positive** but that the characteristic (the number to the left of the decimal point) may be **positive or negative**. As the entire log  $-4.44$  is negative, it is obvious that one cannot look up the antilog of  $-0.44$ . Using modern calculators, the order of entry of functions can be checked by remembering that a neutral solution (pH 7) has a hydronium ion-concentration of  $1 \times 10^{-7}$  g-ion/L.

**Table 15-4. Hydronium ion and hydroxyl ion concentrations**

	pH	Normality in Terms of Hydroniumion	Normality in Terms of Hydroxylion
	0	10 <sup>0</sup> (=1)	10 <sup>-14</sup>
	1	10 <sup>-1</sup>	10 <sup>-13</sup>
	2	10 <sup>-2</sup>	10 <sup>-12</sup>
Increasing acidity	3	10 <sup>-3</sup>	10 <sup>-11</sup>
	4	10 <sup>-4</sup>	10 <sup>-10</sup>
	5	10 <sup>-5</sup>	10 <sup>-9</sup>
Neutral point	6	10 <sup>-6</sup>	10 <sup>-8</sup>
	7	10 <sup>-7</sup>	10 <sup>-7</sup>
	8	10 <sup>-8</sup>	10 <sup>-6</sup>
Increasing alkalinity	9	10 <sup>-9</sup>	10 <sup>-5</sup>
	10	10 <sup>-10</sup>	10 <sup>-4</sup>
	11	10 <sup>-11</sup>	10 <sup>-3</sup>
	12	10 <sup>-12</sup>	10 <sup>-2</sup>
	13	10 <sup>-13</sup>	10 <sup>-1</sup>
	14	10 <sup>-14</sup>	10 <sup>0</sup> (=1)

**Box 15-5**

Calculate the pK<sub>a</sub> of atropine given that the K<sub>b</sub> is 4.5 × 10<sup>-5</sup>.

$$K_a \times K_b = K_w$$

$$K_a = \frac{1 \times 10^{-14}}{4.5 \times 10^{-5}}$$

$$K_a = 222 \times 10^{-10}$$

$$\text{p}K_a = 9.65$$

OR

$$K_b \text{ is } 4.5 \times 10^{-5} \text{ so } \text{p}K_b = 4.35$$

$$\text{p}K_a = 14.00 - \text{p}K_b = 9.65$$

**Species concentration**

When a weak acid, H<sub>n</sub>A is added to water, n+1 species, including the unionized acid, can exist. After equilibrium is established, the sum of the concentrations of all species must be equal to C<sub>a</sub>, the stoichiometric (added) concentration of acid. Thus, for a triprotic acid H<sub>3</sub>A,

$$C_a = [\text{H}_3\text{A}] + [\text{H}_2\text{A}^-] + [\text{HA}^{2-}] + [\text{A}^{3-}] \quad (37)$$

In addition, the concentrations of all acidic and basic species in solution vary with pH, and can be represented solely in terms of equilibrium constants and the hydronium ion concentration. These relationships may be expressed as

$$[\text{H}_n\text{A}] = [\text{H}_3\text{O}^+]^n C_a / D \quad (38)$$

$$[\text{H}_{n-j}\text{A}^{-j}] = [\text{H}_3\text{O}^+]^{n-j} K_1, \dots, K_j C_a / D \quad (39)$$

in which *n* represents the total number of dissociable hydrogens in the parent acid, *j* is the number of protons dissociated, C<sub>a</sub> is the stoichiometric concentration of acid, and *K* represents the acid dissociation constants. The term *D* is a power series in [H<sub>3</sub>O<sup>+</sup>] and *K*, starting with [H<sub>3</sub>O<sup>+</sup>] raised to the *n*th power. The last term is the product of all the dissociation constants. The intermediate terms can be generated from the last term by substituting [H<sub>3</sub>O<sup>+</sup>] for K<sub>n</sub> to obtain the next-to-last term, then substituting [H<sub>3</sub>O<sup>+</sup>] for K<sub>n-1</sub> to obtain the next term, and onward until the first term is reached. The following examples show the denominator, *D*, to be used for various types of acids:

$$\text{H}_3\text{A: } D = [\text{H}_3\text{O}^+]^3 + K_1[\text{H}_3\text{O}^+]^2 + K_1K_2[\text{H}_3\text{O}^+] + K_1K_2K_3 \quad (40)$$

$$\text{H}_2\text{A: } D = [\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2 \quad (41)$$

$$\text{HA: } D = [\text{H}_3\text{O}^+] + K_a \quad (42)$$

The numerator in all instances is C<sub>a</sub> multiplied by the term from the denominator that has [H<sub>3</sub>O<sup>+</sup>] raised to the *n-j* power. Thus, for diprotic acids such as carbonic, succinic, tartaric, and so on,

$$[\text{H}_2\text{A}] = \frac{[\text{H}_3\text{O}^+]^2 C_a}{[\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2} \quad (43)$$

$$[\text{HA}^-] = \frac{K_1[\text{H}_3\text{O}^+] C_a}{[\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2} \quad (44)$$

$$[\text{A}^{2-}] = \frac{K_1K_2[\text{H}_3\text{O}^+] C_a}{[\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2} \quad (45)$$

See Box 15-6.

**Box 15-6**

Calculate the concentrations of all succinic acid species in a 1.0 × 10<sup>-3</sup> M solution of succinic acid at pH 6. Assume that K<sub>1</sub> = 6.4 × 10<sup>-5</sup> and K<sub>2</sub> = 2.3 × 10<sup>-6</sup>.

As all the equations have the same denominator, *D*, it can be calculated as

$$\begin{aligned} D &= [\text{H}_3\text{O}^+]^2 + K_1[\text{H}_3\text{O}^+] + K_1K_2 \\ &= 1.0 \times 10^{-12} + 6.4 \times 10^{-5} \times 1.0 \times 10^{-6} + 6.4 \times 10^{-5} \times 2.3 \times 10^{-6} \\ &= 1.0 \times 10^{-12} + 6.4 \times 10^{-11} + 14.7 \times 10^{-11} \\ &= 21.2 \times 10^{-11} \end{aligned}$$

Therefore,

$$\begin{aligned} [\text{H}_2\text{A}] &= \frac{[\text{H}_3\text{O}^+]^2 C_a}{D} \\ &= \frac{1.0 \times 10^{-12} \times 1.0 \times 10^{-3}}{21.2 \times 10^{-11}} = 4.7 \times 10^{-6} \text{ M} \end{aligned}$$

$$\begin{aligned} [\text{HA}^-] &= \frac{K_1[\text{H}_3\text{O}^+] C_a}{D} \\ &= \frac{6.4 \times 10^{-5} \times 1.0 \times 10^{-3}}{21.2 \times 10^{-11}} = 3.0 \times 10^{-4} \text{ M} \end{aligned}$$

$$\begin{aligned} [\text{A}^{2-}] &= \frac{K_1K_2 C_a}{D} \\ &= \frac{14.7 \times 10^{-11} \times 1.0 \times 10^{-3}}{21.2 \times 10^{-11}} = 6.9 \times 10^{-4} \text{ M} \end{aligned}$$

**PROTON-BALANCE EQUATION**

In the Brønsted–Lowry system, the total number of protons released by the acidic species must equal the total number of protons consumed by basic species. This results in a very useful relationship known as the proton-balance equation (PBE), in which the sum of the concentration terms for species that form by proton consumption is equated to the sum of the concentration terms for species that are formed by the release of protons. The PBE forms the basis of a unified approach to pH calculations, as it is an exact accounting of all proton transfers occurring in solution.

When HCl is added to water, for example, it dissociates yielding one Cl<sup>-</sup> for each proton released. Thus, Cl<sup>-</sup> is a species formed by the release of a proton. In the same solution, and actually in all aqueous solutions

where H<sub>3</sub>O<sup>+</sup> is formed by proton consumption and OH<sup>-</sup> is formed by proton release. Thus, the PBE is

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] + [\text{Cl}^-] \quad (46)$$

In general, the PBE can be formed in the following manner:

1. Start with the species added to water.
2. Place all species that can form when protons are released on the right side of the equation.
3. Place all species that can form when protons are consumed on the left side of the equation.
4. Multiply the concentration of each species by the number of protons gained or lost to form that species.
5. Add  $[\text{H}_3\text{O}^+]$  to the left side of the equation and  $[\text{OH}^-]$  to the right side of the equation. These result from the interaction of two molecules of water as shown above.

See Box 15-7.

### Box 15-7

1. When  $\text{H}_3\text{PO}_4$  is added to water, the species  $\text{H}_2\text{PO}_4^-$  forms with the release of one proton;  $\text{HPO}_4^{2-}$  forms with the release of two protons; and  $\text{PO}_4^{3-}$  forms with the release of three protons, which gives the following PBE:

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] + [\text{H}_2\text{PO}_4^-] + 2[\text{HPO}_4^{2-}] + 3[\text{PO}_4^{3-}]$$

2. When  $\text{Na}_2\text{HPO}_4$  is added to water, it dissociates into two  $\text{Na}^+$  and one  $\text{HPO}_4^{2-}$ . The sodium ion is neglected in the PBE because it is not formed from the release or consumption of protons. The species  $\text{HPO}_4^{2-}$ , however, may react with water to give  $\text{H}_2\text{PO}_4^-$  with the consumption of one proton,  $\text{H}_3\text{PO}_4$  with the consumption of two protons, and  $\text{PO}_4^{3-}$  with the release of one proton to give the following PBE:

$$[\text{H}_3\text{O}^+] + [\text{H}_2\text{PO}_4^-] + 2[\text{H}_3\text{PO}_4] = [\text{OH}^-] + [\text{PO}_4^{3-}]$$

## CALCULATION OF PH OF SOLUTIONS: ACIDS, BASES, AND SALTS

### Calculation of pH for strong acids

For our purposes, a strong acid is one which is completely dissociated in water (e.g., HCl or  $\text{H}_2\text{SO}_4$ ). When a strong acid such as HCl is added to water, the following reactions occur:

(note this reaction will proceed to completion)

The PBE for this system would be

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] + [\text{Cl}^-] \quad (47)$$

As fully ionised,  $[\text{Cl}^-] = C_a$  (the stoichiometric concentration of the acid)

$$\text{Thus } [\text{H}_3\text{O}^+] = [\text{OH}^-] + C_a \quad (48)$$

From previous equations, we know

$$K_w = [\text{H}_3\text{O}^+][\text{OH}^-] \text{ so } [\text{OH}^-] = \frac{K_w}{[\text{H}_3\text{O}^+]} \quad (49)$$

Substituting into Equation 48

$$[\text{H}_3\text{O}^+] = \frac{K_w}{[\text{H}_3\text{O}^+]} + C_a \quad (50)$$

Multiplication by  $[\text{H}_3\text{O}^+]$  to remove the denominator gives

$$[\text{H}_3\text{O}^+]^2 - C_a[\text{H}_3\text{O}^+] - K_w = 0 \quad (51)$$

This is a quadratic equation\* that yields the solution (because  $[\text{H}_3\text{O}^+]$  can never be negative)

$$[\text{H}_3\text{O}^+] = \frac{C_a + \sqrt{C_a^2 + 4K_w}}{2} \quad (52)$$

\*The solution to a quadratic equation is

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

In most instances, the concentration of the acid ( $C_a$ ) will be greater than  $1 \times 10^{-6}\text{M}$  which is much greater than  $4K_w$  ( $4 \times 10^{-14}$ ). Thus equation 52 simplifies to  $[\text{H}_3\text{O}^+] = C_a$  and pH is therefore equal to the negative of the logarithm of  $C_a$ .

Calculate the pH of 0.1 M HCl

$$0.1\text{M HCl} = 0.1\text{M H}_3\text{O}^+ = 10^{-1}\text{M pH} = 1$$

Similarly for  $1 \times 10^{-6}\text{M HCl}$ , the pH can be calculated to be 6. For dilute solutions of weak acids, this simplification is not valid and equation 52 must be used. See Box 15-8.

### Box 15-8

Calculate the pH of  $1 \times 10^{-8}\text{M HCl}$  (pH cannot equal 8)

$$[\text{H}_3\text{O}^+] = \frac{1 \times 10^{-8} + \sqrt{(1 \times 10^{-8})^2 + 4 \times 10^{-14}}}{2}$$

$$[\text{H}_3\text{O}^+] = \frac{1 \times 10^{-8} + \sqrt{4.01 \times 10^{-14}}}{2}$$

$$[\text{H}_3\text{O}^+] = \frac{2.1 \times 10^{-7}}{2}$$

$$[\text{H}_3\text{O}^+] = 1.05 \times 10^{-7}$$

$$\text{pH} = 6.98$$

In a similar manner a relationship can be derived for strong bases

$$[\text{OH}^-] = \frac{C_b + \sqrt{C_b^2 + 4K_w}}{2} \quad (53)$$

where  $C_b$  = concentration of base. For non-dilute solutions of a base such as NaOH (where  $C_b > 1 \times 10^{-6}$ ), then

$$[\text{OH}^-] = [\text{Na}^+] = C_b$$

and the pH of a 0.005M solution of NaOH would be

$$\text{pOH} = -\log 0.005 = 2.30$$

$$\text{pH} = \text{p}K_w - \text{pOH}$$

$$\text{pH} = 14 - 2.30 = 11.70$$

### pH of solutions of weak acids and bases

#### SOLUTIONS CONTAINING WEAK ACID ONLY

If a weak acid, HA, is added to water, it will equilibrate with its conjugate base,  $\text{A}^-$ , as

Accounting for the ionization of water gives the following PBE for this system:

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] + [\text{A}^-] \quad (54)$$

The concentration of  $\text{A}^-$  as a function of hydronium ion concentration can be obtained as shown previously to give

$$[\text{H}_3\text{O}^+] = [\text{OH}^-] + \frac{K_a C_a}{[\text{H}_3\text{O}^+] + K_a} \quad (55)$$

Algebraic simplification yields

$$[\text{H}_3\text{O}^+] = K_a \frac{(C_a - [\text{H}_3\text{O}^+] + [\text{OH}^-])}{([\text{H}_3\text{O}^+] - [\text{OH}^-])} \quad (56)$$

In most instances for solutions of weak acids,  $[\text{H}_3\text{O}^+] \gg [\text{OH}^-]$ , and the equation simplifies to give

$$[\text{H}_3\text{O}^+]^2 + K_a[\text{H}_3\text{O}^+] - K_a C_a = 0$$

This is a quadratic equation as before that yields

$$[\text{H}_3\text{O}^+] = \frac{-K_a + \sqrt{K_a^2 + 4K_a C_a}}{2} \quad (57)$$

because  $[\text{H}_3\text{O}^+]$  can never be negative. Furthermore, if  $[\text{H}_3\text{O}^+]$  is less than 5% of  $C_a$ , Equation 57 is simplified further to give

$$[\text{H}_3\text{O}^+] = \sqrt{K_a C_a} \quad (58)$$

It generally is preferable to use the simplest equation to calculate  $[\text{H}_3\text{O}^+]$ . However, when  $[\text{H}_3\text{O}^+]$  is calculated, it must be compared to  $C_a$  in order to determine whether the assumption  $C_a \gg [\text{H}_3\text{O}^+]$  is valid. If the assumption is not valid, the quadratic equation should be used. See Box 15-9.

### Box 15-9

Calculate the pH of a  $5.00 \times 10^{-5} M$  solution of a weak acid having a  $K_a = 1.90 \times 10^{-5}$ .

$$\begin{aligned} [\text{H}_2\text{O}^+] &= \sqrt{K_a C_a} \\ &= \sqrt{1.90 \times 10^{-5} \times 5.00 \times 10^{-5}} \\ &= 3.08 \times 10^{-5} M \end{aligned}$$

As  $C_a$  ( $5.00 \times 10^{-5} M$ ) is not much greater than  $[\text{H}_3\text{O}^+]$ , the quadratic equation (Equation 57) should be used.

$$\begin{aligned} [\text{H}_2\text{O}^+] &= \frac{-1.90 \times 10^{-5} + \sqrt{(1.90 \times 10^{-5})^2 + (5.00 \times 10^{-5})}}{2} \\ &= 7.06 \times 10^{-3} \\ \text{pH} &= -\log(7.06 \times 10^{-3}) = 2.15 \end{aligned}$$

Note that the assumption  $[\text{H}_3\text{O}^+] \gg [\text{OH}^-]$  is valid. The hydronium ion concentration calculated from Equation 58 has a relative error of about 100% when compared to the correct value obtained from Equation 57.

When a salt obtained from a strong acid and a weak base—such as ammonium chloride, morphine sulfate, or pilocarpine hydrochloride—is dissolved in water, it dissociates as

in which  $\text{BH}^+$  is the protonated form of the base B, and  $\text{X}^-$  is the anion of a strong acid. Because  $\text{X}^-$  is the anion of a strong acid, it is too weak a base to undergo any further reaction with water. The protonated base, however, can act as a weak acid to give

Thus, Equations 57 and 58 are valid, with  $C_a$  being equal to the concentration of the salt in solution. If  $K_a$  for the protonated base is not available, it can be obtained by dividing  $K_b$  for the base B, into  $K_w$ . See Box 15-10.

### SOLUTIONS CONTAINING WEAK BASE ONLY

When a weak base, B, is dissolved in water it ionizes to give the conjugate acid as

The PBE for this system is

$$[\text{BH}^+] + [\text{H}_3\text{O}^+] = [\text{OH}^-] \quad (59)$$

Substituting  $[\text{BH}^+]$  as a function of hydronium ion concentration and simplifying, in the same manner as shown for a weak acid, gives

$$[\text{OH}^-] = K_b \frac{(C_b - [\text{OH}^-] + [\text{H}_3\text{O}^+])}{([\text{OH}^-] - [\text{H}_3\text{O}^+])} \quad (60)$$

If  $[\text{OH}^-] \gg [\text{H}_3\text{O}^+]$ , as is true generally, then

$$[\text{OH}^-]^2 + K_b[\text{OH}^-] + K_b C_b = 0 \quad (61)$$

### Box 15-10

Calculate the pH of a  $0.026 M$  solution of ammonium chloride. Assume that  $K_b$  for ammonia is  $1.74 \times 10^{-5}$  and  $K_w$  is  $1.00 \times 10^{-14}$ .

$$K_a = \frac{K_w}{K_b} = \frac{1.00 \times 10^{-14}}{1.74 \times 10^{-5}} = 5.75 \times 10^{-10}$$

$$\begin{aligned} [\text{H}_3\text{O}^+] &= \sqrt{K_a C_a} \\ &= \sqrt{5.75 \times 10^{-10} \times 2.6 \times 10^{-2}} \\ &= 3.87 \times 10^{-6} M \end{aligned}$$

$$\text{pH} = -\log(3.87 \times 10^{-6}) = 5.41$$

As  $C_a$  is much greater than  $[\text{H}_3\text{O}^+]$  and  $[\text{H}_3\text{O}^+]$  is much greater than  $[\text{OH}^-]$ , the assumptions are valid and the value calculated for pH is sufficiently accurate.

which is a quadratic with the following solution:

$$[\text{OH}^-] = \frac{-K_b + \sqrt{K_b^2 + 4K_b C_b}}{2} \quad (62)$$

If  $C_b \gg [\text{OH}^-]$ , the quadratic equation simplifies to

$$[\text{OH}^-] = \sqrt{K_b C_b} \quad (63)$$

or the more useable

$$[\text{H}_3\text{O}^+] = \sqrt{\frac{K_a K_w}{C_b}} \quad (64)$$

See Box 15-11.

### Box 15-11

Calculate the pH of a  $0.05 M$  solution of sodium acetate. Assume that  $K_a$  for acetic acid =  $1.75 \times 10^{-5}$  and  $K_w = 1 \times 10^{-14}$ .

$$[\text{H}_3\text{O}^+] = \sqrt{\frac{1.75 \times 10^{-5} \times 1.00 \times 10^{-14}}{0.05}}$$

$$[\text{H}_3\text{O}^+] = \sqrt{3.5 \times 10^{-18}}$$

$$[\text{H}_3\text{O}^+] = 1.87 \times 10^{-9}$$

$$\text{pH} = 8.73$$

### SOLUTIONS CONTAINING AMPHOLYTES

Substances such as  $\text{NaHCO}_3$  and  $\text{NaH}_2\text{PO}_4$  are termed **ampholytes** and are capable of functioning both as acids and bases. When an ampholyte of the type  $\text{NaHA}$  is dissolved in water, the following series of reactions can occur:

The total PBE for the system is

$$[\text{H}_3\text{O}^+] + [\text{H}_2\text{A}] = [\text{OH}^-] + [\text{A}^{2-}] \quad (65)$$

Substituting both  $[\text{H}_2\text{A}]$  and  $[\text{A}^{2-}]$  as a function of  $[\text{H}_3\text{O}^+]$  yields

$$\begin{aligned} [\text{H}_3\text{O}^+] &= \frac{[\text{H}_3\text{O}^+]^2 C_s}{[\text{H}_3\text{O}^+]^2 + K_1 [\text{H}_3\text{O}^+] + K_1 K_2} \\ &= \frac{K_u}{[\text{H}_3\text{O}^+]} + \frac{K_1 K_2 C_s}{[\text{H}_3\text{O}^+]^2 + K_1 [\text{H}_3\text{O}^+] + K_1 K_2} \end{aligned} \quad (66)$$

where  $C_s$  is the concentration of salt. This gives a fourth-order equation in  $[H_3O^+]$ , which can be simplified using certain judicious assumptions to

$$[H_3O^+] = \sqrt{\frac{K_1 K_2 C_s}{K_1 + C_s}} \quad (67)$$

In most instances,  $C_s \gg K_1$ , and the equation further simplifies to

$$[H_3O^+] = \sqrt{K_1 K_2} \quad (68)$$

and  $[H_3O^+]$  becomes independent of the concentration of the salt. A special property of ampholytes is that the concentration of the species  $HA^-$  is maximal at the pH corresponding to Equation 68.

### Zwitterions

When the simplest amino acid salt, glycine hydrochloride, is dissolved in water, it acts as a diprotic acid and ionizes as

The form,  ${}^+NH_3CH_2COO^-$ , is an ampholyte because it also can act as a weak base:

Glycine when titrated in water shows two  $pK_a$  values. One at 2.4 corresponding to the proton gained and one at 9.8 for the proton loss.

The term **zwitterion** was introduced on 1897 to describe this type of “internal salt”, which carries both a charged acidic and a charged basic moiety on the same molecule. Because the two charges balance each other, the molecule acts essentially as a neutral molecule. The pH at which the zwitterion concentration is maximal is known as the **isoelectric point**, which can be calculated from Equation 68. For a simple amino acid, such as glycine, the  $pI$  is simply the average of the two  $pK_a$  values. For more complex amino acids, such as glutamic acid or arginine which have ionisable groups in the side-chains, the  $pI$  is given by averaging the two  $pK_a$  values that lie on either side of the zwitterion.

On the acid side of the isoelectric point, amino acids and proteins are cationic and incompatible with anionic materials such as the naturally occurring gums used as suspending and/or emulsifying agents. On the alkaline side of the isoelectric point, amino acids and proteins are anionic and incompatible with cationic materials such as benzalkonium chloride. However, not all amphoteric substances having both acidic and basic groups are zwitterions. *m*-Aminophenol has 2  $pK_a$  values, 4.4 and 9.8 and although it is an ampholyte, it does not exist as a zwitterion. A substance is often suspected to be a zwitterion if it is more soluble in water, less soluble in organic solvents, has a higher melting point and related substances with one ionizable group.

### Solutions containing salts of weak acids and weak bases

When a salt such as ammonium acetate (which is derived from a weak acid and a weak base) is dissolved in water, it undergoes the following reactions:

The total PBE for this system is

$$[HA] + [H_3O^+] = [OH^-] + [B] \quad (69)$$

Replacing  $[HA]$  and  $[B]$  as a function of  $[H_3O^+]$ , gives

$$[H_3O^+] + \frac{[H_3O^+]C_s}{[H_3O^+] + K_a} = [OH^-] + \frac{K'_a C_s}{[H_3O^+] + K'_a} \quad (70)$$

in which  $C_s$  is the concentration of salt,  $K_a$  is the ionization constant of the conjugate acid formed from the reaction between  $A^-$  and water, and  $K'_a$  is the ionization constant for the

protonated base,  $BH^+$ . In general,  $[H_3O^+]$ ,  $[OH^-]$ ,  $K_a$ , and  $K'_a$  usually are smaller than  $C_s$  and the equation simplifies to

$$[H_3O^+] = \sqrt{K_a K'_a} \quad (71)$$

See Box 15-12.

#### Box 15-12

Calculate the pH of a 0.01 M solution of ammonium acetate. The ammonium ion has a  $K_a$  equal to  $5.75 \times 10^{-10}$ , which represents  $K'_a$  in Equation 71. Acetic acid has a  $K_a$  of  $1.75 \times 10^{-5}$ , which represents  $K_a$  in Equation 71:

$$\begin{aligned} [H_3O^+] &= \sqrt{1.75 \times 10^{-5} \times 5.75 \times 10^{-10}} \\ [H_3O^+] &= 1 \times 10^{-7} \\ \text{pH} &= 7 \end{aligned}$$

All of the assumptions are valid.

### BUFFERS

The terms **buffer**, **buffer solution**, and **buffered solution**, when used with reference to hydrogen-ion concentration or pH, refer to the ability of a system, particularly an aqueous solution, to resist a change of pH on adding acid or alkali, or on dilution with a solvent.

If an acid or base is added to water, the pH of the latter is changed markedly, for water has no ability to resist change of pH; it is completely devoid of buffer action. Even a very weak acid such as carbon dioxide changes the pH of water, decreasing it from 7 to 5.7 when the small concentration of carbon dioxide present in air is equilibrated with pure water. This extreme susceptibility of distilled water to a change of pH upon adding very small amounts of acid or base is often of great concern in pharmaceutical operations where the majority of drugs are either weak acids or weak bases. Solutions of neutral salts, such as sodium chloride, similarly lack ability to resist change of pH on adding acid or base; such solutions are called **unbuffered**.

When partially neutralized weak acids or bases are present in aqueous solution, the addition of small amount of strong acid or strong base causes little or no detectable change in pH. This resistance was described in 1900 by Fernbach and Hubert as buffering. In Brønsted-Lowry terms, the common feature of these solutions is the presence of a weak acid and a salt of the weak acid, or a weak base and a salt of the weak base. An example of the former system is acetic acid and sodium acetate; and of the latter, ammonium hydroxide and ammonium chloride. From the proton concept of acids and bases discussed earlier, it is apparent that such buffer action involves a conjugate acid–base pair in the solution. It will be recalled that acetate ion is the conjugate base of acetic acid, and that ammonium ion is the conjugate acid of ammonia (the principal constituent of what commonly is called ammonium hydroxide).

The mechanism of action of the acetic acid–sodium acetate buffer pair is that the acid, which exists largely in molecular (nonionized) form, combines with hydroxyl ion that may be added to form acetate ion and water; thus,

The acetate ion, which is a base, combines with the hydrogen (or more exactly hydronium) ion that may be added to form essentially nonionized acetic acid and water, represented as

As will be illustrated later by an example, the change of pH is slight as long as the amount of hydronium or hydroxyl ion added does not exceed the capacity of the buffer system to neutralize it.

The ammonia-ammonium chloride pair functions as a buffer because the ammonia combines with hydronium ion that may be added to form ammonium ion and water; thus,

Ammonium ion, which is an acid, combines with added hydroxyl ion to form ammonia and water, as

Again, the change of pH is slight if the amount of added hydronium or hydroxyl ion is not in excess of the capacity of the system to neutralize it.

Besides these two general types of buffers, a third appears to exist. This is the buffer system composed of two salts, as monobasic potassium phosphate,  $\text{KH}_2\text{PO}_4$ , and dibasic potassium phosphate,  $\text{K}_2\text{HPO}_4$ . This is not, however, a new type of buffer; it is actually a weak-acid/conjugate-base buffer in which an ion,  $\text{H}_2\text{PO}_4^-$ , serves as the weak acid, and  $\text{HPO}_4^{2-}$  is its conjugate base. When hydroxyl ion is added to this buffer the following reaction takes place:

and when hydronium ion is added,

It is apparent that the mechanism of action of this type of buffer is essentially the same as that of the weak-acid/conjugate-base buffer composed of acetic acid and sodium acetate.

A buffer system composed of a conjugate acid-base pair,  $\text{NaA-HA}$  (such as sodium acetate and acetic acid), would have a PBE of

$$[\text{H}_3\text{O}^+] + [\text{HA}] = [\text{OH}^-] + [\text{A}^-] \quad (72)$$

Replacing  $[\text{HA}]$  and  $[\text{A}^-]$  as a function of hydronium ion concentration gives

$$[\text{H}_3\text{O}^+] + \frac{[\text{H}_3\text{O}^+]\text{C}_b}{[\text{H}_3\text{O}^+] + \text{K}_a} = [\text{OH}^-] + \frac{\text{K}_a\text{C}_a}{[\text{H}_3\text{O}^+] + \text{K}_a} \quad (73)$$

where  $\text{C}_b$  is the concentration of the salt,  $\text{NaA}$ , and  $\text{C}_a$  is the concentration of the weak acid,  $\text{HA}$ . This equation can be rearranged to give

$$[\text{H}_3\text{O}^+] + \text{K}_a \left( \frac{\text{C}_a - [\text{H}_3\text{O}^+] + [\text{OH}^-]}{\text{C}_b + [\text{H}_3\text{O}^+] - [\text{OH}^-]} \right) \quad (74)$$

Equation 74 is an exact equation and can be used to determine the pH of a weak acid, a weak base or a conjugate pair. An activity correction can be applied to this equation (usually when concentrations exceed 0.01M).

$$[\text{H}_3\text{O}^+] + \text{K}_a \left( \frac{\text{C}_a - [\text{H}_3\text{O}^+] + [\text{OH}^-]}{\text{C}_b + [\text{H}_3\text{O}^+] - [\text{OH}^-]} \right) \left( \frac{\gamma_{\text{HA}}}{\gamma_{\text{H}_3\text{O}^+} + \gamma_{\text{A}^-}} \right)$$

### Assumptions and simplifications

If only an acid is present, then  $b = 0$  and  $[\text{H}_3\text{O}^+] \gg [\text{OH}^-]$ , the equations simplify to

$$[\text{H}_3\text{O}^+]^2 = \text{K}_a[\text{H}_3\text{O}^+] - \text{K}_a\text{C}_a = 0 \quad (75)$$

This obviously solves to the same approximation as before, that is, Equation 57. Similarly, if only a base is present, then  $a = 0$  and  $[\text{OH}^-] \gg [\text{H}_3\text{O}^+]$ , the equation simplifies to

$$[\text{H}_3\text{O}^+] = \frac{\text{K}_a[\text{OH}^-]}{\text{C}_b + [\text{OH}^-]} = \frac{\text{K}_a\text{K}_w}{[\text{H}_3\text{O}^+]\text{C}_b - \text{K}_w} \quad (76)$$

The equation can be solved for either  $[\text{H}_3\text{O}^+]$  or  $[\text{OH}^-]$  but it is most useful on terms of  $[\text{H}_3\text{O}^+]$ , giving the quadratic equation

$$\text{C}_b[\text{H}_3\text{O}^+]^2 - \text{K}_w[\text{H}_3\text{O}^+] - \text{K}_a\text{K}_w = 0 \quad (77)$$

This solves to

$$[\text{H}_3\text{O}^+] = \text{K}_w + \sqrt{\frac{\text{K}_w^2 + 4\text{C}_b\text{K}_a\text{K}_w}{2\text{C}_b}} \quad (78)$$

Application of judicious assumptions leads to the equation 79, which has previously been described for calculating pH of a solution of a weak base

$$[\text{H}_3\text{O}^+] = \sqrt{\frac{\text{K}_a\text{K}_w}{\text{C}_b}} \quad (79)$$

If a single conjugate pair is present, then in general, both  $\text{C}_a$  and  $\text{C}_b$  are much greater than  $[\text{H}_3\text{O}^+]$ , which is in turn much greater than  $[\text{OH}^-]$  and the equation simplifies to

$$[\text{H}_3\text{O}^+] = \frac{\text{K}_a\text{C}_a}{\text{C}_b} \quad (80)$$

Expressed in terms of pH, this becomes

$$\text{pH} = \text{pH}_a + \log \frac{\text{C}_b}{\text{C}_a} \quad (81)$$

This equation generally is called the **Henderson-Hasselbalch equation** or the **Buffer equation**. It applies to all buffer systems formed from a single conjugate acid-base pair, regardless of the nature of the salts. For example, it applies equally well to the following buffer systems: ammonia-ammonium chloride, monosodium phosphate-disodium phosphate, and phenobarbital-sodium phenobarbital. In the ammonia-ammonium chloride system, ammonia is obviously the base and the ammonium ion is the acid ( $\text{C}_a$  equal to the concentration of the salt). In the phosphate system, monosodium phosphate is the acid and disodium phosphate is the base. For the phenobarbital buffer system, phenobarbital is the acid and the phenobarbital anion is the base ( $\text{C}_b$  equal to the concentration of sodium phenobarbital). See Box 15-13.

### Box 15-13

As an example of the application of this equation, the pH of a buffer solution containing acetic acid and sodium acetate, each in 0.1 M concentration, may be calculated. The  $\text{K}_a$  of acetic acid, as defined above, is  $1.8 \times 10^{-5}$ , at 25°C.

What is the pH of an acetate buffer containing 0.1M acetic acid and 0.05M sodium acetate ( $\text{pK}_a = 4.76$ )?

$$\text{pH} = 4.76 + \log \left( \frac{0.05}{0.1} \right) = 4.76 - 0.3 = 4.46$$

Calculate the pH of 0.1M acetic acid

$$[\text{H}_3\text{O}^+] = \sqrt{\text{K}_a\text{C}_a}$$

$$[\text{H}_3\text{O}^+] = \sqrt{1.74 \times 10^{-5} \times 0.1}$$

$$[\text{H}_3\text{O}^+] = 1.32 \times 10^{-3}$$

pH = 2.88

Add sodium acetate to make a solution of 0.1M with respect to the salt. What is the pH of the resultant solution?

$$\text{pH} = 4.76 + \log \left( \frac{0.1}{0.1} \right) = 4.76$$

The Henderson Hasselbalch equation predicts that any solutions containing the same molar concentration of acetic acid as of sodium acetate will have the same pH. Thus, a solution of 0.01 M concentration of each will have the same pH, i.e., 4.74, as one of 0.1 M concentration of each component. Actually, there will be some difference in the pH of the solutions, for the **activity coefficient** of the components varies with concentration. For most practical purposes, however, the approximate values of pH calculated by the equation are satisfactory. It should be pointed out that the buffer of higher concentration of each component will have a much greater capacity for neutralizing added acid or base and this point will be discussed further in the discussion of buffer capacity.

An acid exists in water in equilibrium between its ionised and molecular form. If a strong base such as sodium hydroxide is added, the hydroxyl ions combine with the hydrogen ions, disrupting the equilibrium. This increases the ratio of ionised to unionised species. Thus, if one mole equivalent of sodium hydroxide is added, the acid, HA, will be quantitatively converted to its anion ( $A^-$ ) and the pH will increase. It should be noted that when the concentrations of acid and conjugate base are equal, then the  $pH = pK_a$ . When looking at the titration curve of a weak acid with a strong base (Figure 15-3), this can be used to estimate the  $pK_a$ , that is, at 0.5 the pH equals the  $pK_a$ . This is because if  $pH = pK_a$  then the log term in the Henderson-Hasselbalch equation is 1 and  $[unionised] = [ionised]$ .

Derivations of the Henderson-Hasselbalch equation are used to quantify the **percentage ionised** (or  $\alpha$ , **fraction ionised**). They can, however easily be derived from first principles, for the example HA below.

$$\alpha = \frac{[A^-]}{[HA] + [A^-]} = \frac{C_b}{C_a + C_b} \quad (82)$$

Know

$$[H_3O^+] = K_a \frac{C_a}{C_b} \quad (83)$$

Therefore

$$C_a = \frac{C_b [H_3O^+]}{K_a} \quad (84)$$

$$C_a + C_b = C_b + \frac{C_b [H_3O^+]}{K_a} \quad (85)$$

$$C_a + C_b = C_b \left( 1 + \frac{[H_3O^+]}{K_a} \right) \quad (86)$$

$$C_a + C_b = C_b \left( \frac{K_a + [H_3O^+]}{K_a} \right) \quad (87)$$

$$\alpha = \frac{C_b}{C_a + C_b} = \left( \frac{K_a}{K_a + [H_3O^+]} \right) \quad (88)$$

When  $C_a = C_b$ ,  $pH = pK_a$ , either can be substituted into equations 88 and

$$\alpha = \frac{K_a}{K_a + K_a} = \frac{1}{2} = 50\% \quad (89)$$

A similar relationship can be derived for a weak base

$$\alpha = \frac{[H_3O^+]}{K_a + [H_3O^+]} \quad (90)$$

If the pH of the solution is increased to one unit above the  $pK_a$  of the acid (or one unit below the  $pK_a$  of the conjugate acid), then the percentage of the compound ionised increases to approximately 90% (90.9%). If the pH increases to two units above the  $pK_a$  (or two units below for a base), the percentage ionised

Figure 15-3. Titration curve for a weak acid with a strong base.

Figure 15-4. Variation in fraction ionised with pH.

increases to 99%, because both pH and  $pK_a$  are logarithmic relationships, and so on to 99.9%, 99.99% etc. This approximation is useful when estimating the fraction ionised ( $\alpha$ ) in Figure 15-4.

For weak acids:

$pH = pK_a$  compound is approximately 50% ionised

$pH = pK_a - 1$  compound is approximately 90% ionised

$pH = pK_a - 2$  compound is approximately 99% ionised

$pH = pK_a - 3$  compound is approximately 99.9% ionised

For weak bases:

$pH = pK_a$  compound is approximately 50% ionised

$pH = pK_a + 1$  compound is approximately 90% ionised

$pH = pK_a + 2$  compound is approximately 99% ionised

$pH = pK_a + 3$  compound is approximately 99.9% ionised

The Henderson Hasselbalch equation is useful also for calculating the ratio of molar concentrations of a buffer system required to produce a solution of specific pH. As an example, suppose that an acetic acid–sodium acetate buffer of pH 4.5 must be prepared. What ratio of the buffer components should be used?

### Solution

Rearranging Equation 81, which is used to calculate the pH of weak acid–salt type buffers, gives

$$pH - pK_a = \log \frac{C_b}{C_a}$$

$$= 4.5 - 4.76 = -0.24$$

Antilog of  $-0.24$  is 0.575

The interpretation of this result is that the **proportion** of sodium acetate to acetic acid should be 0.575 mol of the former to 1 mol of the latter to produce a pH of 4.5. A solution containing 0.0575 mol of sodium acetate and 0.1 mol of acetic acid per liter would meet this requirement, as would also one containing 0.00575 mol of sodium acetate and 0.01 mol of acetic acid per liter. The actual concentration selected would depend chiefly on the desired buffer capacity.

Buffers solutions are frequently found in pharmaceutical formulations, for example aqueous eye drops and oral solutions. Many different buffer systems are available, such as phosphate buffer saline and Sørensen's buffers. Sørensen's buffer comprises a mixture of the salts of sodium phosphate. For solutions intended for parenteral administration or application to mucous membranes, discomfort (and even injury), is minimized by adjusting the solution to approximate isotonicity with body fluid (equivalent to 0.90% sodium chloride at 37°C). Pharmacopeiae and reference sources contain details of buffers, and their ionic strengths, that can be used to control pH.

The body contains many buffer systems, which function to control the pH of body compartments and fluids. For example, there are three main buffer systems which function to maintain plasma pH at 7.4. Dissolved carbon dioxide, giving rise to carbonic acid ( $H_2CO_3$ ) in solution, and its sodium salt (usually sodium bicarbonate,  $NaHCO_3$ ) is responsible for most of the buffering capacity. The other two buffers are dihydrogenphosphate ( $H_2PO_4^-$ ), also with its sodium salt, and protein macromolecules.

## Buffer capacity

When determining which buffer form is suitable, buffer capacity should be maximised by selection of a buffer with a  $pK_a$  close to the pH of interest. **Buffer capacity** is the ability of a buffer solution to resist changes in pH upon addition of acid or alkali.

The concentration of acid in a weak-acid/conjugate-base buffer determines the capacity to “neutralize” added base, whereas the concentration of salt of the weak acid determines the capacity to neutralize added acid. Similarly, in a weak-base/conjugate-acid buffer the concentration of the weak base establishes the buffer capacity toward added acid, whereas the concentration of the conjugate acid of the weak base determines the capacity toward added base. When the buffer is equimolar in the concentrations of weak acid and conjugate base, or of weak base and conjugate acid, it has equal buffer capacity toward added strong acid or strong base.

Van Slyke, the biochemist, introduced a quantitative expression for evaluating buffer capacity. This may be defined as the amount, in gram-equivalents (geq) per liter, of strong acid or strong base required to be added to a solution to change its pH by 1 unit; a solution has a buffer capacity of 1 when 1 L requires 1 geq of strong base or acid to change the pH 1 unit. (In practice, considerably smaller increments are measured, expressed as the ratio of acid or base added to the change of pH produced.) From this definition it is apparent that the smaller the pH change in a solution caused by the addition of a specified quantity of acid or alkali, the greater the buffer capacity of the solution. See Box 15-14.

As is in part evident from the example in Box 14, and may be further evidenced by calculations of pH changes in other systems, the degree of buffer action and, therefore, the buffer capacity, depend on the kind and concentration of the buffer components, the pH region involved and the kind of acid or alkali added.

Buffer capacity can be calculated more exactly using the equation developed by Koppel and Spiro

$$\beta = 2.303C \frac{K_a [H_3O^+]}{(K_a + [H_3O^+])^2} \quad (91)$$

where C is the total buffer concentration, that is, the sum of the molar concentrations  $C_a + C_b$ . The maximum buffer capacity exists when there are equimolar concentrations of acid and conjugate base, that is  $pH = pK_a$ . On substitution of  $K_a$  for  $[H_3O^+]$ , or vice versa, into the equation above, a relationship can be defined for maximal buffer capacity,

$$\beta = 2.303C \frac{K_a^2}{(2K_a)^2} \quad \beta = 2.303C \frac{[H_3O^+]^2}{(2[H_3O^+])^2}$$

$$\beta = \frac{2.303C}{4} \quad (92)$$

$$\beta_{MAX} = 0.576C$$

## THE DETERMINATION OF IONIZATION CONSTANTS

There are a variety of ways to determine the ionization constants including conductivity measurements and partition coefficients, but the most convenient method to determine  $pK_a$  is by **potentiometric titration** and is normally the method of choice if applicable.

It involves the measurement of the pH during stepwise titration of a known weight of substance with accurately standardised base or acid. In this method the **mole-ratio** of the acid-base conjugate pairs is calculated from the titrant added. The method involves the universal equation

$$[H_3O^+] = K_a \left( \frac{C_a - [H_3O^+] + [OH^-]}{C_b + [H_3O^+] - [OH^-]} \right) \quad (93)$$

In **acidic** conditions  $pH < 4$ ,  $[H_3O^+] \gg [OH^-]$  and the  $[OH^-]$  term can be ignored. Similarly, in **basic** conditions  $pH > 10$ ,  $[OH^-] \gg [H_3O^+]$ ; ignore  $[H_3O^+]$  term.

### Box 15-14

These examples illustrate certain basic principles and calculations concerning buffer action and buffer capacity.

1. What is the change of pH on adding 0.01 mol of NaOH to 1 L of 0.10 M acetic acid?

i. Calculate the pH of a 0.10 molar solution of acetic acid:

$$[H_3O^+] = \sqrt{K_a C_a} = \sqrt{1.75 \times 10^{-4} \times 1.0 \times 10^{-1}} = 4.18 \times 10^{-3}$$

$$pH = -\log 4.18 \times 10^{-3} = 2.38$$

ii. On adding 0.01 mol of NaOH to a liter of this solution, 0.01 mol of acetic acid is converted to 0.01 mol of sodium acetate, thereby decreasing  $C_a$  to 0.09 M, and  $C_b = 1.0 \times 10^{-2} M$ . Using the Henderson-Hasselbach equation gives

$$pH = 4.76 + \log \frac{0.01}{0.09} = 4.76 - 0.95 = 3.81$$

The pH change is, therefore, 1.43 unit. The buffer capacity as defined above is calculated to be

$$\frac{\text{mols of NaOH added}}{\text{change in pH}} = 0.011$$

2. What is the change of pH on adding 0.1 mol of NaOH to 1 L of buffer solution 0.1 M in acetic acid and 0.1 M in sodium acetate?

a. The pH of the buffer solution before adding NaOH is

$$pH = \log \frac{[\text{base}]}{[\text{acid}]} + pK_a$$

$$= \log \frac{0.1}{0.1} + 4.76 = 4.76$$

b. On adding 0.01 mol of NaOH per liter to this buffer solution, 0.01 mol of acetic acid is converted to 0.01 mol of sodium acetate, thereby decreasing the concentration of acid to 0.09 M and increasing the concentration of base to 0.11 M. The pH is calculated as

$$pH = \log \frac{0.11}{0.09} + 4.76$$

$$= 0.087 + 4.76 = 4.85$$

The change of pH in this case is only 0.09 unit, about 1/10 the change in the preceding example. The buffer capacity is calculated as

$$\frac{\text{mols of NaOH added}}{\text{change of pH}} = \frac{0.01}{0.09} = 0.11$$

Thus, the buffer capacity of the acetic acid–sodium acetate buffer solution is approximately 10 times that of the acetic acid solution.

This can be illustrated by the worked example of the determination of the  $pK_a$  of boric acid which is a commonly used buffer in ophthalmic solutions. Potentiometric titrations are most accurately carried out in water that has been boiled to remove any dissolved carbon dioxide. Results are commonly portrayed in a table (Table 15-5). In this case, no correction is required for hydronium or hydroxyl ions. The  $pK_a$  of boric acid is 9.25 (and can be refined by correcting for  $[OH^-]$  at later values).

When the pH values fall outside the range 4-10, it is necessary to include a correction for the contribution of  $[H_3O^+]$  and  $[OH^-]$  as in the worked example for benzoic acid (Table 15-6) where column 6 is the calculation

$$\frac{a - [H_3O^+]}{b + [H_3O^+]} \quad (94)$$

5.0	8.18	0	0.01	$6.61 \times 10^{-9}$			

Errors can arise from impurities in both the titrant and the substance undergoing titration with water being a common impurity if the substance is not thoroughly dried. If this is not possible, or if there is a degree of solvation, then the  $Z$  function, as defined by Benet and Goyan,<sup>3</sup> can be determined. It is the sum of 4 known concentrations at any part of the titration. For a weak acid (HA) being titrated with, for example KOH, then the  $Z$  function would be

$$Z = [A^-] = [K^+] + [H_3O^+] - [OH^-] \quad (95)$$

As  $C_a$  is the sum of [HA] and [A<sup>-</sup>] at equilibrium, for an acid, a plot of  $Z$  versus  $Z/[H_3O^+]$  will yield a straight line with slope equal to the negative reciprocal of the ionization constant and an intercept equal to  $C_o$  where

$$Z = C_o - \frac{1}{K_a^c} Z[H_3O^+] \quad (96)$$

The corresponding relationship for determination of  $pK_a$  of a weak base is

$$Z = C_o - K_a^c \frac{Z}{[H_3O^+]} \quad (97)$$

Thus, in addition to obtaining an accurate value for  $pK_a$ , the stoichiometric concentration of the substance being titrated is also obtained.

The dissociation constants for diprotic acids can be obtained by defining  $P$  as the average number of protons dissociated per mole of acid, or

$$P = Z / C_a \quad (98)$$

and

$$\frac{[H_3O^+]^2 P}{(2-P)} = K_1 K_2 + \frac{K_1 [H_3O^+] (1-P)}{(2-P)} \quad (99)$$

A plot of Equation 99 should yield a straight line with a slope equal to  $K_1$  and an intercept of  $K_1 K_2$ . Dividing the intercept by the slope yields  $K_2$ .

The addition of solvents to achieve adequate solubility for determination of  $pK_a$  by potentiometric titration is useful to rank a series of related compounds but because changes in ionization result and complications which cannot be easily extrapolated arise, **spectrophotometric methods** are used as an alternative.

Determination of  $pK_a$  by UV spectroscopy is also useful when the  $pK_a$  is particularly low or high (<2 or >11). It relies on the selection of an **analytical wavelength**, at which the difference between the absorbances of the unionized and the ionized species are maximal. The first step is therefore the determination of pure spectra for the two species involved in the equilibrium and the choice of the suitable wavelength. The absorbances of the ionized species ( $A_i$ ) and the molecular (unionized species,  $A_m$ ) are then recorded. Two component mixtures of the species are prepared by adjusting the pH of the buffer used and, assuming Beer-Lambert law is followed, the absorbance of the partially ionized acid or base is solely determined by the ratio of the species).

By rearrangement of the Henderson-Hasselbalch equation, the  $pK_a$  for weak acids can be determined as below

$$pK_a = pH + \log \left( \frac{A_i - A_t}{A_t - A_m} \right) \quad (100)$$

**Table 15-7. pK<sub>a</sub> determination of acridine by UV spectroscopy (adapted from Albert & Serjeant<sup>2</sup>)**

pH	A <sub>t</sub>	A <sub>i</sub> -A <sub>t</sub>	A <sub>i</sub> -A <sub>m</sub>	Log column(4/3)	pK <sub>a</sub> (column 1+ 5)
6.30	0.125	0.483	0.100	-0.68	5.62
6.10	0.170	0.438	0.145	-0.48	5.62
5.89	0.235	0.373	0.210	-0.25	5.64
5.68	0.299	0.309	0.274	-0.05	5.63
5.47	0.367	0.241	0.342	0.15	5.62
5.27	0.429	0.179	0.404	0.36	5.63
5.08	0.474	0.134	0.449	0.53	5.61
4.85	0.523	0.085	0.498	0.77	5.62

where A<sub>t</sub> is the absorbance of the test mixture. Once an approximate pK<sub>a</sub> is known, an exact determination can be made by preparing solutions of the substance in buffers over a range close to the approximate pK<sub>a</sub> (pK<sub>a</sub> ± 0.5)

If the substance is a weak base, then the following equation may be used

$$pK_a = pH + \log \left( \frac{A_t - A_m}{A_i - A_t} \right) \quad (101)$$

The data in Table 15-7 were obtained from a 0.0002M solution of the weak base, acridine, illustrating how the pK<sub>a</sub> can be determined in this manner. The absorbance of the unionized species (A<sub>m</sub>) is 0.025 whereas the absorbance of the ionised species (A<sub>i</sub>) is 0.608.

### Micro dissociation constants

The dissociation constants for polyprotic acids, as determined by potentiometric titration, are known generally as **macro**, or **titration**, **constants**. As it is known that carboxyl groups are stronger acids than protonated amino groups, there is no difficulty in assigning K<sub>1</sub> and K<sub>2</sub>, as determined by Equation 37, to the carboxyl and amino groups, respectively, of a substance such as glycine hydrochloride.

In other chemicals or drugs such as phenylpropanolamine, in which the two acidic groups are the phenolic and the protonated amino group, the assignment of dissociation constants is more difficult. This is because, in general, both groups have dissociation constants of equal magnitude. Thus, there will be two ways of losing the first proton and two ways of losing the second, resulting in four possible species in solution. This can be illustrated using the convention of assigning a plus (+) to a positively charged group, a 0 to an uncharged group, and a minus (-) to a negatively charged group. Thus, +0 would represent the fully protonated phenylpropanolamine, +/- the dipolar ion, 00 the uncharged molecule, and 0-, the anion. The total ionization scheme, therefore, can be written

The micro constants are related to the macro constants as

$$K_1 = k_1 + k_2 \quad (102)$$

$$K_1 K_2 = k_1 k_3 = k_2 k_4 \quad (103)$$

It can be seen from Equation 102 that unless  $k_1$  or  $k_2$  is very much smaller than the other, the observed macro constant is a composite of the two and cannot be assigned to one or the other acidic group in a nonambiguous way. Methods for determining  $k_1$  are given by Riegelman *et al.*<sup>4</sup> and Niebergall *et al.*<sup>5</sup> Once  $k_1$ ,  $K_1$ , and  $K_2$  have been determined, all of the other micro constants can be obtained from equations 102 and 103.

Other approaches to accurate pK<sub>a</sub> determination include capillary electrophoresis and chromatographic, typically HPLC approaches<sup>5</sup> but, it is often useful to be able to predict the pK<sub>a</sub> of a substance prior to synthesis or when only small quantities are available especially with current high-through put methods of drug discovery.

There are several commercially available software packages using linear free energy relations based on the classical Hammett equation-based fragment approaches for the calculation of microscopic and macroscopic ionization constants.<sup>6</sup> More recent QSPR pK<sub>a</sub> prediction methods have used a variety of descriptors including atomic charges, topological and E-states descriptors, chemical reactivity models, atom types, and group philicity. Online chemical modeling systems such as SPARC are now relatively mature and are used widely in academic, government and industrial laboratories and are useful for monoprotic substances but sometimes fail to match with more complex reactivities.<sup>7,8</sup>

## PHARMACEUTICAL SIGNIFICANCE

pK<sub>a</sub> is one of the most important physicochemical properties of a molecule and the impact of pH on drug systems is widespread. Both solubility and lipophilicity are both governed by pK<sub>a</sub>, therefore understanding and prediction of ADME behaviour is impacted. The metabolic profile is highly influenced by the parent compound's pK<sub>a</sub> which is also extremely relevant in metabolite identification. Phase II reactions, mechanism-based inhibition are also influenced by pK<sub>a</sub>. Receptor binding can also be strongly influenced by pK<sub>a</sub> because most drugs are ionized in physiological conditions.

### SALT FORMATION

When the first "drugs" or alkaloids were isolated from plant materials they were purified as well-crystallising salts such as morphine hydrochloride, atropine sulphate, codeine phosphate, quinine sulphate and pilocarpine nitrate. In contrast to the free bases, the salts were found to be water soluble and also more stable rendering them more suitable for use as therapeutic agents. Around 50% of drugs are administered as salts.<sup>10</sup> Salt formation is a simple way of modifying the properties of a drug having ionisable functional groups in order to overcome some undesirable characteristic of the parent drug, normally poor solubility. This affords the opportunity to modify other physicochemical characteristics, such as melting point, hygroscopicity, chemical stability, dissolution rate, solution pH, and crystal form; and mechanical properties, such as hardness and elasticity of the potential drug substance and to develop dosage forms with acceptable bioavailability, stability, manufacturability, and patient compliance.

Salts are formed when compound that is ionised in solution forms a strong ionic interaction with an oppositely charged compound leading to the precipitation of the salt form. The counterions are attracted by intermolecular coulombic forces. These interactions change the potential energy landscape and lead to stronger interaction between the charged active pharmaceutical ingredient and polar aqueous solvents, which can result in enhanced dissolution rates and higher apparent solubility on physiological timescales, resulting in increased drug delivery rates *in vivo*. For the salt to be dissolved the solvent must overcome the crystal lattice energy of the solid and create space for the solute. Thus, the solubility of the salt depends on its polarity, lipophilicity, ionization potential, and size. A salt's solubility also depends on the properties of the solvent and solid, such as the crystal packing and the presence of solvates.

The advantages and disadvantages of salt formation for manipulation of drug properties are summarised in Table 15-8. A large number of different salt forms are potentially available for application as the counterion and the following criteria are desirable for a particular salt form:

**Table 15-8. Advantages and disadvantages of salt formation (data from Kumar<sup>9</sup>)**

Advantages
Altered solubility and dissolution rate
Controlled-release potential
Improved thermal, hydrolytic and photostability
Reduced hygroscopicity
Improved permeability
Improved organoleptic properties
Improved drug efficacy
Reduced pain on injection
Altered melting point resulting in improved milling and formulation properties
Ease of purification and handling
Improved compactability
Extended patent protection
Disadvantages
Only suitable for ionizable compounds
Decreased percentage of active content
Increased potential for formation of solvates and polymorphs
Reduced dissolution rate or solubility for hydrochloride salts in gastric fluid
Increased chance of poor solid-state stability at the microenvironment pH of the salt e.g. precipitation of the free acid in the gastrointestinal environment.
Corrosiveness of salts, resulting in tableting problems
Possible dissociation of hydrochloride and hydrobromide salts, resulting in the release of hydrohalide gas or reaction with excipients or process-related chemicals
Additional step in synthesis of medicinal product

- high aqueous solubility, over a wide pH range, depending on the intended pharmaceutical profile
- high degree of crystallinity
- low hygroscopicity, for consistent performance
- optimal chemical and solid-state stability under accelerated conditions.

A serious deficiency in any of these characteristics should exclude the salt for further development. Other influential criteria are:

- limited number of polymorphs
- ease of synthesis, handling and formulation development.

The **solubility product** of a salt,  $K_{sp}$ , needs to be taken into account when predicting the solubility of a salt in a particular environment that contains other salts with a common counterion.

In spite of the abundance of available counterions, few are used frequently. USP (2006) showed that salt forms (56.15%) are generally preferred over free acid or base forms of a drug (43.85%).<sup>10</sup> Hydrochloride (63%) and sodium (40%) salts remain the favourite counterions in salt formation with basic and acidic drugs, respectively. Because of the low solubility of many basic drugs, where  $pH_{max}$  (pH of maximum solubility of the salt) is very low, most common carboxylic acids do not form acceptable salts and it is anticipated that the use of relatively strong counterions will continue in the future. Similarly, 14 out of 19 salt forms of new chemical entities approved by the FDA from 1995 to 2006 are prepared with strong alkalis such as NaOH and KOH, and this trend is also expected to continue in the future.<sup>11</sup>

If a salt, NaA, is added to water to give a concentration  $C_s$ , the following reactions occur:

If the pH of the solution is lowered, more of the  $A^-$  would be converted to the unionized acid, HA, in accordance with Le Chatelier's principle. Eventually, a pH will be obtained, below which the amount of HA formed exceeds its **intrinsic aqueous solubility**,  $S_0$ , and the acid will precipitate from solution; this pH can be designated as  $pH_p$ . At this point, at which the amount of HA formed just equals  $S_0$ , a mass balance on the total amount of drug in solution yields

$$C_s = [HA] + [A^-] = S_0 + [A^-] \quad (104)$$

Replacing  $[A^-]$  as a function of hydroniumion concentration gives

$$C_s = S_0 + \frac{K_a C_s}{[H_3O^+]_p + K_a} \quad (105)$$

where  $K_a$  is the ionization constant for the conjugate acid, HA, and  $[H_3O^+]_p$  refers to the hydroniumion concentration above which precipitation will occur. This equation can be rearranged to give

$$[H_3O^+]_p = K_a \frac{S_0}{C_s - S_0} \quad (106)$$

Taking logarithms gives

$$pH_p = pK_a + \log \frac{C_s - S_0}{S_0} \quad (107)$$

Thus, the pH below which precipitation occurs is a function of the amount of salt added initially, the  $pK_a$  and the solubility of the free acid formed from the salt.

The analogous equation for salts of weak bases and strong acids (such as pilocarpine hydrochloride, cocaine hydrochloride, or codeine phosphate) is

$$pH_p = pK_a + \log \frac{S_0}{C_s - S_0} \quad (108)$$

in which  $pK_a$  refers to the protonated form of the weak base.

For both acids and bases, when  $pH = pK_a$ ,  $[H_3O^+] = K_a$ . If either is substituted the solution is as below,

$$C_s = S_0 \left( \frac{[H_3O^+] + [H_3O^+]}{[H_3O^+]} \right) \quad (109)$$

It can be seen that at 50% ionization, the solubility is always equal to twice the intrinsic solubility ( $S_0$ ).

## Ionic liquids

Ionic liquids (ILs) are salt-like materials that are liquid below 100°C and whose melts are composed of discrete cations and anions, thus there is no molecular species present. Although they have been known for over a century, interest is increasing due to their appealing solvent properties. They are miscible with water or organic solvents their use can be classified as process chemicals (e.g., solvents, separation media) and performance chemicals (e.g., electrolytes, lubricants) and are useful solvents for extraction processes.

Other properties of ILs are that they have practically no vapor pressure and are reported to have a wide window of electrochemical stability, good electrical conductivity, high ionic mobility, and excellent chemical stability. The third and most recent generation of ILs involve active pharmaceutical ingredients, which are being used to produce ILs with biological activity.<sup>12</sup>

## DRUG STABILITY

One of the most diversified and fruitful areas of study is the investigation of the effect of hydrogen-ion concentration on the stability or, in more general terms, the reactivity of pharmaceutical systems. The evidence for enhanced stability of systems

when these are maintained within a narrow range of pH, as well as of progressively decreasing stability as the pH de-parts from the optimum range, is abundant. Stability (or instability) of a system may result from gain or loss of a proton (hydrogen ion) by a substrate molecule—often accompanied by an electronic rearrangement—that reduces (or increases) the reactivity of the molecule. **Instability** results when the substance desired to remain unchanged is converted to one or more other, unwanted, substances. In aqueous solution, instability may arise through the catalytic effect of acids or bases—the former by transferring a proton to the substrate molecule, the latter by accepting a proton.

Specific illustrations of the effect of hydrogen-ion concentration on the stability of medicinals are myriad; only a few will be given here, these being chosen to show the importance of pH adjustment of solutions that require sterilization.

Morphine solutions are not decomposed during a 60-min exposure at a temperature of 100°C if the pH is less than 5.5; neutral and alkaline solutions, however, are highly unstable. Minimum hydrolytic decomposition of solutions of cocaine occurs in the range of pH of 2 to 5; in one study a solution of cocaine hydrochloride, initially at a pH of 5.7, remained stable during 2 months (although the pH dropped to 4.2 in this time), whereas another solution buffered to about pH 6 under-went approximately 30% hydrolysis in the same time. Similarly, solutions of procaine hydrochloride containing some hydrochloric acid showed no appreciable decomposition; when dissolved in water alone, 5% of the procaine hydrochloride hydrolyzed, whereas when buffered to pH 6.5, from 19 to 35% underwent decomposition by hydrolysis. Solutions of thiamine hydrochloride may be sterilized by autoclaving without appreciable decomposition if the pH is below 5; above this, thiamine hydrochloride is unstable.

The stability of many disperse systems, and especially of certain emulsions, is often pH dependent. Information concerning specific emulsion systems, and the effect of pH upon them, may be found in Chapter 20.

## DRUG ACTIVITY

Drugs that are weak acids or weak bases—and hence may exist in ionized or nonionized form (or a mixture of both)—may be active in one form but not in the other; often such drugs have an optimum pH range for maximum activity. Thus, mandelic acid, benzoic acid, or salicylic acid have pronounced antibacterial activity in their nonionized forms but have practically no such activity in the equivalent ionized form. Accordingly, these substances require an acidic environment to function effectively as antibacterial agents. For example, sodium benzoate is effective as a preservative in 4% concentration at pH 7, in 0.06 to 0.1% concentration at pH 3.5 to 4, and in 0.02 to 0.03% concentration at pH 2.3 to 2.4. Other antibacterial agents are active principally, if not entirely, in cationic form. Included in this category are the acridines and quaternary ammonium compounds.

## DRUG ABSORPTION

The degree of ionization and lipid solubility of a drug are two important factors that determine the rate of **absorption** of drugs from the gastrointestinal tract, and indeed their passage through cellular membranes generally. Drugs that are weak organic acids or bases, and that in nonionized form are soluble in lipids, apparently are absorbed through cellular membranes by virtue of the lipoidal nature of the membranes. Completely ionized drugs, on the other hand, are absorbed poorly, if at all. Rates of absorption of a variety of drugs are related to their ionization constants and in many cases may be predicted quantitatively on the basis of this relationship. Thus, not only the degree of the acidic or basic character of a drug, but also consequently the pH of the physiological medium (e.g., gastric or intestinal fluid, plasma, cerebrospinal fluid) in which a drug is dissolved or dispersed—because this pH determines the extent to which the drug will be converted to ionic or nonionic form—become important parameters of drug absorption. Further information on drug absorption is given in Chapter 39.

## BASIC DEFINITIONS

If a solution is placed in contact with a membrane that is permeable to molecules of the solvent, but not to molecules of the solute, the movement of solvent through the membrane is called *osmosis*. Such a membrane often is called *semipermeable*. As the several types of membranes of the body vary in their permeability, it is well to note that they are *selectively* permeable. Most normal living-cell membranes maintain various solute concentration gradients. A selectively permeable membrane may be defined either as one that does not permit free, unhampered diffusion of all the solutes present or as one that maintains at least one solute concentration gradient across itself. Osmosis, then, is the diffusion of water through a membrane that maintains at least one solute concentration gradient across itself.

Assume that Solution A is on one side of the membrane, and Solution B of the same solute but of a higher concentration is on the other side; the solvent will tend to pass into the more concentrated solution until equilibrium has been established. The pressure required to prevent this movement is the osmotic pressure. It is defined as the excess pressure, or pressure greater than that above the pure solvent, that must be applied to Solution B to prevent passage of solvent through a perfect semipermeable membrane from A to B. The concentration of a solution with respect to effect on osmotic pressure is related to the number of particles (un-ionized molecules, ions, macromolecules, aggregates) of solute(s) in solution and, thus, is affected by the degree of ionization or aggregation of the solute. See Chapter 13 for review of colligative properties of solutions.

Body fluids, including blood and lacrimal fluid, normally have an osmotic pressure that often is described as corresponding to that of a 0.9%w/v solution of sodium chloride. The body also attempts to keep the osmotic pressure of the contents of the gastrointestinal (GI) tract at about this level, but there the normal range is much wider than that of most body fluids. The 0.9%w/v sodium chloride solution is said to be *iso-osmotic* with physiological fluids. In medicine, the term isotonic, meaning equal tone, is commonly used interchangeably with iso-osmotic. However, terms such as isotonic and tonicity should be used *only* with reference to a physiological fluid. Iso-osmotic actually is a physical term that compares the osmotic pressure (or another colligative property, such as freezing-point depression) of two liquids, neither of which may be a physiological fluid, or which may be a physiological fluid only under certain circumstances. For example, a solution of boric acid that is iso-osmotic with

both blood and lacrimal fluid is isotonic only with the lacrimal fluid. This solution causes hemolysis of red blood cells because molecules of boric acid pass freely through the erythrocyte membrane, regardless of concentration. Thus, isotonicity infers a sense of physiological compatibility where iso-osmoticity need not. As another example, a *chemically defined elemental diet* or enteral nutritional fluid can be iso-osmotic with the contents of the GI tract but would not be considered a physiological fluid or suitable for parenteral use.

A solution is isotonic with a living cell if there is no net gain or loss of water by the cell, or no other change in the cell, when it is in contact with that solution. Physiological solutions with an osmotic pressure lower than that of body fluids, or of 0.9% sodium chloride solution, are referred to commonly as being *hypotonic*. Physiological solutions having a greater osmotic pressure are termed *hypertonic*.

Such qualitative terms are of limited value, and it has become necessary to state osmotic properties in quantitative terms. To do so, a term must be used that will represent all the particles that may be present in a given system. The term used is *osmol*: the weight, in grams, of a solute, existing in a solution as molecules (and/or ions, macromolecules, aggregates, etc.), which is osmotically equivalent to a mole of an ideally behaving nonelectrolyte. Thus, the osmol weight of a nonelectrolyte, in a dilute solution, generally is equal to its gram molecular weight. A *milliosmol*, abbreviated mOsm, is the weight stated in milligrams.

If one extrapolates this concept of relating an osmol and a mole of a nonelectrolyte as being equivalent, then one also may define an osmol in the following ways. It is the amount of solute that will provide 1 Avogadro's number ( $6.02 \times 10^{23}$ ) of particles in solution, and it is the amount of solute that, on dissolution in 1 kg of water, will result in an osmotic pressure increase of 17 000 torr at 0° or 19 300 torr at 37°. One mOsmol is 1/1000 of an osmol. For example, 1 mol of anhydrous glucose is equal to 180 g. One osmol of this nonelectrolyte is also 180 grams. One mOsmol would be 180 mg. Thus, 180 mg of this solute dissolved in 1 kg of water will produce an increase in osmotic pressure of 19.3 torr at body temperature.

For a solution of an electrolyte such as sodium chloride, one molecule of sodium chloride represents one sodium and one chloride ion. Hence, 1 mol will represent 2 osmol of sodium chloride theoretically. Accordingly, 1 osmol NaCl = 58.5 g/2 or 29.25 g. This quantity represents the sum total of  $6.02 \times 10^{23}$  ions as the total number of particles. Ideal solutions infer very dilute solutions or infinite dilution.

However, as pH or concentration is increased, other factors enter. Strong electrolyte, interionic attraction causes a decrease in their effect on colligative properties. In addition, the charge of ions must also follow an electrical gradient which operates to intensify or reduce their colligative effect *in vivo* physiological conditions. Body pH is actively maintained at differing values throughout the gastro-intestinal tract with more minor variations in other organs. A combination of electrochemical gradient and chemical concentration maintains pH at different values across membranes, often forcing a change in state of organic acids or bases between ionized (multiple species) and un-ionized (one species) states. The body uses these systems for absorption of nutrition and medications but also excretion of waste products.

Therefore, it is very difficult and often impossible to predict accurately the osmoticity of a solution. It may be possible to do so for a dilute solution of a single pure and well-characterized solute entering a similarly well defined environment, but not for most parenteral and enteral medicinal and/or nutritional fluids; experimental determination is likely required to predict behavior *in vivo*.

### THERAPEUTIC CONSIDERATIONS

Generally it is accepted that osmotic effects have a major place in the maintenance of homeostasis (the state of equilibrium in the living body, with respect to various functions and to the chemical composition of the fluids and tissues, e.g., temperature, heart rate, blood pressure, water content, or blood sugar). To a great extent these effects occur within or between cells and tissues where they cannot be measured. One of the most troublesome problems in clinical medicine is the maintenance of adequate body fluids and proper balance between extracellular and intracellular fluid volumes in seriously ill patients. It should be kept in mind, however, that fluid and electrolyte abnormalities are not diseases but are the manifestations of disease.

The physiological mechanisms that control water intake and output appear to respond primarily to serum osmoticity. Renal regulation of output is influenced by variation in rate of release of pituitary antidiuretic hormone (ADH) and other factors in response to changes in serum osmoticity. Osmotic changes also serve as a stimulus to moderate thirst. This mechanism is sufficiently sensitive to limit variations in osmoticity in the normal individual to less than about 1%. Body fluid continually oscillates around a narrow genetically determined set point in the normal range of 280–295 mOsmol/L. An increase of plasma osmoticity of 1% will stimulate ADH release, resulting in a reduction of urine flow, and, at the same time, stimulate thirst that results in increased water intake. Both the increased renal reabsorption of water (without solute) stimulated by circulating ADH and the increased water intake tend to lower serum osmoticity.

The transfer of water through the cell membrane occurs so rapidly that any lack of osmotic equilibrium between the two fluid compartments in any given tissue usually is corrected within a few seconds and, at most, within a minute or so. However, this rapid transfer of water does not mean that complete equilibration occurs between the extracellular and intracellular compartments throughout the entire body within this same short period of time. The reason is that fluid usually enters the body through the gut and then must be transported by the circulatory system to all tissues before complete equilibration can occur. In the normal person it may require 30 to 60 minutes to achieve reasonably good equilibration throughout the body after drinking water. Osmoticity is the property that largely determines the physiological acceptability of a variety of solutions used for therapeutic and nutritional purposes.

Pharmaceutical and therapeutic consideration of osmotic effects has been, to a great extent, directed toward the side effects of ophthalmic and parenteral medicinals due to abnormal osmoticity, and either to formulating to avoid the side effects or

to finding methods of administration to minimize them. More recently this consideration has been extended to total (central) parenteral nutrition, to enteral hyperalimentation (“tube” feeding), and to concentrated-fluid infant formulas.<sup>1,2</sup> Also, in recent years, the importance of osmometry of serum and urine in the diagnosis of many pathological conditions has been recognized.

There are a number of examples of the direct therapeutic effect of osmotic action, such as the *intravenous* (IV) use of mannitol as a diuretic that is filtered at the glomeruli and thus increases the osmotic pressure of tubular urine. Water must then be reabsorbed against a higher osmotic gradient than otherwise, so reabsorption is slower and diuresis is observed. The same fundamental principle applies to the IV administration of 30% urea used to affect intracranial pressure in the control of cerebral edema. Peritoneal dialysis fluids tend to be somewhat hyperosmotic to withdraw water and nitrogenous metabolites. Two to 5% sodium chloride solutions or dispersions in an oleaginous base (Muro, *Bausch & Lomb*) and a 40% glucose ointment are used topically for corneal edema. Ophthalmalgan (*Wyeth-Ayerst*) is ophthalmic glycerin employed for its osmotic effect to clear edematous cornea to facilitate an ophthalmoscopic or gonioscopic examination. Glycerin solutions in 50% concentration (Osmoglyn, *Alcon*) and isosorbide solution (Ismotic, *Alcon*) are oral osmotic agents for reducing intraocular pressure.

The osmotic principle also applies to plasma extenders, such as polyvinylpyrrolidone and to saline laxatives, such as magnesium sulfate, magnesium citrate solution, magnesium hydroxide (via gastric neutralization), sodium sulfate, sodium phosphate, sodium biphosphate oral solution, and enema (*Fleet*).

An interesting osmotic laxative that is a nonelectrolyte is a lactulose solution. Lactulose is a nonabsorbable disaccharide that is colon-specific, wherein colonic bacteria degrade some of the disaccharide to lactic and other simple organic acids. These, in total, lead to an osmotic effect and laxation. An extension of this therapy is illustrated by Cephulac (*Marion Merrell Dow*) solution, which uses the acidification of the colon via lactulose degradation to serve as a trap for ammonia migrating from the blood to the colon. The conversion of ammonia of blood to the ammonium ion in the colon ultimately is coupled with the osmotic effect and laxation, thus expelling undesirable levels of blood ammonia. This product is employed to prevent and treat frontal systemic encephalopathy.

Osmotic laxation is observed with the oral or rectal use of glycerin and sorbitol. Epsom salt has been used in baths and compresses to reduce edema associated with sprains. Another approach is the indirect application of the osmotic effect in therapy via osmotic pump drug delivery systems.<sup>3</sup>

### OSMOLALITY AND OSMOLARITY

It is necessary to use several additional terms to define expressions of concentration in reflecting the osmoticity of solutions. The terms include *osmolality*, the expression of osmolal concentration, and *osmolality*, the expression of osmolar concentration.

#### OSMOLALITY (OSMOL/KG)

A solution has an osmolal concentration of 1 when it contains 1 osmol of solute/kg of water. A solution has an osmolality of  $n$  when it contains  $n$  osmol/kg of water. Osmolal solutions, like their counterpart molal solutions, reflect a weight-to-weight relationship between the solute and the solvent. Because an osmol of any nonelectrolyte is equivalent to 1 mol of that compound, a 1 osmolal solution is synonymous to a 1 molal solution for a typical nonelectrolyte.

With a typical electrolyte like sodium chloride, 1 osmol is approximately 0.5 mol of sodium chloride. Thus, it follows that a 1 osmolal solution of sodium chloride essentially is equivalent to a 0.5 molal solution. Recall that a 1 osmolal solution of glucose or sodium chloride each will contain the same particle

concentration. In the glucose solution there will be  $6.02 \times 10^{23}$  molecules/kg of water, and in the sodium chloride solution, one will have  $6.02 \times 10^{23}$  total ions/kg of water, one-half of which are  $\text{Na}^+$  ions and the other half  $\text{Cl}^-$  ions.

As in molal solutions, osmolal solutions usually are employed where quantitative precision is required, as in the measurement of physical and chemical properties of solutions (i.e., colligative properties). The advantage of the  $\omega/\omega$  relationship is that the concentration of the system is not influenced by temperature.

### OSMOLARITY (osmol/L)

The relationship observed between molality and osmolality is shared similarly between molarity and osmolality. A solution has an osmolar concentration of 1 when it contains 1 osmol of solute per liter of solution. Likewise, a solution has an osmolality of  $n$  when it contains  $n$  osmols/L of solution. Osmolar solutions, unlike osmolal solution, reflect a weight in volume relationship between the solute and final solution. It is of note that concentrations expressed as Osmolarity are temperature dependent, whereas Osmolality are independent of temperature. For sodium chloride a 1 osmolar solution would contain 1 osmol of sodium chloride per liter, which approximates a 0.5 molar solution. The advantage of employing osmolar concentrations over osmolal concentrations is the ability to relate a specific number of osmols or milliosmols to a volume, such as a liter or milliliter. Thus, the osmolar concept is simpler and more practical. Volumes of solution, rather than weights of solution, are more practical in the delivery of liquid dosage forms.

Many health professionals do not have a clear understanding of the difference between osmolality and osmolality. In fact, the terms have been used interchangeably. A 1 osmolar solution of a solute always will be more concentrated than a 1 osmolal solution. With dilute solutions the difference may be acceptably small. For example, a 0.9%  $\omega/v$  solution of sodium chloride in water contains 9 g of sodium chloride/L of solution, equivalent to 0.308 osmolar; or 9 g of sodium chloride/996.5 g of water, equivalent to 0.309 osmolal, less than a 1% error. For concentrated solutions the percent difference between osmolality and osmolality is much greater and may be highly significant; 3.5% for 5%  $\omega/v$  glucose solution and 25% for 25%  $\omega/v$  glucose solution. One should be alerted to the sizable errors that may occur with concentrated solutions or fluids, such as those employed in total parenteral nutrition, enteral hyperalimentation, and oral nutritional fluids for infants.

Reference has been made to the terms hypertonic and hypotonic. Analogous terms are hyperosmotic and hypo-osmotic. Assuming normal serum osmolality to be 285 mOsmol/kg, as serum osmolality increases due to water deficit, the following signs and symptoms usually are found to accumulate progressively at approximately these values: 294 to 298—thirst (if the patient is alert and communicative); 299 to 313—dry mucous membranes; 314 to 329—weakness, doughy skin; above 330—disorientation, postural hypotension, severe weakness, fainting, CNS changes, stupor, and coma. As serum osmolality decreases due to water excess, the following may occur: 275 to 261—headache; 262 to 251—drowsiness, weakness; 250 to 233—disorientation, cramps; below 233—seizures, stupor, and coma.

Serum osmolality is often loosely stated to be about 300 mOsmol/L, with a variety of normal bands reported across literature: 280 to 295 mOsmol/L, 275 to 300 mOsmol/L, 290 mOsmol/L, 306 mOsmol/L, and 275 to 295 mOsmol/kg.

In recent years much attention has been directed at determining osmoticity of total parenteral nutrition solutions, enteral formulas, and parenteral and enteral medications.<sup>4-6</sup> Hyperosmoticity of parenteral and enteral formulas and medications serves as an indicator for potential risks, including thrombophlebitis, pain at injection site, diarrhea, and abdominal cramping. However, the terms osmolality and osmolality often have been used interchangeably and caused much confusion for

practitioners. Often, when the term osmolality is used, one cannot discern whether this simply is incorrect terminology or if osmolality actually has been calculated from osmolality.

Another current practice that can cause confusion is the use of the terms *normal* or *physiological* for isotonic sodium chloride solution (0.9%). The solution surely is iso-osmotic. However, as to being physiological, the concentration of ions is each of 154 mEq/L, whereas serum contains about 140 mEq of sodium and about 103 mEq of chloride.

The range of mOsmol values found for serum raises the question as to what really is meant by the terms hypotonic and hypertonic for medicinal and nutritional fluids. One can find the statement that fluids with an osmolality of 50 mOsmol or more above normal are hypertonic; and if they are 50 mOsmol or more below normal, they are hypotonic. One also can find the statement that peripheral infusions should not have an osmolality exceeding 700 to 800 mOsmol/L.<sup>7</sup> Examples of osmol concentrations of solutions used in peripheral infusions are (D5W) 5% glucose solution, 252 mOsmol/L; (D10W) 10% glucose solution, 505 mOsmol/L; Hartmann's solution, 278 mOsmol/L and Lactated Ringer's 5% Glucose, 525 mOsmol/L. When a fluid is hypertonic, undesirable effects often can be decreased by using relatively slow rates of infusion and/or relatively short periods of infusion. For example, 25% glucose solution (D25W)—4.25% Amino Acids is a representative of a highly osmotic hyperalimentation solution. It has been stated that when osmol loading is needed, a maximum safe tolerance for a normally hydrated subject would be an approximate increase of 25 mOsmol/kg of water over four hours.<sup>8</sup>

### COMPUTATION OF OSMOLARITY

Several methods are used to obtain numerical values of osmolality. The osmolar concentration, sometimes referred to as the *theoretical osmolality*, is calculated from the  $\omega/v$  concentration using the following equation:

$$\frac{\text{g}}{\text{L}} \times \frac{\text{mols}}{\text{g}} \times \frac{\text{osmol}}{\text{mol}} \times \frac{1000 \text{mOsmol}}{\text{osmol}} = \frac{\text{mOsmol}}{\text{L}} \quad (1)$$

The number of osmol/mol is equal to 1 for nonelectrolytes and is equal to the number of ions per molecule for strong electrolytes.

This calculation omits consideration of factors such as solvation and interionic forces. By this method of calculation, 0.9% sodium chloride has an osmolar concentration of 308 mOsmol/L and a concentration of 154 mOsmol/L in either sodium or chloride ion.

Two other methods compute osmolality from values of osmolality. The determination of osmolality will be discussed later. One method has a strong theoretical basis of physical-chemical principles<sup>9</sup> using values of the partial molal volume(s) of the solute(s). An 0.9% sodium chloride solution, found experimentally to have an osmolality of 286 mOsmol/kg, was calculated to have an osmolality of 280 mOsmol/L, rather different from the value of 308 mOsmol/L calculated as above. The method, using partial molal volumes, is relatively rigorous, but many systems appear to be too complex and/or too poorly defined to be dealt with by this method.

The other method is based on calculating the weight of water from the solution density and concentration:

$$\frac{\text{g water}}{\text{mL solution}} = \frac{\text{g solution}}{\text{mL solution}} - \frac{\text{g solute}}{\text{mL solution}} \quad (2)$$

then,

$$\text{osmolality} \left( \frac{\text{mOsmol}}{\text{L solution}} \right) = \text{osmolality} \left( \frac{\text{mOsmol}}{1000 \text{g water}} \right) \times \frac{\text{g water}}{\text{mL solution}} \quad (3)$$

The experimental value for the osmolality of 0.9% sodium chloride solution was 292.7 mOsmol/kg; the value computed for osmolality was 291.4 mOsmol/L. This method uses easily obtained values of density of the solution and of its solute content and can

be used with all systems. For example, the osmolality of a nutritional product was determined by the freezing-point depression method to be 625 mOsmol/kg; its osmolality was calculated as  $625 \times 0.839 = 524 \text{ mOsmol/L}$  (Bray AJ, Evansville: Mead Johnson Nutritional Division, personal communication, 1978).

US pharmacopeia monographs may require labeling of osmolality for IV solutions, nutrients, or electrolytes, and for osmotic diuretics such as mannitol.<sup>10</sup> Where, the osmolar concentration is demanded, it is specified in mosmol/L; however, when the contents are less than 100 mL, or when the label states the article is not for direct injection but is to be diluted before use, the label alternatively may state the total osmolar concentration in mOsmol/mL. The European pharmacopeia, in contrast, has very few monographs requiring osmolality labeling; it has been required only in solutions for Haemofiltration & Peritoneal Dialysis<sup>11</sup> but specifying regulatory osmolality test limits for in excess of 30 specific monographs and blood products.

An example of the use of the first method described above is the computation of the approximate osmolar concentration (*theoretical osmolality*) of a Lactated Ringer's 5% Glucose Solution (*Abbott*), which is labeled to contain, per liter, glucose (hydrous) 50 g, sodium chloride 6 g, potassium chloride 300 mg, calcium chloride 200 mg, and sodium lactate 3.1 g. Also stated is that the total osmolar concentration of the solution is approximately 524 mOsmol/L, in part contributed by 130 mEq of Na<sup>+</sup>, 109 mEq of Cl<sup>-</sup>, 4 mEq of K<sup>+</sup>, 3 mEq of Ca<sup>2+</sup>, and 28 mEq of lactate ion.

The derivation of the osmolar concentrations from the stated composition of the solution may be verified by calculations using Equation 1.

Glucose

$$\frac{50 \text{ g}}{\text{L}} \times \frac{1 \text{ mol}}{198 \text{ g}} \times \frac{1 \text{ osmol}}{\text{mol}} \times \frac{1000 \text{ mOsmol}}{\text{Osmol}} = 252 \text{ mOsmol/L} \quad (4)$$

Sodium Chloride

$$\frac{0.3 \text{ g}}{\text{L}} \times \frac{1 \text{ mol}}{74.6 \text{ g}} \times \frac{2 \text{ osmol}}{\text{mol}} \times \frac{1000 \text{ mOsmol}}{\text{osmol}} = \frac{8.04 \text{ mOsmol}}{\text{L}} \left\{ \begin{array}{l} (4.02 \text{ mOsmol K}^+) \\ (4.02 \text{ mOsmol Cl}^-) \end{array} \right. \quad (5)$$

Potassium Chloride

$$\frac{0.3 \text{ g}}{\text{L}} \times \frac{1 \text{ mol}}{74.6 \text{ g}} \times \frac{2 \text{ osmol}}{\text{mol}} \times \frac{1000 \text{ mOsmol}}{\text{osmol}} = \frac{8.04 \text{ mOsmol}}{\text{L}} \left\{ \begin{array}{l} (4.02 \text{ mOsmol K}^+) \\ (4.02 \text{ mOsmol Cl}^-) \end{array} \right. \quad (6)$$

Calcium Chloride

$$\frac{0.2 \text{ g}}{\text{L}} \times \frac{1 \text{ mol}}{111 \text{ g}} \times \frac{3 \text{ osmol}}{\text{mol}} \times \frac{1000 \text{ mOsmol}}{\text{osmol}} = \frac{5.41 \text{ mOsmol}}{\text{L}} \left\{ \begin{array}{l} (1.80 \text{ mOsmol Ca}^{2+}) \\ (3.61 \text{ mOsmol Cl}^-) \end{array} \right. \quad (7)$$

Sodium Lactate

$$\frac{3.1 \text{ g}}{\text{L}} \times \frac{1 \text{ mol}}{112 \text{ g}} \times \frac{2 \text{ osmol}}{\text{mol}} \times \frac{1000 \text{ mOsmol}}{\text{osmol}} = \frac{55.4 \text{ mOsmol}}{\text{L}} \left\{ \begin{array}{l} (27.7 \text{ mOsmol Na}^+) \\ (27.7 \text{ mOsmol lactate}) \end{array} \right. \quad (8)$$

The total osmolar concentration of the five solutes in the solution is 526, in good agreement with the labeled total osmolar concentration of approximately 524 mOsmol/L.

The mOsmol of sodium in 1 L of the solution is the sum of the mOsmol of the ion from sodium chloride and sodium lactate:  $102 + 27.6 = 129.6 \text{ mOsmol}$ . Chloride ions come from the sodium chloride, potassium chloride, and calcium chloride, the total osmolar concentration being  $102 + 4.02 + 3.61 = 109.6 \text{ mOsmol}$ . The mOsmol values of potassium, calcium, and lactate are calculated to be 4.02, 1.80, and 27.6, respectively.

The osmolality of a mixture of complex composition, such as an enteral hyperalimentation fluid, cannot be calculated with any acceptable degree of certainty; therefore, the *osmolality* of such preparations should be determined experimentally.

## OSMOMETRY AND THE CLINICAL LABORATORY

Serum and urine osmometry may assist in the diagnosis of certain fluid and electrolyte problems. However, osmometry values have little meaning unless the clinical situation is known. Osmometry is used in renal dialysis as a check on the electrolyte composition of the fluid. In the clinical laboratory, as stated above, the term *osmolality* is used generally but usually is reported as mOsmol/L. It may seem unnecessary to mention that osmolality depends not only on the number of solute particles but also on the quantity of water in which they are dissolved. However, it may help one to understand the statement that the normal range of urine osmolality is 50 to 1400 mOsmol/L, and for a random specimen is 500 to 800 mOsmol/L.

### SERUM OSMOTICITY

Sodium is by far the principal solute involved in serum osmoticity. Therefore, abnormal serum osmoticity is most likely to be associated with conditions that cause abnormal sodium concentration and/or abnormal water volume.

Thus, hyperosmotic serum is likely to be caused by an increase in serum sodium and/or loss of water. It may be associated with diabetes insipidus, hypercalcemia, and diuresis during severe hyperglycemia, or with early recovery from renal shutdown. Alcohol ingestion is said to be the most common cause of the hyperosmotic state and of coexisting coma and the hyperosmotic state. An example of hyperosmoticity is a comatose diabetic with a serum osmoticity of 365 mOsmol/L.

In a somewhat analogous fashion, hypo-osmotic serum is likely to be due to decrease in serum sodium and/or excess of water. It may be associated with the postoperative state (especially with excessive water replacement therapy), treatment with diuretic drugs and low-salt diet (as with patients with heart failure, cirrhosis, etc.), adrenal disease (e.g., Addison's disease, adrenogenital syndrome), or SIADH (syndrome of inappropriate ADH secretion). There are many diseases that cause ADH to be released inappropriately (i.e., in spite of serum osmoticity and volume having been normal initially). These include oat-cell carcinoma of the lung, bronchogenic carcinoma, congestive heart failure, inflammatory pulmonary lesions, porphyria, severe hypothyroidism, or cerebral disease (such as tumor, trauma, infection, and vascular abnormalities). It also may be found with some patients with excessive diuretic use. Serum and urine osmoticity are measured when SIADH is suspected. In SIADH there is hypo-osmoticity of the blood in association with a relative hyperosmoticity of urine. The usual cause is a malfunction of the normal osmotic response of osmoreceptors, an excess of exogenous vasopressin, or a production of a vasopressin-like hormone that is not under the regular control of serum osmoticity. The diagnosis is made by simultaneous measurement of urine and serum osmolality. The serum osmolality will be lower than normal and much lower than the urine osmolality, indicating inappropriate secretion of a concentrated urine in the presence of a dilute serum.

Cardiac, renal, and hepatic disease characteristically reduce the sodium/osmolality ratio, this being partially attributed to the effects of increased blood sugar, urea, or unknown metabolic products. Patients in shock may develop disproportionately elevated measured osmolality, compared to calculated osmolality, which points toward the presence of circulating metabolic products.

There are several approximate methods for estimating serum osmolality from clinical laboratory values for sodium ion. They may be of considerable value in an emergency situation.

1. Serum osmolality may be estimated from (Na in mEq/L, blood sugar and Blood Urea Nitrogen (BUN) in mg/100 mL).

$$\text{mOsmol} = (1.86 \text{ sodium}) + \frac{\text{blood sugar}}{18} + \frac{\text{BUN}}{2.8} + 5 \quad (9)$$

2. A quick approximation is:

$$\text{mOsmol} = 2\text{Na} + \frac{\text{BS}}{20} + \frac{\text{BUN}}{3} \quad (10)$$

3. The osmolality is usually, *but not always*, very close to two times the sodium reading plus 10.

## URINE OSMOTICITY

The two main functions of the kidney are glomerular filtration and tubular reabsorption. Clinically, tubular function is measured best by tests that determine the ability of the tubules to concentrate and dilute the urine. Tests of urinary dilution are not as sensitive in the detection of disease as those that test the concentration of urine. Concentration of urine occurs in the renal medulla (interstitial fluids, loops of Henle, capillaries of the medulla, and collecting tubules), a disease process that disturbs the function or structure of the medulla and produces early impairment of the concentrating power of the kidney. Such diseases include acute tubular necrosis, obstructive uropathy, pyelonephritis, papillary necrosis, medullary cysts, hypokalemic and hypercalcemic nephropathy, and sickle cell disease.

Measurement of urine osmolality is an accurate test for the diluting and concentrating ability of the kidneys. In the absence of ADH, the daily urinary output is likely to be six to eight liters or more. The normal urine osmolality depends on the clinical setting; normally, with maximum ADH stimulation, it can be as much as 1200 mOsmol/kg, and with maximum ADH suppression as little as 50 mOsmol/kg. Simultaneous determination of serum and urine osmolality often is valuable in assessing the distal tubular response to circulating ADH. For example, if the patient's serum is hyperosmolal or in the upper limits of normal ranges, and the patient's urine osmolality measured at the same time is much lower, a decreased responsiveness of the distal tubules to circulating ADH is suggested.

Measurement of urine osmolality during water restriction is an accurate, sensitive test of decreased renal function. For example, under the conditions of one test, normal osmolality would be greater than 800 mOsmol/kg. With severe impairment the value would be less than 400 mOsmol/kg. Knowledge of urine osmolality may point to a problem even though other tests are normal (e.g., the Fishberg concentration test, blood urea nitrogen, PSP excretion, creatinine clearance, or IV pyelogram). Knowledge of its value may be useful, especially in diabetes mellitus, essential hypertension, and silent pyelonephritis. The urine/serum osmolality ratio should be calculated and should be equal to or greater than 3.

## UNDESIRABLE EFFECTS OF ABNORMAL OSMOTICITY

### OPHTHALMIC MEDICATION

It is generally accepted that ophthalmic preparations intended for instillation into the cul-de-sac of the eye should, if possible,

be approximately isotonic to avoid irritation (see Chapter 28). It also has been stated that the abnormal tonicity of contact lens solutions can cause the lens to adhere to the eye and/or cause burning or dryness and photophobia.

### NEONATAL ENTERAL AND TOTAL PERIPHERAL MEDICATION

Adult tolerances of osmoticity cannot be expected in pediatric and neonatal therapy. Paracetamol solutions have an osmolality approaching ~15000 mOsm/L with a target of less than 500 mOsmol/L suitable for enteral feed, modifications, or dilutions of these formulations and must be considered to prevent the risks of *pneumatosis intestinalis*, hypernatraemia,<sup>2</sup> particularly in the cases of significant imbalance of ADH caused by existing trauma or acute diarrhea states.<sup>12,13</sup>

Because of the different fluid and protein requirements of neonates and pediatric patients, the final concentration of glucose and amino acids are often different from those of an adult. It is now expected that these variations are available to the clinician and that calculation or active measurement of the osmolality of a system should be made. Many automated compounding systems are now capable of calculation of the full bag osmolality, using previously recorded individual coefficients of variations for the individual components. Large validation cycles allow these calculations to be clinically relied upon but pharmacists must take particular care with regard to the extemporaneous addition of compounds to these systems, for these concentrated systems are not been governed by the more simple calculations.

### HYPEROSMOTIC AGENTS

Therapies directly applying osmotic gradients therapeutically are few. However, pediatric and mature cystic fibrosis patients infrequently make use of salt solutions in the range of 295–700 mOsm/L for their direct osmotic effect. Upon nebulization of these solutions, water movement is increased through the lungs' transepithelial surface to dilute any mucus volume. Higher osmolalities produce transepithelial movement through tight junctions,<sup>14–15</sup> further accelerating tracheobronchial mucociliary clearance.<sup>16</sup>

### DIAGNOSTIC CONTRAST AGENTS

Radiopharmaceutical and tomography contrast agents demand a pharmaceutical concentration to be held in a specific area of interest allowing appropriate imaging. This requirement can produce localized concentrations in the region of 600 mOsm resulting in tissue shrinkage and the potential for resultant cell death.<sup>17</sup> Since dilution of the agent is not possible only after treatment or reformulation with alternate agents could be considered.

### PARENTERAL MEDICATION

Osmoticity is of great importance in parenteral injections, its effects depending on such factors as the degree of deviation from tonicity, the concentration, the location of the injection, the volume injected, the speed of the injection, and the rapidity of dilution and diffusion. When formulating hypotonic parenterals, they usually have tonicity adjusted by the addition of glucose or sodium chloride. Hypertonic parenteral drug solutions cannot be adjusted, but if prepared from a dry powder, they may be reconstituted in a different solvent volume. Hypotonic and hypertonic solutions usually are administered slowly, in small volumes, or into a large vein such as the subclavian, where dilution and distribution occur rapidly. Solutions that differ from the serum in tonicity generally cause tissue irritation, pain on injection, and electrolyte shifts, the effect depending on the degree of deviation from tonicity:

- Excessive infusion of *hypotonic* fluids may cause swelling of red blood cells, hemolysis, and water invasion of the body's cells in general. When this is beyond the body's

tolerance for water, water intoxication results, with convulsions and edema, such as pulmonary edema.

- Excessive infusion of *isotonic* fluids can cause an increase in extracellular fluid volume, which can result in circulatory overload.
- Excessive infusion of *hypertonic* fluids leads to a wide variety of complications. For example, the sequence of events when the body is presented with a large IV load of hypertonic fluid, rich in glucose, is as follows: hyperglycemia, glycosuria and intracellular dehydration, osmotic diuresis, loss of water and electrolytes, dehydration, and coma.

One cause of osmotic diuresis is the infusion of glucose at a rate faster than the ability of the patient to metabolize it (as greater than perhaps 400–500 mg/kg per hour for an adult on total parenteral nutrition). A heavy load of unmetabolizable glucose increases the osmoticity of blood and acts as a diuretic; the increased solute load requires more fluid for excretion, 10 to 20 mL of water being required to excrete each gram of glucose. Solutions such as those for total parenteral nutrition should be administered by means of a metered constant-infusion apparatus over a lengthy period (usually more than 24 hours) to avoid sudden hyperosmotic glucose loads. Such solutions may cause osmotic diuresis; if this occurs, water balance is likely to become negative because of the increased urinary volume, and electrolyte depletion may occur because of excretion of sodium and potassium secondary to the osmotic diuresis. If such diuresis is marked, body weight falls abruptly and signs of dehydration appear. Urine should be monitored for signs of osmotic diuresis, such as glycosuria and increased urine volume.

If the IV injection rate of hypertonic solution is too rapid, there may be catastrophic effects on the circulatory and respiratory systems. Blood pressure may fall to dangerous levels, cardiac irregularities or arrest may ensue, respiration may become shallow and irregular, and there may be heart failure and pulmonary edema. Probably the precipitating factor is a bolus of concentrated solute suddenly reaching the myocardium and the chemoreceptors in the aortic arch and carotid sinus.<sup>8</sup>

Abrupt changes in serum osmoticity can lead to cerebral hemorrhage. It has been shown experimentally that rapid infusions of therapeutic doses of hypertonic saline with osmotic loads produce a sudden rise in cerebrospinal fluid (CSF) pressure and venous pressure (VP), followed by a precipitous fall in CSF pressure. This particularly may be conducive to intracranial hemorrhage, for the rapid infusion produces an increase in plasma volume and venous pressure at the same time the CSF pressure is falling. During the CSF pressure rise, there is a drop in hemoglobin and hematocrit, reflecting a marked increase in blood volume.

Hyperosmotic medications, such as sodium bicarbonate (osmolarity of 1560 at 1 mEq/mL), which are administered intravenously, should be diluted prior to use and should be injected slowly to allow dilution by the circulating blood. Rapid *push* injections may cause a significant increase in blood osmoticity.<sup>9</sup>

Safety, therefore, demands that all IV injections, especially highly osmotic solutions, be performed slowly, usually being given preferably over a period not less than that required for a complete circulation of the blood (one minute). The exact danger point varies with the state of the patient, the concentration of the solution, the nature of the solute, and the rate of administration.

Hyperosmotic solutions also should not be discontinued suddenly. In dogs, marked increase in levels of intracranial pressure have occurred when hyperglycemia produced with glucose infusions was suddenly reversed by stopping the infusion and administering saline. It also has been shown that the CSF pressure in humans rises during treatment of diabetic ketoacidosis in association with a fall in the plasma concentration of glucose and a fall in plasma osmolality. These observations may be explained by the different rates of decline in glucose content of the brain and of plasma. The concentration of glucose in the brain may fall more slowly than in the plasma, causing a shift of fluid from

the extracellular fluid space to the intracellular compartment of the CNS, resulting in increased intracranial pressure.

## CLINICAL APPLICATIONS

Although there are many issues with abnormal osmoticity, most pharmacists are concerned with preventable adverse effects, such as thrombophlebitis and pain at the injection site. The understanding of these potential risks from hyperosmotic parenteral medications has fine-tuned IV administration techniques. The site of administration—peripheral versus central venous catheter—plays a significant role in determining the final concentration of parenteral medications infused IV. Attention should be directed toward establishing the optimal osmolarity of IV administered parenteral medications via the peripheral venous route that will result in the least adverse effects.

Since the introduction of parenteral nutrition support, hyperosmoticity of these nutrition solutions remains a concern. The commonly accepted osmolarity of less than 900 mOsmol/L has been quoted for safe peripheral administration of parenteral nutrition solutions.<sup>18,19</sup> All attempts should be made to prepare solutions with osmoticity close to that of serum osmoticity or no greater than 900 mOsmol/L. This can be achieved by carefully selecting the diluent for dilution and determining the final concentration of the parenteral medication. Glucose 5% in Water for Injection and Sodium Chloride 0.9% have been used routinely as diluents. When comparing the two diluents, parenteral medications diluted with Glucose 5% in Water for Injection have a lower osmolarity than do solutions diluted with Sodium Chloride 0.9% at the same final concentration.

Several studies have been conducted to determine optimal final concentration of commonly used parenteral medications.<sup>4–6</sup> The published final concentrations for most parenteral medications are recommended for peripheral as well as central venous catheter IV administration for patients with no special needs, such as fluid restriction. In the event that fluid restriction is required or the recommended final concentration is not achievable, the parenteral medication should be administered via a central venous catheter, by which immediate dilution and distribution is achieved rapidly. This will minimize potential for phlebitis and pain at the injection site.

Osmoticity issues associated with parenteral medications are also applicable to *total parenteral nutrition* (TPN) solutions, especially via peripheral venous administration. Peripheral parenteral nutrition support remains an integral part of therapeutic options for hospitalized patients. The peripheral route of administration often is preferred for patients who require short-term therapy or supplemental nutrition support.

## OSMOTICITY AND ENTERAL HYPERALIMENTATION

Some aspects of nutrition have already been discussed. Here, we present the potential side effects caused with repeated nutritional replacement. There exists an increasing dialogue on nutrition through professional bodies. The professional organizations of The American Society for Parenteral and Enteral Nutrition (ASPEN) and The British Association for Parenteral and Enteral Nutrition (BAPEN) aim to advance clinical nutrition by enforcing best practice standards among dietitians, doctors, nurses, pharmacists, patients, industry representatives and others concerned with the research, development, manufacture, supply, provision, and consumption.

Osmoticity has been of special importance in the IV infusion of large volumes of highly concentrated nutritional solutions. Hyperosmoticity has been a major factor in the requirement that they must be injected centrally into a large volume of rapidly moving blood in preference to peripheral infusion. Technology expansion has led to routes of administration directly to the gastrointestinal tract through instillation directly into specific regions either orally or by nasogastric tube, feeding gastrostomy, or needle-catheter jejunostomy. These oral routes

are always more beneficial to the patient but do raise their own osmotically related challenges.

Enteral nutritional formulas can be modular, allowing individual supplementation of protein, carbohydrate, or fat. Other formulas are called *defined formula diets* and contain protein, carbohydrate, fat, minerals, and vitamins. These nutritionally complete formulations can be monomeric (or oligomeric), based on amino acids, short peptides, and simple carbohydrates or can be polymeric, based on complex protein and carbohydrates. These complex systems cannot have osmolality calculated, and experimental determination must be performed; however, knowledge of these experimental determinations has allowed clinically significant predictions to be validated for routine use.

Enteral diets are necessarily relatively high in osmoticity because their smaller molecules result in more particles per gram than in normal foods. An example is a fluid consisting of L-amino acids, glucose oligosaccharides, vitamins (including fat-soluble vitamins), fat as a highly purified safflower oil or soybean oil, electrolytes, trace minerals, and water. Components not in solution as part of an oily phase (fat) do not contribute to osmoticity. However, the potential for interactions between these phases can cause some significant changes in total particle concentration and indirectly affect the osmoticity.<sup>20</sup>

Although it is easily digested, glucose contributes more particles than most other carbohydrate sources, such as starch, and is more likely to cause osmotic diarrhea, especially with bolus feeding. For enteral feeds, osmoticity is improved (decreased) by replacing glucose with glucose oligosaccharides (carbohydrates that yield on hydrolysis 2 to 10 monosaccharides).<sup>21</sup> Additional flavorings, not required for all patients, will also increase the osmoticity of a product.

Commercial diets are packaged as fluids or as powders for reconstitution with water. Categorized on caloric density (calories/mL), protein content, or osmolality (mOsm/kg of H<sub>2</sub>O), parenteral nutritional products differ because they are labeled in terms of osmolality (mOsm/L).

The enteral route for nutrition is frequently overlooked in many diseases or post-trauma states. If the patient is not readily responsive to traditional oral feedings, there is no reason that the gastrointestinal tract or regions of it should not be used.

However, when large volumes of osmotically mismatched fluids are administered, they cause an upset in the normal water balance within the body. The nutritional components below are listed in order of decreasing osmotic effect per gram:<sup>22</sup>

1. Electrolytes such as sodium chloride
2. Relatively small organic molecules, such as dextrose (glucose) and amino acids
3. Dextrose oligosaccharides
4. Starches
5. Proteins
6. Fats (no osmotic effect, only producing variation in other components).

Foods with high proportions of electrolytes, amino acids, and simple sugars have the greatest effect on osmolality and, as a result, the level of tolerance that can be expected

in specific patients. The approximate osmolality of common foods and an illustrative parenteral nutrition solution is given in Table 16-1.

When nutrition of high osmoticity is ingested, large amounts of water will transfer to the stomach and intestines from fluid surrounding the organs in an attempt to lower the osmoticity. The higher the osmoticity, the larger the amount of water required; a large amount of water in the gastrointestinal tract can cause distention, cramps, nausea, vomiting, hypermotility, and shock. The food may move through the tract too rapidly for the water to be reabsorbed, and result is diarrhea and dehydration. The hyperosmotic enteral effects have been observed by the administration of undiluted hypertonic oral medication.<sup>23,24</sup> The table in Appendix A lists average osmolality values of some commercially available drug solutions and suspensions. Thus, there is some analogy to the effect of hyperosmotic IV infusions.

Hyperosmotic feedings may result in mucosal damage in the GI tract. Rats given hyperosmotic feeding showed transient decrease in disaccharidase activity and an increase in alkaline phosphatase activity. They also showed morphological alterations in the microvilli of the small intestines. After a period of severe gastroenteritis, the bowel may be unusually susceptible to highly osmotic formulas, and their use may increase the frequency of diarrhea. Infant formulas that are hyperosmotic may affect preterm infants adversely during the early neonatal period, and they may produce or predispose neonates to necrotizing enterocolitis when the formulas delivered to the jejunum through a nasogastric tube. The body attempts to keep the osmoticity of the contents of the stomach and intestines at approximately the same level as that of the fluid surrounding them. As a fluid of lower osmoticity requires the transfer of less water to dilute it, it should be tolerated more than one of higher osmoticity.

As to tolerance, there is a great variation from one individual to another in sensitivity to the osmoticity of foods. The majority of patients receiving nutritional formulas, either orally or by tube, are able to tolerate feedings with a wide range of osmoticities when the formulas are administered slowly and when adequate additional fluids are given. However, certain patients are more likely to develop symptoms of intolerance when receiving fluids of high osmoticity. These include debilitated patients, patients with GI disorders, pre- and post-operative patients, gastrostomy and jejunostomy-fed patients, and patients whose GI tracts have not been challenged for an extended period of time. Thus, osmoticity always should be considered in the selection of the formula for each individual patient.

With all products additional fluid intake may be indicated for individuals with certain clinical conditions. Frequent feedings of small volume or a continual instillation (pumped) may be of benefit initially in establishing tolerance to a formula. For other than iso-osmotic formulas, feedings of reduced concentration (osmolality less than 400 mOsmol/kg) also may be helpful initially if tolerance problems arise in sensitive individuals. Concentration and size of feeding then can be increased gradually to normal as tolerance is established.

A common disturbance of intake encountered in elderly individuals relates to excess solid intake rather than to reduced water intake. For example, an elderly victim of a cerebral vascular accident who is being fed by nasogastric tube may be given a formula whose solute load requires a greatly increased water intake. Thus, tube feeding containing 120g of protein and 10g of salt will result in the excretion of more than 1000 mOsmol of solute. This requires the obligatory excretion of a volume of urine between 1200 and 1500 mL when the kidneys are capable of normal concentration ability. Because elderly individuals often have significant impairment in renal function, water loss as urine may exceed 2000 to 2500 mL per day. Such an individual would require three to four liters of water per day simply to meet the increased demand created by this high solute intake. Failure of the physician to provide such a patient with the

**Table 16-1.**

	mOsmol/kg
Whole milk	295
Tomato juice	595
Orange juice	935
Ice cream	1150
Parenteral nutrition	1400

increased water intake needed will result in a progressive water deficit that rapidly may become critical. The importance of knowing the complete composition of the tube feeding formulas used for incapacitated patients cannot be overemphasized.

### OSMOLALITY DETERMINATION

The need for experimental determination of osmolality has been established. In regard to this there are four properties of solutions that depend only on the number of *particles* in the solution. They are *osmotic-pressure elevation*, *boiling-point elevation*, *vapor-pressure depression*, and *freezing-point depression*. These are called *colligative properties*, and if one of them is known, the others can be calculated from its value. Osmotic-pressure elevation is the most difficult to measure satisfactorily. The boiling-point elevation may be determined, but the values are rather sensitive to changes in barometric pressure. Also, for an aqueous solution the molal boiling point elevation is considerably less than the freezing-point depression. Thus, it is less accurate than the freezing-point method. Determinations of vapor-pressure lowering are quite easy, rapid, and convenient. A vapor pressure osmometer with a precision of 2 mOsmol/kg is reported by Dickerson *et al.*<sup>23</sup> Another commonly used method is that of freezing-point depression, which can be determined quite readily with a fair degree of accuracy (see *Freezing-Point Depression* in Chapter 13). It should be noted that the data in Appendix A can be converted readily to vapor-pressure lowering, if desired.

The results of investigations by Lund *et al.*,<sup>25</sup> indicate that the freezing point of normal, healthy human blood is  $-0.52^{\circ}\text{C}$ . In as much as water is the medium in which the various constituents of blood are either suspended or dissolved in this method, it is assumed that *any aqueous solution* freezing at  $-0.52^{\circ}\text{C}$  is *isotonic with blood*. Now, it is rare that a simple aqueous solution of the therapeutic agent to be injected parenterally has a freezing point of  $-0.52^{\circ}\text{C}$ , and to obtain this freezing point, it is necessary either to add some other therapeutically inactive solute if the solution is hypotonic (freezing point above  $-0.52^{\circ}\text{C}$ ) or to dilute the solution if it is hypertonic (freezing point below  $-0.52^{\circ}\text{C}$ ). The usual practice is to add either sodium chloride or glucose to adjust hypotonic parenteral solutions to isotonicity. Certain solutes, including ammonium chloride, boric acid, urea, glycerin, and propylene glycol, cause hemolysis even when they are present in a concentration that is iso-osmotic, and such solutions obviously are not isotonic and do not act as a solvent, semi-permeable membrane. (See Appendix A.)

In a similar manner, solutions intended for ophthalmic use may be adjusted to have a freezing point identical to that of lacrimal fluid, namely  $-0.52^{\circ}\text{C}$ . Ophthalmic solutions with higher freezing points usually are made isotonic by the addition of boric acid or sodium chloride.

In laboratories where the necessary equipment is available, the method usually followed for adjusting hypotonic solutions is to determine the freezing-point depression produced by the ingredients of a given prescription or formula, and then to add a quantity of a suitable inert solute calculated to lower the freezing point to  $-0.52^{\circ}\text{C}$ , whether the solution is for parenteral injection or ophthalmic application. A final determination of the freezing-point depression may be made to verify the accuracy of the calculation. If the solution is hypertonic, it must be diluted if an isotonic solution is to be prepared, but it must be remembered that some solutions cannot be diluted without impairing their therapeutic activity. For example, solutions to be used for treating varicose veins require a high concentration of the active ingredient (solute) to make the solution effective. Dilution to isotonic concentration is not indicated in such cases.

### FREEZING-POINT CALCULATIONS

As explained in the preceding section, freezing-point data often may be employed in solving problems of isotonicity adjustment.

Obviously, the utility of such data is limited to those solutions where the solute does not penetrate the membrane of the tissue (e.g., red blood cells) with which it is in contact. In such cases, Appendix A, which gives the freezing-point depression of solutions of different concentrations of various substances, provides information essential for solving the problem.

For most substances listed in the table in Appendix B, the concentration of an isotonic solution (one that has a freezing point of  $-0.52^{\circ}\text{C}$ ) is given. If this is not listed in the table, it may be determined with sufficient accuracy by simple proportion using, as the basis for calculation, the figure that most nearly produces an isotonic solution. Actually, the depression of the freezing point of a solution of an electrolyte is not absolutely proportional to the concentration but varies according to dilution; for example, a solution containing 1 g of procaine hydrochloride in 100 mL has a freezing-point depression of  $0.12^{\circ}\text{C}$ , whereas a solution containing 3 g of the same salt in 100 mL has a freezing-point depression of  $0.33^{\circ}\text{C}$ , *not*  $0.36^{\circ}\text{C}$  ( $3 \times 0.12^{\circ}\text{C}$ ). Because typical adjustments to isotonicity need not be absolutely exact, approximation are made. Nevertheless, adjustments to isotonicity should be as exact as practicable or confirmed experimentally.

### EFFECT OF SOLVENTS

Besides water, certain other solvents frequently are employed in nose drops, eardrops, and other preparations to be used in various parts of the body. Liquids such as glycerin, propylene glycol, or alcohol may compose part of the solvent. In solving isotonicity adjustment problems for such solutions, it should be kept in mind that these solvent components contribute to the freezing-point depression, but they may or may not have an effect on the tone of the tissue to which they are applied; thus, an *iso-osmotic* solution may not be *isotonic*. In such cases, it is apparent that the utility of the methods described above—or for that matter, of any other method of evaluating *tonicity*—is questionable.

### TONICITY TESTING BY OBSERVING ERYTHROCYTE CHANGES

Observation of the behavior of human erythrocytes when suspended in a solution is the ultimate and direct procedure for determining whether the solution is isotonic, hypotonic, or hypertonic. If hemolysis or marked change in the appearance of the erythrocytes occurs, the solution is not isotonic with the cells. If the cells retain their normal characteristics, the solution is isotonic.

Hemolysis may occur when the osmotic pressure of the fluid in the erythrocytes is greater than that of the solution in which the cells are suspended, but the specific chemical reactivity of the solute in the solution often is far more important in producing hemolysis than is the osmotic effect. There is no certain evidence that any single mechanism of action causes hemolysis. The process appears to involve such factors as pH, lipid solubility, molecular and ionic sizes of solute particles, and possibly inhibition of cholinesterase in cell membranes and denaturing action on plasma membrane protein.

Some investigators test the tonicity of injectable solutions by observing variations of red blood cell volume produced by these solutions. This method appears to be more sensitive to small differences in tonicity than those based on observation of a hemolytic effect. Much useful information concerning the effect of various solutes on erythrocytes has been obtained by this procedure.

### METHODS OF ADJUSTING TONICITY

There are several methods for adjusting the tonicity of an aqueous solution, provided, of course, that the solution is hypotonic when the drug and additives are dissolved. The most prominent of these methods are the freezing-point depression method, the sodium chloride equivalent method, and the isotonic solution

V-value method. The first two of these methods can be used with a three-step problem-solving process, based on sodium chloride.

1. Identify a reference solution and the associated tonicity parameter.
2. Determine the contribution of the drug(s) and additive(s) to the total tonicity.
3. Determine the amount of sodium chloride needed by subtracting the contribution of the actual solution from the reference solution.

The result of the third step also indicates whether the actual solution is hypotonic, isotonic, or hypertonic. If the actual solution contributes less to the total tonicity than the reference solution, then the actual solution is hypotonic. If, however, the actual solution contributes a greater amount to tonicity than the reference solution, the actual solution is hypertonic and can be adjusted to isotonicity only by dilution. This may not be possible on therapeutic grounds.

The amount of sodium chloride resulting in the third step also can be converted into an amount of other materials, such as glucose, to render the actual solution isotonic.

### FREEZING-POINT-DEPRESSION METHOD

The freezing-point method makes use of a *D value* (found in Appendix A) which has the units of degree centigrade/(*x*% drug). For example, in Appendix A, dexamethasone sodium phosphate has *D* values of 0.050°/(0.5% drug), 0.180°/(2.0% drug), 0.52°/(6.75% drug), etc. It is apparent that the *D* value is nearly proportional to concentration. If a *D* value is needed for a concentration of drug not listed in Appendix A, a *D* value can be calculated from the appendix by direct proportion, using a *D* value closest to the concentration of drug in the actual solution.

The reference solution for the freezing-point-depression method is 0.9% sodium chloride, which has a freezing-point depression of  $\Delta T_f = 0.52^\circ$ . Using the three steps described above, the dexamethasone sodium phosphate solution in Example 1 can be rendered isotonic as follows:

#### Example 1

Dexamethasone Sodium Phosphate	0.1%
Purified Water qs	30 mL

#### Mft Isotonic Solution

Step 1—Reference solution: 0.9% sodium chloride.  
 $\Delta T_f = 0.52^\circ$

$D = 0.050^\circ/0.5\%$  (dexamethasone sodium phosphate)

Step 2—Contribution of drug.

$$\frac{0.050^\circ}{0.5\% \text{ drug}} \times 0.1\% \text{ drug} = 0.010^\circ \quad (11)$$

Step 3—Reference solution – Actual solution.

$$0.52^\circ - 0.01^\circ = 0.51^\circ$$

Sodium chloride needed.

$$\frac{0.9\% \text{ NaCl}}{0.52^\circ} \times 30 \text{ mL} = 0.265 \text{ g NaCl} \quad (12)$$

$$\frac{0.883 \text{ g NaCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.265 \text{ g NaCl} \quad (13)$$

The above solution could be made isotonic with any appropriate material other than sodium chloride by using the *D* value for that material. For example, to make the solution isotonic with glucose with a *D* value,  $D = 0.091^\circ/1\%$ ;

$$\frac{1\% \text{ Dextrose}}{0.091^\circ} \times 0.51^\circ = 5.60\% \text{ Dextrose} \quad (14)$$

$$\frac{5.60 \text{ g Dextrose}}{100 \text{ mL}} \times 30 \text{ mL} = 1.68 \text{ g Dextrose} \quad (15)$$

#### Example 2

Naphazoline HCl (N.HCl)	0.02%
Zinc Sulfate	0.25%
Purified Water qs	30 mL

#### Mft Isotonic solution

Step 1—Reference solution: 0.9% sodium chloride.

$$\Delta T_f = 0.52^\circ$$

$D = 0.14^\circ/1\%$  (naphazoline HCl)

$D = 0.086^\circ/1\%$  (zinc sulfate)

Step 2—Contribution of drugs.

$$\frac{0.14^\circ}{1\% \text{ N.HCl}} \times 0.02\% \text{ N.HCl} = 0.003^\circ \quad (16)$$

$$\frac{0.086^\circ}{1\% \text{ ZnSO}_4} \times 0.25\% \text{ ZnSO}_4 = 0.022^\circ \quad (17)$$

Step 3—Reference solution – actual solution.

$$0.52^\circ - 0.025^\circ = 0.495^\circ$$

Sodium chloride needed.

$$\frac{0.9\% \text{ NaCl}}{0.52^\circ} \times 0.495^\circ = 0.857\% \text{ NaCl} \quad (18)$$

$$\frac{0.857 \text{ g NaCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.257 \text{ g NaCl} \quad (19)$$

The above solution could be made isotonic with any appropriate material, other than sodium chloride, by using the *D* value for that material.

For example, to make the solution isotonic with glucose with a *D* value,  $D = 0.091^\circ/1\%$ ;

$$\frac{1\% \text{ Dextrose}}{0.091^\circ} \times 0.495^\circ = 5.44\% \text{ Dextrose} \quad (20)$$

$$\frac{5.44 \text{ g Dextrose}}{100 \text{ mL}} \times 30 \text{ mL} = 1.63 \text{ g Dextrose} \quad (21)$$

### Sodium Chloride Equivalent Method

A sodium chloride equivalent, *E value*, is defined as the weight of sodium chloride that will produce the same osmotic effect as 1 g of the drug. For example, in Appendix A, dexamethasone sodium phosphate has an *E* value of 0.18 g NaCl/g drug at 0.5% drug concentration, 0.17 g NaCl/g drug at 1% drug concentration and a value of 0.16 g NaCl/g drug at 2% drug. This slight variation in the sodium chloride equivalent with concentration is due to changes in interionic attraction at different concentration of drug; the *E* value is not directly proportional to concentration, as was the freezing-point-depression.

The reference solution for the sodium chloride equivalent method is 0.9% sodium chloride, as it was for the freezing-point-depression method.

The dexamethasone sodium phosphate solution in Example 1 can be rendered isotonic, using the sodium chloride equivalent method as follows:

#### Example 1

Dexamethasone Sodium Phosphate	0.1%
Purified Water qs	30 mL

#### Mft Isotonic Solution

Step 1—Reference solution: 0.9% sodium chloride.

$$\frac{0.9 \text{ g NaCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.270 \text{ g NaCl} \quad (22)$$

$$E = 0.18 \text{ g NaCl/g drug}$$

Step 2—Contribution of drug.

$$\frac{0.18 \text{ g NaCl}}{1 \text{ g drug}} \times \frac{0.1 \text{ g drug}}{100 \text{ mL}} \times 30 \text{ mL} = 0.0054 \text{ g NaCl} \quad (23)$$

Step 3—Reference solution – Actual solution.

$$0.270 \text{ g NaCl} - 0.0054 \text{ g NaCl} = 0.265 \text{ g NaCl}$$

The above solution can be made isotonic with a material other than sodium chloride, such as glucose, by using the E value of that material. For example, to make the solution isotonic with glucose,  $E = 0.16 \text{ g NaCl/g glucose}$ , the amount of sodium chloride needed in Step 3, can be converted to glucose as follows:

$$\frac{1 \text{ g Dextrose}}{0.16 \text{ g NaCl}} \times 0.265 \text{ g NaCl} = 1.66 \text{ g Dextrose} \quad (24)$$

### Example 2

Naphazoline HCl (N.HCl)	0.02%
Zinc Sulfate	0.25%
Purified Water qs	30 mL

Mft Isotonic Solution

Step 1—Reference solution: 0.9% sodium chloride.

$$\frac{0.9 \text{ g NaCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.270 \text{ g NaCl} \quad (25)$$

$$E = 0.27 \text{ g NaCl/g N.HCl}$$

$$E = 0.15 \text{ g NaCl/g ZnSO}_4$$

Step 2—Contribution of drugs.

$$\frac{0.27 \text{ g NaCl}}{1 \text{ g N.HCl}} \times \frac{0.02 \text{ g N.HCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.002 \text{ g NaCl} \quad (26)$$

$$\frac{0.15 \text{ g NaCl}}{1 \text{ g ZnSO}_4} \times \frac{0.25 \text{ g ZnSO}_4}{100 \text{ mL}} \times 30 \text{ mL} = 0.011 \text{ g NaCl} \quad (27)$$

$$0.002 \text{ g NaCl} + 0.011 \text{ g NaCl} = 0.013 \text{ g NaCl}$$

Step 3—Reference solution actual solution.

$$0.270 \text{ g NaCl} - 0.013 \text{ g NaCl} = 0.257 \text{ g NaCl}$$

$$\frac{1 \text{ g Dextrose}}{0.16 \text{ g NaCl}} \times 0.257 \text{ g NaCl} = 1.61 \text{ g Dextrose} \quad (28)$$

The above solution can be made isotonic with a material other than sodium chloride, such as glucose, by using the E value of that material. For example, to make the solution isotonic with glucose,  $E = 0.16 \text{ g NaCl/g glucose}$ , the amount of sodium chloride needed in Step 3 can be converted to glucose as follows:

## ISOTONIC SOLUTION V VALUES

The *V value* of a drug is the volume of water to be added to a specified weight of drug (0.3 g or 1.0 g, depending on the table used) to prepare an isotonic solution. Appendix B gives such values for some commonly used drugs. The reason for providing data for 0.3 g of drug is for convenience in preparing 30 mL (approximately 1 fluid ounce) of solution, a commonly prescribed volume. The basic principle underlying the use of V values is to prepare an isotonic solution of the prescribed drug and then dilute this solution to final volume with a suitable isotonic vehicle.

The two solutions in the previous examples can be prepared as follows using the V-value method:

### Example 1

Dexamethasone Sodium Phosphate	0.1%
Purified Water qs	30 mL

Mft Isotonic Solution

Step 1—The V value for dexamethasone sodium phosphate can be calculated from the sodium chloride equivalent, *E*, as outlined in the footnote in Appendix B.

$$\frac{100 \text{ mL Soln}}{0.9 \text{ g NaCl}} \times \frac{0.17 \text{ g NaCl}}{1 \text{ g drug}} \times 0.3 \text{ g drug} = 5.67 \text{ mL Soln} \quad (29)$$

for a dilute solution:

$$5.67 \text{ mL Soln} \cong 5.67 \text{ mL H}_2\text{O} \text{ there } V \\ = (5.67 \text{ mL H}_2\text{O}) / (0.3 \text{ g drug})$$

Step 2—Amount of drug needed.

$$\frac{0.1 \text{ g drug}}{100 \text{ mL}} \times 30 \text{ mL} = 0.030 \text{ g drug} \quad (30)$$

Volume of water needed to prepare an isotonic solution.

$$\frac{5.67 \text{ mL H}_2\text{O}}{0.3 \text{ g drug}} \times 0.030 \text{ g} = 0.57 \text{ mL H}_2\text{O} \quad (31)$$

Step 3—To prepare the solution, dissolve 0.030 g of drug in 0.57 mL water, and qs to volume with a suitable isotonic vehicle, such as 0.9% sodium chloride solution, 5.51% glucose, or an isotonic phosphate buffer.

### Example 2

Naphazoline HCl (N.HCl)	0.02%
Zinc Sulfate	0.25%
Purified Water qs	30 mL

Mft Isotonic Solution

Step 1—The V value for naphazoline HCl can be calculated from the sodium chloride equivalent, *E*, as outlined in the footnote in Appendix B; the V value for zinc sulfate is taken directly from Appendix B.

$$\frac{100 \text{ mL Soln}}{0.9 \text{ g NaCl}} \times \frac{0.27 \text{ g NaCl}}{1 \text{ g N.HCl}} \times 0.3 \text{ g N.HCl} = 9.00 \text{ mL Soln} \quad (32)$$

for a dilute solution:

$$9.00 \text{ mL Soln} \cong 9.00 \text{ mL H}_2\text{O} \text{ there } V \\ = (9.00 \text{ mL H}_2\text{O}) / (0.3 \text{ g N.HCl}) \\ V = 5.00 \text{ mL H}_2\text{O} / 0.3 \text{ g ZnSO}_4$$

Step 2—Amount of drugs needed.

$$\frac{0.02 \text{ g N.HCl}}{100 \text{ mL}} \times 30 \text{ mL} = 0.006 \text{ g N.HCl}$$

$$\frac{0.25 \text{ g ZnSO}_4}{100 \text{ mL}} \times 30 \text{ mL} = 0.075 \text{ g ZnSO}_4$$

Volume of water needed to prepare an isotonic solution:

$$\frac{9.00 \text{ mL H}_2\text{O}}{0.3 \text{ g N.HCl}} \times 0.006 \text{ g drug} = 0.18 \text{ mL H}_2\text{O}$$

$$\frac{5.00 \text{ mL H}_2\text{O}}{0.3 \text{ g ZnSO}_4} \times 0.075 \text{ g ZnSO}_4 = 1.25 \text{ mL H}_2\text{O}$$

Step 3—To prepare the solution, dissolve 0.006 g of naphazoline HCl and 0.075 g zinc sulfate in 1.43 mL water, and qs to volume with a suitable isotonic vehicle, such as 0.9% sodium chloride solution, 5.51% glucose, or an isotonic phosphate buffer.

This chapter is intended as a general introduction to Chemical Kinetics. A comprehensive review of experimental approaches and interpretation of data can be found in several texts, such as the books by House, Epenson, and Houston, and the compilation of information relative to kinetic studies on pharmaceuticals by Garrett.<sup>1</sup>

### CHEMICAL REACTIONS

A chemical reaction is said to have occurred when one or more molecules undergoes a process in which electrons are either lost or gained by an atom or molecule, or the electrons go through a transition process in which they are shared differently between atoms which result in the breaking or forming of bonds. These result in the formation of one or more new chemical species with different chemical structures and properties than that of the original starting material. Such chemical processes usually result in changes in energy and/or degree of randomness in going from the initial to the final state which is the basis for thermodynamics. Thermodynamic parameters, such as  $\Delta G$ ,  $\Delta E$ ,  $\Delta H$ , and  $\Delta S$ , are state functions that only depend on the initial and final states of a chemical process—usually defined as the state of the reactants and products at certain temperatures, pressures and physical states—and are independent of the pathway taken to get to the final state from the initial state. Spontaneous reactions are said to occur when the reactants proceed to products when the energy contained within the products is less than the energy contained in the reactants (i.e.,  $\Delta G < 0$ ) which usually result in the release in heat (i.e.,  $\Delta H < 0$ ) and/or an increase in randomness of the chemical system (i.e.,  $\Delta S > 0$ ). However, it has been observed that in some cases, whereas some reactions are thermodynamically favorable to proceed spontaneously, the conversion of reactants to products may proceed at very slow rates over relatively long periods of time. This serves to point out that thermodynamics is essentially a snap shot of the differences between the properties of the product and reactant states of a chemical reaction which provides no indication of the chemical processes or the time that it took to go from reactant to product state.

*Chemical kinetics* is the discipline that is concerned with the mechanism by which a chemical process gets to its final state from its initial state and the rate in which this reaction proceeds. Therefore, chemical kinetics involves the study of rate of chemical change and the way in which this rate is influenced by the conditions of the concentration of reactants, products, and other chemical species that may be present, and by factors such as solvent, pressure, and temperature. From these studies, one or more mechanisms involving a series of elementary processes may be postulated to explain how the reactants are converted to products during a chemical process.

Applied to pharmaceuticals, chemical kinetic information permits a rational approach to the stabilization of drug products, and prediction of shelf life and optimum storage conditions.

### REACTION MECHANISM

There are two basic ways in which chemical reactions can occur. One method involves the absorption of electromagnetic radiation which excites certain electrons within an atom or molecule to a higher energy state or even the ejection of the electron creating a free radical which is a very reactive chemical species.

This may be indicated by the elementary processes such as:

and

where  $h\nu$  represents a quantum of electromagnetic radiation absorbed by chemical species A,  $A^*$  represents the higher energy, excited state of chemical species A,  $A \cdot$  represents the free radical of species A, and  $e^-$  represents an electron. If the excited electrons were originally involved in a bond between atoms, then the bond may be weakened or broken which may cause the molecule to dissociate into smaller molecules or possibly cause the molecule to internally rearrange its bonds as shown by the elementary processes:

or

where species B and C are the products of the disintegration of species A, and H is a resulting product caused by the rearrangement of species A upon absorption of a quantum of electromagnetic energy. If an excited molecule collides with another atom/molecule under the right conditions, a new bond may form creating a new molecule as shown by the elementary process:

where D represent a reactant species that collides and reacts with the excited species  $A^*$  to produce the product species F. At other times, the excited electrons may revert back to a lower energy level or even the original energy level through a release of electromagnetic radiation as shown by the elementary process:

The other common method in which a reaction can occur is when a transfer of energy occurs when an atom or molecule collides with another atom, molecule or even the wall of a container. For example, an atom or molecule with a certain amount of kinetic and potential energy collides with a wall of a container that is at a higher temperature than that of the atom or molecule. The atom/molecule absorbs some of this thermal energy resulting in an increase in its kinetic energy, which causes it to increase its velocity, or, in the case of a molecule, may absorb enough energy to disrupt bonds within the molecule. A similar process can occur when there is a collision between

atoms/molecules where there may be a transfer of energy. In such cases where the atoms/molecules collide and bounce off one another, one atom/molecule may increase its kinetic or potential energy at the cost of energy of the other atom/molecule. Such processes can be represented by:

where W represents either a molecule or the wall of a container in which chemical species A has collided creating a higher energy, activated species A\*. It should be noted that W in such cases has lost some of its energy upon such collisions. The higher energy atom/molecule may then go on to collide with other atoms/molecules. If there is sufficient energy between the colliding molecules/atoms and other conditions, such as intermolecular orientation, are right, intermolecular interactions may be sufficient to cause the colliding entities to "stick" together creating an intermediate species as indicated by the elementary process:

where  $[A-B]^*$  and  $AB^*$  represent intermediate or transition state species. During this process, either a transfer of energy can occur before the entities separate creating an excited species, certain electrons of the two entities can form a bond creating a new chemical species, or the transition state entity can break apart to form a new chemical species as shown by the elementary processes:

or

or

Thus, when a chemical reaction does occur, it may occur via a mechanism in a single reaction step, known as an elementary process, or by a series of two or more elementary processes which, when totaled, will give the net chemical reaction. For example:

which when summed together gives

However, because the transition state  $AB^*$  and the activated molecule  $F^*$  appear in both reactant and product sides of the reaction in the same stoichiometric quantities, they can be treated as intermediates and removed from the reaction to give the net reaction:

## REACTION RATE

The rate of a reaction is the velocity with which a reactant or reactants undergoes a chemical change. Experimentally, the rate of a reaction must be determined by directly or indirectly following the change in the concentration of the reactants or products as a function of time. When there is more than one reactant, such changes need to be normalized according to the stoichiometry of the reaction. For a reaction of the type

where the uppercase letters represent chemical species and the lowercase letters represent stoichiometric coefficients, the rate in which reactants go to products can be determined by following the rate of the disappearance of the reactants as a function of time.

$$\text{Rate} = -\frac{d[A]}{adt} = -\frac{d[B]}{bdt} \quad (1)$$

The brackets denote concentration (usually molar concentration unless otherwise indicated) and  $d$  represents the derivative

function. The negative sign signifies that the concentration of the reactants is decreasing, as the rate must always be positive as long as the reaction is progressing from reactants to products.

The rate at which a reaction proceeds for the reaction type shown above also can be determined by following the appearance of the products as a function of time:

$$\text{Rate} = +\frac{d[C]}{cdt} = +\frac{d[D]}{dtd} \quad (2)$$

where the positive signs indicate that the concentrations of the products are increasing. Note that these two expressions for rate are only for the type of reaction where the reactants go irreversibly to products, without going through any intermediates.

If  $[A]_0$ ,  $[B]_0$ ,  $[C]_0$ , and  $[D]_0$  represent the initial concentration (i.e.,  $t = 0$ ) of each of the reactants and products, at some time  $t$  (i.e.,  $t = t$ ), the concentration of A decreases by  $aX$  (i.e.,  $[A]_t = [A]_0 - aX$ ) and the concentration of B decreases by  $bX$  (i.e.,  $[B]_t = [B]_0 - bX$ ). Similarly, the concentrations of the products C and D increase by  $cX$  and  $dX$ , respectively (i.e.,  $[C]_t = [C]_0 + cX$  and  $[D]_t = [D]_0 + dX$ ) after some time  $t$ . Thus, upon normalization, the rate expressed in Equations 1 and 2 can be shown to reduce to Equation 3.

$$\text{Rate} = +\frac{dX}{dt} \quad (3)$$

The *law of mass action* relates these experimentally determined rates to the concentration of all of the reacting species. This law states that, at a given temperature, the rate of the reaction is at each instant proportional to the product of the concentration of each of the reacting species raised to a power equal to the number of molecules of each of these species participating in the process. Accordingly, the law of mass action applied to the above reaction gives the following rate equation,

$$\text{Rate} = k[A]^n[B]^m \quad (4)$$

where the proportionality constant  $k$  (referred to as the *specific rate constant* or as the *rate constant*) should be independent of the concentrations of all chemical species at a given temperature. The exponents,  $n$  and  $m$ , are known as the *order of the reaction* with respect to the components A and B, respectively; their sum represents the overall order of the reaction.

Equation 4 can be applied to each individual elementary process which makes up a reaction. In such cases, the exponents of each of the reacting species are equal to their stoichiometric coefficients for the balanced equation representing the processes. These exponents indicate the number of molecules/atoms of each reacting species that participate in a simultaneous collision to form the reactants with the rate of the process controlled by the specific rate constant,  $k$ , during that specific elementary process. It is interesting to note that statistically collisions involving more than two bodies are extremely rare and collisions involving more than three bodies are nearly impossible; the specific rate constants for these rare processes will be very small and the reactions very slow.

It is important to note that for a *net chemical reaction*, which is the sum of all of the elementary processes, there is no requirement that the order of the reaction with respect to a chemical species be identical to its stoichiometric coefficient indicated in the net chemical equation. This is because chemical species that appeared as both reactants and products in the various elementary processes have been removed to create a balanced net equation. Further, it may be necessary for some elementary processes to occur more than once in order to arrive at net balanced equation. Additionally, some elementary processes may be reversible (i.e., products revert to reactants) during an overall chemical reaction. Therefore, unlike for elementary processes in which the species which enter into Equation 4, can only be reactants, Equation 4 for a net chemical reaction can include products as well as reactants. However, a proper rate equation for a net chemical equation should not contain any chemical species that exists as an intermediate during a chemical reaction.

It should be noted that unless the stoichiometric coefficient of the reactant or product that is being followed to determine the rate of the reaction is *unity* (one), the rate of the reaction is not equivalent to the change in the concentration of the chemical species with respect to time. For the case where there is only one chemical reactant, which has a stoichiometric coefficient that is greater than one, authors of articles and textbooks on kinetics often base the reaction rate only on the disappearance of the reactant without accounting for the stoichiometry. When this occurs, the resulting rate constant will be greater than the true rate constant by a factor equal to the stoichiometric coefficient. Thus, care must be taken to determine how the rates of reactions were determined when comparing rate constants of a reaction.

## FIRST-ORDER REACTIONS

When the rate of a reaction is proportional to the first power of the concentration of a reactant, the rate equation is given by

$$\frac{dX}{dt} = k[A]_t = k([A]_0 - aX) \quad (5)$$

where  $a$  represents the stoichiometric coefficient for reactant A. Rearrangement of Equation 5 gives

$$\int \frac{dX}{[A]_0 - aX} = k \int dt \quad (6)$$

When Equation 6 is integrated over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the following first-order integrated rate equation is obtained:

$$[A]_t = [A]_0 e^{-akt} \quad (7)$$

Figure 17-1 shows a typical plot where reactant A exponentially decays to products according to Equation 7. The rate of the reaction - that is - the negative value of the tangent of this curve at any time, decreases with time as the concentration of the reactant decreases. Equation 7 can be linearized by rearrangement to give Equation 8.

$$\ln[A]_t = -akt + \ln[A]_0 \quad (8)$$

Equation 8 suggests that a plot of the natural logarithm of the concentration of the reactant as a function of time should give a linear plot with a slope equal to  $-ak$  and a y-intercept equal to the natural logarithm of the initial concentration of the reactant (Fig 17-2). Commonly, a plot of the common logarithm of the concentration versus time is found in the literature for first-order reactions. In this case, according to Equation 9, the slope of this line would be equal to  $-ak/2.303$ , and the y-intercept would be equal to the common logarithm of the initial concentration of the reactant.

$$\log[A]_t = -\frac{akt}{2.303} + \log[A]_0 \quad (9)$$

**Figure 17-1.** Plot of concentration of A versus time for a first-order reaction.

**Figure 17-2.** Plot of natural logarithm of the concentration of A versus time for a first-order reaction.

In such a case, the rate constant,  $k$ , for a first-order reaction has a unit of reciprocal time (e.g.,  $s^{-1}$ ).

Sometimes it may be necessary to determine the rate constant  $k$  from only two concentrations of the reactant,  $[A]_1$  and  $[A]_2$ , obtained at two different times,  $t_1$  and  $t_2$ , in which case Equation 10 may be used.

$$k = \frac{1}{a(t_2 - t_1)} \ln \frac{[A]_1}{[A]_2} \quad (10)$$

Another useful method for determining  $k$  is the fractional-life method, of which the half-life method is the most common. The *half-life method* involves measuring the time ( $t = t_{1/2}$ ) that it takes for half of the initial concentration of the reactant to undergo reaction:  $[A]_t = [A]_0/2$ . Substituting these values into Equation 7 and rearranging to solve for  $k$  yields

$$k = \frac{\ln 2}{at_{1/2}} \quad (11)$$

It is apparent from Equation 11 that the half-life period for first-order reactions is constant and independent of the amount of reactant present. Thus, half of the initial concentration of the reactant undergoes a reaction during the first half-life period, leaving 50% of the original concentration unreacted. During the second half-life period, which is identical in time to the first half-life period for a first-order reaction, half of the reactant remaining after the first half-life period reacts, leaving 25% of the initial concentration of the reactant unreacted. Similarly, after the third half-life period, 12.5% of the initial reactant would remain unreacted. After 10 first-order, half-life periods, only 0.098% of the original reactant remains unreacted. For precise studies, the rate of disappearance of a reactant should be followed over at least two or three half-life periods.

In some drug stability studies, it is necessary to determine the time that it takes for the loss of 10% of the drug, leaving 90% of the original drug concentration; that is,  $[A]_t = 0.90[A]_0$  at  $t = t_{0.90}$ . This time can be determined with the knowledge of the rate constant and the stoichiometric coefficient  $a$  by substituting these expressions into Equation 7 and rearranging to yield

$$t_{0.90} = \frac{\ln 0.90}{ak} \quad (12)$$

A common example of a chemical reaction that follows first order chemical kinetics is the decomposition of liquid hydrogen peroxide to produce molecular oxygen and liquid water:

It should be noted that the “ $a$ ” term, representing the stoichiometric coefficient for hydrogen peroxide is 2 and has to be used in all of the above kinetic equations. Because this is a first-order process, the rate of decomposition of hydrogen peroxide is directly proportional to the hydrogen peroxide concentration.

First-order rate processes are not restricted to chemical reactions. The passive diffusion of drugs across biological membranes and processes of drug absorption, distribution, metabolism, and excretion often can be shown to occur at rates proportional to the concentration of a drug, and thus can be described as first-order rate processes. The rate of growth and the rate of killing or inactivation of microorganisms by heat or chemical agents usually follow first-order kinetic processes. Radioactive decay always follows first-order kinetics.

## SECOND-ORDER REACTIONS

There are two forms of second-order reactions. For the first case, it is assumed that the rate of reaction is proportional to the concentration of reactant A raised to the power of 2 - that is, the reaction is second order with respect to A, in which case the rate equation takes the form

$$\frac{dX}{dt} = [A]_t^2 = ([A]_0 - \alpha X)^2 \quad (13)$$

where  $\alpha$  represents the stoichiometric coefficient of the reactant in the net equation. Equation 13 can be rearranged to give

$$\int \frac{dX}{([A]_0 - \alpha X)^2} = k \int dt \quad (14)$$

When Equation 14 is integrated over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the following second-order integrated rate equation is obtained.

$$\frac{1}{[A]_t} = akt + \frac{1}{[A]_0} \quad (15)$$

It should be noted that because the stoichiometry was taken into account in this derivation, the stoichiometric coefficient,  $\alpha$ , has been incorporated into Equation 15. If the rate of reaction was determined solely on the disappearance of reactant A without considering the stoichiometry (i.e.,  $\alpha$  is assumed to be equal to 1), then the rate constant for this reaction would be twice as large as the true rate constant. The reader should be aware of this situation as this occurs quite frequently in the literature.

The decomposition of hydrogen iodide is a second-order reaction; in the gaseous state, hydrogen iodide forms hydrogen gas and molecular iodine according to the reaction

The integrated rate expression for this reaction follows the form given by Equation 15. With the value of "a" equal to 2.

Equation 15 suggests that, for a second-order reaction, if the reciprocal of the concentration of reactant A is plotted as a function of time, the slope of the line is equal to the rate constant  $2k$ , and the y-intercept is the reciprocal of the initial

**Figure 17-3.** Plot of the reciprocal of the concentration of A versus time for a second-order reaction.

concentration of A (Figure 17-3). Rearranging Equation 15 and solving for  $k$  yields

$$k = \frac{1}{2t} \left( \frac{[A]_0 - [A]_t}{[A]_0[A]_t} \right) \quad (16)$$

The rate constant for second-order reactions has units of reciprocal concentration and seconds (e.g.,  $\text{M}^{-1}\text{s}^{-1}$ ).

The second type of a second-order reaction occurs if the rate of the reaction is proportional to the product of the concentrations of two reactants, each raised to the power of 1, that is, first order with respect to both reactants. Equation 17 shows the rate equation for such a reaction.

$$\frac{dX}{dt} = [A]_t[B]_t = ([A]_0 - \alpha X)([B]_0 - bX) \quad (17)$$

The stoichiometric coefficients of the reactants A and B are represented by  $\alpha$  and  $b$ . Equation 17 can be arranged to give the following:

$$\int \frac{dX}{([A]_0 - \alpha X)([B]_0 - bX)} = k \int dt \quad (18)$$

When Equation 18 is integrated over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the following second-order integrated rate equation is obtained:

$$\ln \frac{[A]_t}{[B]_t} = (b[A]_0 - a[B]_0)kt + \ln \frac{[A]_0}{[B]_0} \quad (19)$$

This suggests that if the left side of Equation 19 is plotted against time, the slope of the line would be equal to  $(b[A]_0 - a[B]_0)k$  and the y-intercept is equal to the natural logarithm of the ratio of the initial concentrations of reactants A and B. Equation 19 does not apply if the initial concentrations of the two reactants consist of a stoichiometric mixture (i.e.,  $b[A]_0$  equals  $a[B]_0$ ) in which case, Equation 18 reduces to a form similar to Equation 14 as shown in Equation 14b.

$$\frac{b}{a} \int \frac{dX}{([A]_0 - \alpha X)^2} = k \int dt \quad (14b)$$

for which the integrated rate equation for this system reduces to Equation 15b.

$$\frac{1}{[A]_t} = \frac{a^2}{b} kt + \frac{1}{[A]_0} \quad (15b)$$

An example of a second-order reaction in which two reactants are involved is the saponification of an ester, such as ethyl acetate, in alkaline solution:

The course of this reaction may be followed by determining, by titration at specified times, the concentration of hydroxide ions remaining unreacted during the course of the reaction. This information and the initial concentrations of the ethyl acetate and hydroxide can be used to determine the rate constant in Equation 19.

Fractional-life methods can be applied readily to second-order reactions for the case when the order of the reaction with respect to one reactant is 2, or for the case when the initial concentrations of each of two reactants are equal when the order with respect to each reactant is 1. For example, the half life of a second-order reaction is given by Equation 20.

$$t_{1/2} = \frac{1}{k[A]_0} \quad (20)$$

Unlike the half-life period for a first-order reaction, the half-life period for a second-order reaction is not constant, but rather is proportional to the reciprocal of the initial concentration of reactant. This means that the half-life period increases as a second-order reaction proceeds with time; thus, it takes twice as long to deplete a second-order reactant from 50 to 25% as it did to deplete the reactant from 100 to 50%.

### THIRD-ORDER REACTIONS

Except for in a condensed phase system, true third-order reactions are rare, as they require a simultaneous three-body collision of chemical species. There are a number of ways in which third-order reaction can occur—from a combination of three different chemical entities, for which the order of the reaction with respect to each of these is 1, to the simplest case in which three identical substances react, for which the order of the reaction with respect to that species is three. For the latter case, assuming the stoichiometric coefficient of the single reacting entity  $A$  is 3, then the rearranged rate equation is given by Equation 21.

$$\int \frac{dX}{([A]_0 - 3X)^3} = k \int dt \quad (21)$$

Upon integration of Equation 21 over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the following third-order integrated rate equation is obtained.

$$\frac{1}{[A]_t^2} = 6kt + \frac{1}{[A]_0^2} \quad (22)$$

Again, it should be noted, that if the stoichiometry was not taken into account and the *rate* was only determined by the rate of disappearance of reactant  $A$ , then Equation 22 would have 2 for the coefficient of  $kt$  instead of 6 and the value for the rate constant would be three times the value of the rate constant in Equation 22.

The equation for the half-life period for the case of Equation 22 is given by

$$t_{1/2} = \frac{1}{2k[A]_0^2} \quad (23)$$

Another type of a third-order reaction occurs when the rate of the reaction is proportional to the product of the concentrations of two reactants, one raised to the power of 1 and the other raised to the power of 2; it is first order with respect to one reactant and second order with respect to the other reactant. Equation 24 shows the rate equation for such a reaction.

$$\frac{dX}{dt} = [A]_t^2[B]_t = ([A]_0 - \alpha X)^2([B]_0 - bX) \quad (24)$$

If the stoichiometric coefficients,  $\alpha$  and  $b$ , are both equal to 1, then Equation 24 can be rearranged and integrated over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ). The rate constant from this resulting equation is given by

$$k = \frac{1}{t} \frac{1}{([B]_0 - [A]_0)} \frac{[A]_0 - [A]_t}{[A]_0[A]_t} \frac{1}{([B]_0 - [A]_0)^2} \ln \frac{[A]_t[B]_0}{[B]_t[A]_0} \quad (25)$$

However, if the stoichiometric coefficients are  $\alpha = 2$  and  $b = 1$ , then when Equation 24 is rearranged and integrated over the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the rate constant is determined by Equation 26.

$$k = \frac{1}{t} \frac{1}{(2[B]_0 - [A]_0)} \frac{[A]_0 - [A]_t}{[A]_0[A]_t} \frac{1}{(2[B]_0 - [A]_0)^2} \ln \frac{[A]_t[B]_0}{[B]_t[A]_0} \quad (26)$$

The rate constant for third-order reactions has units of reciprocal of the square of concentration per second (e.g.,  $M^{-2}s^{-1}$ ).

One well known example of a third order reaction that follows Equation 24 is the cyanide catalyzed dimerization of benzaldehyde,  $\text{PhCHO}$ , to form benzoin,  $\text{PhCH(OH)C(O)Ph}$ :

Whereas this reaction appears to be third order, the reaction mechanism is proposed to occur through several elementary processes in which the net reaction appears to be second order with respect to the benzaldehyde and first order with respect to the cyanide catalyst. It should be noted that the individual elementary processes are often simple first and/or second order reactions, which when combined to give a net reaction, gives the appearance that the net reaction is a higher order reaction. Care must be taken not to interpret reactions, such as this

benzoin condensation, that requires an unlikely elementary process in which all three reactants come together in the rate limiting step.

Because of the rigors of the mathematics, when a third-order reaction is suspected, experimental conditions are often chosen so as to simplify the calculations. For example, for the third-order reaction in which the stoichiometric coefficients of the two reacting species are  $a = 2$  and  $b = 1$ , such as that which led to the development of Equation 26, if the experimental conditions are set such that  $[A]_0 = 2[B]_0$ , it will lead to a much simpler integrated rate equation.

### PSEUDO-ORDER REACTIONS

For some reactions, the rate of the reaction may be independent of the concentration of one or more of the reacting species over a wide range of concentrations. This may occur under these conditions:

1. One or more of the reactants enters into the rate equation in great excess compared to the others.
2. One of the reactants is a catalyst.
3. One or more of the reactants is constantly replenished during the course of a reaction.

If this happens, the constant concentration term(s) in the rate equation is combined with the rate constant to give an *apparent rate constant*. For example, if the concentration of  $A$  in Equation 4 remains constant, then Equation 4 can be rewritten as

$$\text{Rate} = (k[A]^n)[B]^m = k_{\text{app}}[B]^m \quad (27)$$

where the apparent rate constant,  $k_{\text{app}}$  (sometimes referred to as the *pseudo-order rate constant*) now depends on the concentration of  $A$  raised to its power,  $n$ . Unfortunately, no information about  $n$ , the order of reaction with respect to  $A$ , can be determined from a single experiment. Rather, to gain an understanding of  $n$ , multiple experiments must be performed where the concentration of  $A$  is varied. A plot of the natural logarithm of  $k_{\text{app}}$  versus the natural logarithm of the concentration of  $A$  will give a slope that is equal to  $n$ .

In 1850, Wilhelmy performed the first quantitative kinetics study by following the rate of hydrolysis (inversion) of sucrose to glucose and fructose, according to the reaction:

Wilhelmy found that this reaction followed the rate equation:

$$-\frac{d[\text{C}_{12}\text{H}_{22}\text{O}_{11}]}{dt} = k_{\text{app}}[\text{C}_{12}\text{H}_{22}\text{O}_{11}] \quad (28)$$

which, upon rearrangement and integration, gives Equation 29.

$$\ln[\text{C}_{12}\text{H}_{22}\text{O}_{11}] = -k_{\text{app}}t + \ln[\text{C}_{12}\text{H}_{22}\text{O}_{11}]_0 \quad (29)$$

This reaction is now known to be a second-order reaction, as it is first order with respect to both sucrose and water. As for most typical aqueous solutions, the molar concentration of water (approximately 55.5 moles of water per liter) greatly exceeds the concentration of the solute sucrose. Therefore, even at moderate concentrations of sucrose, there is only a minor change in the molar concentration of water and the concentration of the solvent is practically constant over the course of the reaction. This allows the concentration of water to be incorporated into the apparent rate constant and the reaction appears to be first order.

As another example, if component  $A$  reacts in aqueous solution to go to product  $B$ , according to the first-order rate equation given by Equation 5 and the stoichiometric coefficient  $a$  is 1 (unity), then the concentration of  $A$  as a function of time should follow the exponential form of the integrated rate equation given by Equation 7. However, if this reaction occurs in a saturated solution of  $A$  (i.e.,  $[A]_{\text{sat}}$ ) in the presence of excess solid  $A$ , and if the rate of converting solid  $A$  to aqueous  $A$  is

greater than the rate of reaction in solution, then the rate of disappearance of A is given by:

$$\frac{dX}{dt} = k[A]_{\text{sat}} = k_{\text{app}} \quad (30)$$

If Equation 30 is rearranged and integrated between the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ) and defining  $[B]_t = X$ , then the following zero-order rate equation is obtained,

$$[B]_t = k_{\text{app}} t \quad (31)$$

which shows that as long as the solution remains saturated with A, the formation of B will occur at a constant rate. As an example, if a compound for which decomposition in solution is first order is present in excess of its maximum solubility (a suspension), the concentration of the reactant in solution will be invariant so long as there is excess solid reactant present. The kinetics of such a system would then follow Equation 30.

First- and second-order reactions are by far the most common types of rate processes encountered regarding drug stability. If a reaction is of higher order than first order, it often is convenient to adjust experimental conditions so that the concentrations of all but one of the reactants remain constant throughout the experiment. If, for example, the concentration of hydroxide ion in the saponification of an ester is in great excess of the concentration of ester, or if a buffer system is employed to control hydroxide-ion concentration, then the concentration of hydroxide ion essentially is invariant throughout the course of the experiment. The observed rate of the reaction, therefore, depends only on the changing concentration of the ester, and the reaction is said to be *pseudo first-order*. The apparent first-order rate constant,  $k_{\text{app}}$ , thus obtained is  $k[\text{OH}^-]$  and, of course, is different for each hydroxide-ion concentration. The actual rate constant,  $k$ , can be obtained easily by dividing the experimentally determined apparent first-order rate constant,  $k[\text{OH}^-]$ , by the concentration of hydroxide ion maintained throughout the study.

In the study of complex reactions, it is often desirable to use this approach of maintaining the concentration of all but one of the reactants constant to facilitate determining the dependency of the reaction rate on each of the reactants in turn.

## MORE COMPLEX REACTIONS

Many chemical reactions do not follow the simple reaction kinetics listed above, but rather they often consist of two or more elementary processes that may lead to more complicated rate equations. For example, comparison of experimental measurements of the rate of the disappearance of the reactants and the appearance of the products may indicate that the reactants must be forming one or more intermediates before proceeding to form the products. Often chemical reactions proceed reversibly to form products before an equilibrium is established. There are many cases where the reactants simultaneously proceed through different mechanisms to form two or more products. These situations can lead to negative or non-integer orders of reactions with respect to reactants and products within the rate equation. Quite often, a series of experiments must be performed in which certain conditions are controlled in order to establish the order of the reaction of individual species involved in the chemical reaction before an overall rate equation can be established. The next several sections will look as some of the more common complex reactions.

## REVERSIBLE REACTIONS

Many reactions are known to be reversible where the reactants go to form products but the products will reversibly revert back to reactants. The simplest example of this is in the case where reactant A follows a first-order kinetic process with a forward rate constant,  $k_f$ , to produce product B.

However, product B then follows a first-order rate process with a reverse rate constant,  $k_r$ , to reform reactant A.

Because, during the course of this reaction, reactant A is being simultaneously depleted and formed, the rate at which reactant A disappears is related to the forward and reverse rates according to Equations 32 and 33:

$$-\frac{d[A]_t}{dt} = \frac{d[A]_{\text{forward}}}{dt} - \frac{d[A]_{\text{reverse}}}{dt} \quad (32)$$

or

$$-\frac{d[A]_t}{dt} = k_f[A]_t - k_r[B]_t \quad (33)$$

If the initial concentration of B is zero, then at time  $t = 0$  (initially) the rate equation is given solely by the forward rate equation. As the reaction proceeds, the reverse rate equation begins to contribute more and more substantially to the overall rate equation. Finally, a point will be reached at which the rate of the forward reaction is equal to the rate of reverse reaction and the overall rate is equal to 0. This is defined as a *dynamic equilibrium* and the concentration equilibrium constant,  $K_c$ , given by Equation 34, is equal to the ratio of the forward and reverse rate constants, where

$$K_c = \frac{[B]_{\text{eq}}}{[A]_{\text{eq}}} = \frac{k_f}{k_r} \quad (34)$$

where  $[B]_{\text{eq}}$  and  $[A]_{\text{eq}}$  are the equilibrium concentrations of the product and reactant, respectively.

The rate equation expressed in Equation 33 can be rewritten to give

$$\frac{dX}{dt} = k_f([A]_0 - X) - k_r([B]_0 - X) \quad (35)$$

Rearrangement and integration of Equation 35 between the limits of  $t = 0$  (at which  $X = 0$ ) to  $t = t$  (at which  $X = X$ ), the following expressions for the concentrations of A and B as a function of time are obtained:

$$[A]_t = \frac{(k_f[A]_0 - k_r[B]_0) \exp[-(k_f + k_r)t] + k_r([A]_0 + [B]_0)}{(k_f + k_r)} \quad (36)$$

and

$$[B]_t = \frac{k_f([A]_0 + [B]_0) - (k_f[A]_0 - k_r[B]_0) \exp[-(k_f + k_r)t]}{(k_f + k_r)} \quad (37)$$

## SIMULTANEOUS REACTIONS

Another very common reaction is when the reaction of one or more reactants lead to the formation of multiple products through different mechanistic pathways, each with characteristic rates:

and

For the case in which both reaction pathways are first order, then the rate of disappearance of reactant A is then given by Equation 38.

$$-\frac{d[A]_t}{dt} = k_1[A]_t + k_2[A]_t = (k_1 + k_2)[A]_t \quad (38)$$

Rearrangement and integration of Equation 38 gives:

$$[A]_t = [A]_0 \exp[-(k_1 + k_2)t] \quad (39)$$

Because the rate of formation of product B is given by

$$\frac{d[B]_t}{dt} = k_1[A]_t \quad (40)$$

then assuming that the initial concentration of B is 0, rearranging and integrating, and substituting Equation 39 into Equation

40 yields the following expression for the concentration of B as a function of time:

$$[B]_t = \frac{k_1[A]_0}{(k_1 + k_2)}(1 - \exp[-(k_1 + k_2)t]) \quad (41)$$

Using similar arguments, the concentration of C as a function of time is given by Equation 42.

$$[C]_t = \frac{k_2[A]_0}{(k_1 + k_2)}(1 - \exp[-(k_1 + k_2)t]) \quad (42)$$

It is of particular interest to note that if Equation 41 is divided by Equation 42, the ratio of the concentration of the products at any time is given by the ratio of the rate constants.

$$\frac{[B]_t}{[C]_t} = \frac{k_1}{k_2} \quad (43)$$

An example of this type of simultaneous reaction is the reaction of phenol with nitric acid to form both ortho- and para-nitrophenol through two simultaneous first-order reaction pathways. The relative concentrations of these two products are found to be given by Equation 43.

It is clear that if a kinetic experiment was performed without any *a priori* knowledge that the reaction is a simultaneous reaction, there is a danger that only the disappearance of a reactant or the appearance of only one of the products may lead to a faulty conclusion of the reaction mechanism. Care must be taken to attempt to identify and account for all of the chemical species in a chemical reaction to ensure that a proper rate mechanism is obtained.

### CONSECUTIVE REACTIONS

One of the more common complex reactions is when a reactant decays through a series of consecutive reactions, forming one or more intermediates before forming a product. A simple case of a consecutive reaction is when reactant A proceeds through a first-order process to intermediate B which then decays to product C through another first-order process.

For cases such as this, it is often convenient to consider the situation in which the initial concentrations of B and C are 0 and the sum of the concentrations of A, B, and C at any time is equal to the initial concentration of the reactant A. In this case, the rate of disappearance of A is given by Equation 44 and the rate of appearance of product C is given by Equation 45.

$$-\frac{d[A]_t}{dt} = k_1[A]_t \quad (44)$$

and

$$+\frac{d[C]_t}{dt} = k_2[B]_t \quad (45)$$

The derivative of the concentration of the intermediate B with respect to time consists of the rate of formation of B from the product A and the disappearance of B as it proceeds to product C, as shown by

$$\frac{d[B]_t}{dt} = k_1[A]_t - k_2[B]_t \quad (46)$$

Upon integration and rearrangement of Equation 44, the concentration of reactant A as a function of time can be expressed by

$$[A]_t = [A]_0 \exp(-k_1 t) \quad (47)$$

It should be noted that Equations 45 and 46 are not considered to be valid rate equations because, by convention, the concentration of an intermediate may not appear in a final rate equation. Therefore, an expression for the concentration of B as a function of time in terms of only the reactant or product must be developed. Substituting Equation 47 into Equation 46, rearranging and integrating yields the following expression for the concentration of B as a function of time.

$$[B]_t = \frac{k_1[A]_0}{(k_2 - k_1)}(\exp[-k_1 t] - \exp[-k_2 t]) \quad (48)$$

Equation 48 can be substituted into Equations 45 and 46 to give appropriate rate expressions. Then Equation 46 can be rearranged and integrated to give an expression for the concentration of C as a function of time.

$$[C]_t = [A]_0 \left( 1 - \frac{k_2 \exp[-k_1 t]}{(k_2 - k_1)} \right) + \frac{k_1 \exp[-k_2 t]}{(k_2 - k_1)} \quad (49)$$

## EFFECTS ON REACTION RATE

### TEMPERATURE

The application of heat to increase the rate of a chemical reaction is a common laboratory procedure. The rate of most solvolytic reactions of pharmaceuticals is increased roughly 2- to 3-fold by a 10°C increase near room temperature. In 1889, Arrhenius noted that the variation with temperature of the rate constant of chemical reactions could be expressed by

$$k = A \exp[-E_a / RT] \quad (50)$$

where, according to collision theory,  $E_a$  is the Arrhenius activation energy (i.e., the difference between the average energy of reactive molecules and the minimum energy required for reactants to proceed to products); the quantity  $\exp[-E_a/RT]$  is the Boltzmann factor, which represents the fraction of molecules having energies greater than or equal to  $E_a$ ; the pre-exponential term  $A$  is a constant called the frequency factor;  $R$  is the gas constant (8.314 joule/mol-K or 1.987 cal/mol-K); and  $T$  is the absolute temperature. The Arrhenius equation can be expressed in a linear form according to Equation 51.

$$\ln k = -\frac{E_a}{R} \frac{1}{T} + \ln A \quad (51)$$

Equations 50 and 51 are valid so long as the reaction mechanism does not change over the temperature range studied. A plot of the natural logarithm of the rate constant versus the reciprocal of the absolute temperature in which the rate constants are determined gives a negative slope that is equivalent to  $-E_a/R$  (Figure 17-4). If a nonlinear plot is obtained, a thermally induced change in the reaction mechanism has probably occurred.

Differentiation of Equation 51 with respect to temperature, and then integrating between the limits of  $k_2$  and  $k_1$  at temperatures between  $T_2$  and  $T_1$  yields

$$\ln \frac{k_2}{k_1} = \frac{E_a}{R} \left( \frac{T_2 - T_1}{T_1 T_2} \right) \quad (52)$$

This equation allows  $E_a$  to be calculated for a reaction when the rate constants are known at two temperatures, or the rate constant at one temperature to be calculated if  $E_a$  and the rate constant at another temperature are known.

Figure 17-4. Variation of the rate constant with reciprocal absolute temperature, illustrating the Arrhenius equation.

Most solvolytic reactions of pharmaceuticals exhibit activation energies in the range of 8 to 20 kcal/mol. Using Equation 51 and the appropriate activation energy, one readily can calculate that a reaction having an activation energy of 8 kcal/mol would show an approximately 1.5-fold increase in  $k$  for a temperature increase from 25° to 35°; a reaction having an activation energy of 20 kcal/mol would show a 3-fold increase in  $k$  for a similar temperature increase.

When two molecules undergo chemical interaction, it is reasonable to suppose that they first must collide and then, if conditions are right, undergo a rearrangement of certain electrons to form the bonds characteristic of the new molecules. However, not all collisions can cause a chemical change, or else chemical reactions would occur with great rapidity because collision frequencies are very high. Whereas molecules or atoms must first collide if a reaction is to occur, the colliding molecules may not have an energy greater than or equal to the activation energy sufficient to overcome the mutual repulsion of the interacting molecules and enable them to approach close enough to each other to effect certain bond ruptures and/or establish new bonds characteristic of the products. The greater this energy requirement will result in a smaller proportion of colliding molecules that will have energies sufficient to cause a reaction, which, in turn, will lead to slower reaction rates. In the Arrhenius equation,  $A$  is a factor related to frequency of collisions, and the term  $\exp[-E_a/RT]$  expresses the probability that the colliding molecules will have sufficient energies sufficient to cause a reaction at temperature  $T$ . The concept of energy of activation, in relationship to the energy of the reactants and of the products, is illustrated in Figure 17-5.

Eyring, in his transition state theory, proposed that reactants must proceed through an activated complex before proceeding to products. This is demonstrated by the reaction

where the reactants are considered to be in a rapid equilibrium with the activated complex or transition state, represented by  $[AB]^*$ , which then decays to products by a first-order process, according to the rate equation

$$\text{Rate} = k'[AB]^* \quad (53)$$

However, as Equation 53 contains the concentration of the activated complex, an intermediate, it is not a valid rate equation and an expression in terms which include only the reactants or products must be substituted for this expression. Because the activated complex is in equilibrium with the reactants, the concentration of the activated complex can be given by

$$[AB]^* = K^*[A][B] \quad (54)$$

where  $K^*$  is the equilibrium constant. Substituting Equation 54 into Equation 53 yields

$$\text{Rate} = K^*k'[A][B] = k[A][B] \quad (55)$$

**Figure 17-5.** Relation between activation energy and energy levels of reactants, products and activated complex.

where  $k$  is equal to  $K^*k'$  and Equation 55 is a proper rate equation. Eyring was able to show that the rate constant,  $k'$ , of any reaction is given by the expression

$$k' = \frac{RT}{N_a h} K^* \quad (56)$$

where  $R$  is equal to 8.314 ergs/mol-K,  $N_a$  is Avogadro's number, and  $h$  is Planck's constant, which is equal to  $6.625 \times 10^{-27}$  erg-sec.  $K^*$  can be related to the thermodynamic parameters  $\Delta G^*$ ,  $\Delta H^*$ , and  $\Delta S^*$  through the equation

$$K^* = \exp(-\Delta G^*/RT) = \exp(T\Delta S^* - \Delta H^*)/RT \quad (57)$$

If Equation 57 is substituted into Equation 56, after it has been divided by the absolute temperature, the following linear equation is obtained.

$$\ln \frac{k'}{T} = -\frac{\Delta H^*}{R} \frac{1}{T} + \frac{\Delta S^*}{R} + \ln \frac{R}{N_a h} \quad (58)$$

Thus, the thermodynamics of the formation of the activated complex can be determined from a plot of the natural logarithm of the ratio of the rate constant to absolute temperature versus the reciprocal absolute temperature.

## CATALYSIS

In catalytic reactions, a molecule, called a catalyst, interacts with a reactant in a series of elementary processes in such a fashion as to lower the activation energy barrier (*i.e.*,  $E_a$  in Figure 17-5) of an uncatalyzed reaction. This change in mechanism causes the catalyzed reaction to run faster without changing the relative energy levels of either the reactants or products. During a catalytic reaction, the catalyst reacts with a reactant to form an intermediate that undergoes additional reaction(s) to form the product and the original catalytic molecule. Thus, while the catalyst is both consumed and produced in several elementary processes, there is no net change in the concentration of the catalyst during a catalyzed reaction but there is usually a substantial change in the rate in which the reaction occurs.

Whereas there are several types of catalysis, such as homogeneous and heterogeneous catalysis, and autocatalysis, only a few general examples will be discussed here. Additional information about catalysis can be found in some of the references cited in the attached bibliography.

### SPECIFIC ACID AND SPECIFIC BASE CATALYSIS

The terms *specific acid catalysis* and *specific base catalysis* refer to catalysis by the hydronium or hydrogen ion, and by the hydroxide ion, respectively. For example, if the rate of hydrolysis of an ester, such as ethyl acetate, is studied at a constant pH in a strongly buffered solution, the rate of disappearance of the intact ester will be an apparent first-order reaction. If the reaction is studied in solutions buffered at several different pH values in a sufficiently acid pH region, a different apparent first-order rate constant will be observed for each pH value. The observed rate actually depends on the concentration of both the ester and hydrogen ion and, therefore, is a second-order reaction that appears to be a pseudo first-order reaction at the constant hydrogen-ion concentration in the buffer. Therefore, the observed first-order rate constant,  $k_{\text{obs}}$ , is proportional to the hydrogen ion concentration of the buffer system as shown by Equation 59.

$$k_{\text{obs}} = k_{\text{acid}}[H^+] \quad (59)$$

Taking the logarithm of Equation 59 yields

$$\log k_{\text{obs}} = \log k_{\text{acid}} + \log [H^+] \quad (60)$$

this upon applying the definition of pH yields

$$\log k_{\text{obs}} = \log k_{\text{acid}} - \text{pH} \quad (61)$$

Equation 61 suggests that a plot of  $\log k_{\text{obs}}$  versus pH will be linear with a slope of -1 with a y-intercept equal to the term  $\log k_{\text{acid}}$ .

Similarly, if the same hydrolysis reaction is studied in buffered solutions at several pH values in a sufficiently alkaline region of the pH scale, the observed apparent first-order rate constants will be found to vary with hydroxide-ion concentration:

$$k_{\text{obs}} = k_{\text{base}}[\text{OH}^-] \quad (62)$$

and

$$\log k_{\text{obs}} = \log k_{\text{base}} + \log[\text{OH}^-] \quad (63)$$

However, the hydroxide ion concentration is related to the hydrogen ion concentration through the ionization constant of water,  $K_w$ , and Equation 61 becomes

$$\log k_{\text{obs}} = \log k_{\text{base}} + \log K_w + \text{pH} \quad (64)$$

Therefore, a plot of  $\log k_{\text{obs}}$  versus pH in a heavily buffered alkaline solution would yield a straight line with a slope of +1 and a y-intercept equal to the term  $\log k_{\text{base}} + \log K_w$ .

Because of the equilibrium that exists between hydroxide and hydronium ions in aqueous solutions, each of these ions exists at all values of pH and the observed rate constant is actually given by the sum of Equations 59 and 62.

$$k_{\text{obs}} = k_{\text{acid}}[\text{H}^+] + k_{\text{base}}[\text{OH}^-] \quad (65)$$

The complete logarithm  $k_{\text{obs}}$  versus pH profile would be similar to that illustrated in Figure 17-6 for the hydrogen ion and hydroxide ion (specific acid and specific base) catalyzed hydrolysis of the ester atropine.<sup>2</sup> At relatively low values of pH the acid-catalyzed hydrolysis predominates; at relatively high values of pH the base-catalyzed hydrolysis predominates. The pH at which the minimum rate of hydrolysis is observed is a function of the relative magnitude of the specific rate constants  $k_{\text{acid}}$  and  $k_{\text{base}}$ . In the atropine example, the minimum rate of hydrolysis is at pH of 3.7, which indicates that  $k_{\text{base}} > k_{\text{acid}}$ . If  $k_{\text{base}}$  equals  $k_{\text{acid}}$ , then, at 25°, the expected minimum rate of the reaction would be expected to occur at pH 7.

A reaction may be catalyzed not only by hydrogen ion and hydroxide ion, but also by other Brønsted acids or bases such as the solvent water. This is referred to as *general acid/base catalysis*. In this case, the observed rate constant is given by

$$k_{\text{obs}} = k_{\text{water}} + k_{\text{acid}}[\text{H}^+] + k_{\text{base}}[\text{OH}^-] \quad (66)$$

where  $k_{\text{water}}$  is a pseudo-order rate constant that has the concentration of water, which is in large excess, incorporated into it. Figure 17-7 shows how a plot of the logarithm  $k_{\text{obs}}$  versus pH might appear in such a case. The flat region, where the rate of reaction apparently is not pH dependent, is the region where

**Figure 17-6.** Apparent first-order rate of hydrolysis of atropine as a function of pH at 30°C. The reaction is an illustration of specific hydrogen and hydroxide-ion catalysis. (Courtesy Kondritzer AA, Zvirbils P. Stability of atropine in aqueous solution. *J APHA Sci Ed* 1957; 46: 531-5).

**Figure 17-7.** Apparent first-order rate of decomposition as a function of pH for a hypothetical case where  $k_{\text{H}^+} = k_{\text{OH}^-} = 0.1$ ,  $k_{\text{H}_2\text{O}} = 1 \times 10^{-5}$ . The uncatalyzed reaction predominates in the pH region 5 to 9.

the solvent is much more important as a catalyst than either the hydrogen or hydroxide ions.

In some cases, compounds may be weak acids or weak bases in solution and will be in equilibrium with its conjugate acid or base form with the relative concentration of each species of the compound dependent on the pH of the solution and the magnitude of the dissociation constants of the weak acid,  $K_a$ , and/or the weak base,  $K_b$ . The decomposition of each of these forms of the compound may be catalyzed by hydronium ions, hydroxide ions and water in aqueous solution but with different rate constants. For example, a plot of  $k_{\text{obs}}$  versus pH for the hydrolysis of the weakly basic drug procaine is similar to that seen in Figure 17-6, which indicates that procaine undergoes both acid and base hydrolysis<sup>3</sup>. However, there are notable aberrations in this plot at high pH values (*i.e.*, low pOH values) when compared to Figure 17-6. It has been proposed that the kinetics of this system when the pH is greater than 7.0 can be represented by<sup>1</sup>

$$-d[\text{Pr}]_{\text{total}}/dt = k_1[\text{OH}^-][\text{Pr}] + k_2[\text{OH}^-][\text{PrH}^+] \quad (67)$$

which neglects the acid catalyzed hydrolysis of procaine in this pH range. *Pr* represents the nonionized procaine molecule, *PrH*<sup>+</sup> represents the protonated form of procaine, and the total concentration of procaine,  $[\text{Pr}]_{\text{total}}$ , is the sum of the concentrations of ionized and protonated forms. The concentration of each species can be related to the total procaine concentration,  $[\text{Pr}]_{\text{total}}$ , by the relationships

$$[\text{Pr}] = \frac{[\text{OH}^-]}{K_b + [\text{OH}^-]} [\text{Pr}]_{\text{total}} \quad (68)$$

and

$$[\text{PrH}^+] = \frac{K_b}{K_b + [\text{OH}^-]} [\text{Pr}]_{\text{total}} \quad (69)$$

where  $K_b$  is the classical dissociation constant for the weak base procaine. The complete rate expression for procaine hydrolysis in this pH range is given by Equation 70.

$$-\frac{d[\text{Pr}]_{\text{total}}}{dt} = \left[ \frac{k_1[\text{OH}^-]^2 + k_2[\text{OH}^-]K_b}{K_b + [\text{OH}^-]} \right] d[\text{Pr}]_{\text{total}} = k_{\text{obs}}d[\text{Pr}]_{\text{total}} \quad (70)$$

Thus, the observed rate constant,  $k_{\text{obs}}$ , of procaine hydrolysis will depend on the concentration of the hydroxide concentration as illustrated graphically in Figure 17-8,<sup>9</sup> by a plot of  $k_{\text{obs}}$  versus pOH for the pH region 7 to 13. (Note: the values for  $k_{\text{obs}}$  are plotted versus pOH rather than pH to better illustrate the relationship of  $k_{\text{obs}}$  and hydroxide concentration as indicated in equation 70.) At high concentrations of hydroxide ion (*i.e.*,

**Figure 17-8.** Apparent first-order rate of hydrolysis of procaine as a function of hydroxide-ion concentration at 40°C. (From Higuchi T, Lachman L. Inhibition of hydrolysis of esters in solution by formation of complexes. I. Stabilization of benzocaine with caffeine. *J APhA Sci Ed* 1955; 44: 521-6.)

pOH values from 1 to 2.5), the hydroxide ion concentration is much greater than the value of  $K_b$ , and the denominator in equation 70 is predominated by the hydroxide concentration causing  $k_{obs}$  to decrease with decrease in hydroxide ion concentration (i.e., increase in pOH) via a first-order equation. Above pOH of 4.5, the hydroxide concentration is much smaller than the value of  $K_b$ , making the denominator constant with increasing values of pOH, (i.e., decreasing values of  $[OH^-]$ ). This causes  $k_{obs}$  to decrease with a decrease in hydroxide ion concentration (i.e., increase in pOH) via a second order equation as seen in the numerator of Equation 70. Over the range of pOH values of 2.5 to 4.5, the values of the hydroxide concentration and  $K_b$  are similar and  $k_{obs}$  follows the more complex hydroxide ion concentration dependence shown in the bracketed term in equation 70 which shows a slower rate of decrease in  $k_{obs}$  with decrease in hydroxide concentration relative to that exhibited at higher values of hydroxide concentration.

### GENERAL ACID OR BASE CATALYSIS

Acid or base catalysis is not restricted to the effect of hydrogen or hydroxide ion. Undissociated acids and bases often can be demonstrated to produce a catalytic effect and, in some instances, metal ions and various anions can serve as catalysts. Mutarotation of glucose in acetate buffer is catalyzed by hydrogen ion, hydroxide ion, acetate ion, and undissociated acetic acid. Also, the rate of barbiturate hydrolysis in ammonia buffers is increased by increasing buffer concentration at constant pH as a result of catalysis by  $NH_3$ . Hydrolysis of the amide function of chloramphenicol exhibits, in addition to solvent and specific acid-base catalysis, general acid-base catalysis in phosphate and citrate buffers. General acid-base catalysis is to be anticipated if there is evidence of a significant solvent catalysis, as illustrated in the pH-rate profile of Figure 17-7.

### ENZYME CATALYSIS

In biological systems, catalytic molecules, called enzymes (E), reversibly bind to a substrate (S) to form an intermediate (ES) which then decomposes to give a product (P) and the original enzyme.

and

The rate of this reaction,  $v$ , will be given by  $d[P]/dt = k_2[ES]$ . However, this is an improper rate equation as ES is an intermediate. Michaelis and Menten used a steady state approximation (i.e., at sometime during the reaction the time rate of change of the intermediate will be zero) to calculate the concentration of ES.

$$[ES] = \frac{k_f[E]_0[S]_0}{k_f[S]_0 + k_r + k_2} \quad (71)$$

Upon substitution of Equation 71 into the rate equation, the initial rate,  $v_0$ , (i.e., The rate at time equal to zero) is given by Equation 72.

$$v_0 = \frac{k_f k_2 [E]_0}{k_f + \frac{k_r + k_2}{[S]_0}} = \frac{v_m}{1 + \frac{K_m}{[S]_0}} = \frac{v_m [S]_0}{K_m + [S]_0} \quad (72)$$

where  $K_m$ , the Michaelis-Menten constant, is equal to the term  $(k_r + k_2) / k_f$  and  $v_m$ , the maximum initial velocity of the reaction, is equal to the term  $k_2 [E]_0$ . The rate constant  $k_2$  is often referred to as the turnover number which represents the number of molecules of product, P, created per second per mole of enzyme.

Equation 71 does not lend itself well to analysis as plots of  $v_0$  versus  $[S]_0$  only asymptotically approaches the maximum velocity,  $v_m$ . Rearrangement of Equation 72 into Equation 73, known as the Lineweaver-Burk Equation, lends itself more readily to analysis as shown in Figure 17-9.

$$\frac{1}{v_0} = \frac{1}{v_m} + \frac{K_m}{v_m [S]_0} \quad (73)$$

An important area of study in enzyme kinetics is enzyme inhibition. Although there are several cases in which an inhibitor, I, can inhibit an enzyme-catalyzed reaction, only two basic mechanisms will be discussed here. Competitive inhibition occurs when the inhibitor competes with the substrate, S, for the active binding site on the enzyme and blocks the catalytic action of the enzyme. In such a case, the formation of the enzyme-inhibitor complex, EI, is assumed to be in rapid equilibrium with the enzyme and inhibitor.

Equation 74 shows the resulting Lineweaver-Burk Equation for the case of a competitive inhibitor.

$$\frac{1}{v_0} = \frac{1}{v_m} + \left[ 1 + \frac{[I]}{K_i} \right] \frac{K_m}{v_m [S]_0} \quad (74)$$

$K_i$  is the dissociation constant for the enzyme-inhibitor complex and is equal to the term  $[E][I]/[EI]$ . Figure 17-10 shows a typical

**Figure 17-9.** Lineweaver-Burk plot of modified Michaelis-Menten equation (Equation 73).

**Figure 17-10.** Lineweaver-Burk plot for competitive enzyme inhibition (Equation 74).

**Figure 17-11.** Lineweaver-Burk plot for noncompetitive enzyme inhibition (Equation 75).

Lineweaver-Burk graph for competitive inhibition. Each plot represents a different concentration of the competitive inhibitor. Note that all three plots intersect at the same point on the y-axis indicating that the reactions all have the same maximum velocity. However, because they do not intersect at the same point on the x-axis then they have different Michaelis-Menten constants,  $K_m$ .

Another type of enzyme inhibition is noncompetitive inhibition. In this case, the inhibitor does not bind to the active site of the enzyme but rather binds to another part of the enzyme which modifies the normal enzyme binding site changing the ability to form the enzyme-substrate complex, ES.

and

In this case, the equilibrium constant,  $K_I$ , is given by both  $[E][I]/[EI]$  and  $[ES][I]/[ESI]$ . The resulting Lineweaver-Burk equation is given by Equation 75.

$$\frac{1}{v_0} = \left[ \frac{1}{v_m} + \frac{K_m}{v_m[S]_0} \right] \left[ 1 + \frac{[I]}{K_I} \right] \quad (75)$$

Figure 17-11 shows a typical Lineweaver-Burk graph for noncompetitive inhibition. Each plot represents a different concentration of the competitive inhibitor. Note that all three plots intersect at the same point on the x-axis indicating that the reactions all have the same Michaelis-Menten constant,  $K_m$ . However, because the plots do not intersect at the same point on the y-axis, then the reactions have different maximum velocities.

## OTHER EFFECTS

### IONIC STRENGTH

The effects of increasing concentrations of electrolytes on the reaction rate can be largely predicted by consideration of the influence of ionic strength of the solution on interionic attraction through solvation effects. In general, the Debye-Hückel equation may be used to demonstrate that at a constant temperature, increased ionic strength of the solution would be expected to decrease the rate of reaction between oppositely charged ions, and increase the rate of reaction between similarly charged ions when compared to lower ionic strength solutions. The rationale for this is at higher ionic strengths the repulsion affects of like charged reactants and the attractive effects of unlike charged reactants are mediated through shielding by the increased ionic strength solution. Thus, the hydrogen-ion catalyzed hydrolysis of sulfate esters is inhibited by increasing electrolyte concentration.

Reactions between ions and molecules with dipole moments, and reactions between neutral molecules generally are less sensitive to ionic strength effects than are reactions between ionic compounds causing little change in the reaction rate with increased ionic strength of the solution. However, reactions that result in formation of oppositely charged ions as products may exhibit a considerable increase in the reaction rate with increasing ionic strength.

### DIELECTRIC CONSTANT OF SOLVENT

Reactions involving ions of opposite charge are accelerated by solvents with low dielectric constants. For example, the rate of hydrogen ion-catalyzed hydrolysis of sulfate esters is much greater in low dielectric constant solvents, such as methylene chloride, than in water. Reactions between similarly charged species are favored by high dielectric constant solvents. Reactions between neutral molecules, which produce a highly polar transition state, such as the reaction of triethylamine with ethyl iodide to produce a quaternary ammonium salt, also will be enhanced by high dielectric constant solvents.

### HYDROLYSIS (SOLVOLYSIS)

Hydrolysis of esters, such as procaine, aspirin, or atropine, represents one of the more common types of drug instability. *Ester hydrolysis* is either hydrogen- or hydroxide-ion catalyzed, although the catalysis that is important from the viewpoint of drug-product stability depends upon the specific compound and the pH of the solution. Amides generally are more stable than esters but are subject to catalysis by hydrogen and hydroxide ions, and often by general acids and bases. Some examples of the kinds of functional groups subject to hydrolytic cleavage and species shown to be catalysts for the reactions are presented below.

Hydrolysis of the ester function of atropine is typical of ester hydrolysis in that only catalysis by the hydrogen or hydroxide ions is important. Figure 17-6 illustrates a pH-rate profile which might be considered typical for such a reaction. Below pH 3, the principal reaction is hydrogen-ion catalyzed hydrolysis of the protonated form of atropine. Above pH 5, the principal reaction is hydroxide ion catalyzed hydrolysis of the same species. The maximum stability at 30° is at pH 3.7.

Hydrolytic cleavage of aspirin to salicylic acid and acetic acid was studied by Edwards.<sup>5</sup>

Edwards obtained the interesting pH-rate profile reproduced in Figure 17-9. The unusual pH-rate profile obtained for aspirin was attributed to a reaction of the form

$$-\frac{d[\text{Aspirin}]_{\text{total}}}{dt} = k_1[H^+][HA] + k_2[H^+][A^-] + k_3[OH^-][A^-] + k_0[A^-] \quad (76)$$

where *HA* represents undissociated aspirin and *A<sup>-</sup>* represents aspirin anion. The pH-independent anion hydrolysis indicated for the pH region 5 to 9 has been attributed to intramolecular catalysis by orthocarboxylate anion rather than to general acid-base catalysis by water. It is principally this intramolecular catalysis that is responsible for the high instability of aqueous solutions of aspirin in the pharmaceutically useful pH range. Fersht and Kirby<sup>6</sup> represented the intramolecular carboxylate ion reaction as a general base catalysis of attack by a water molecule.

For nucleophiles such as ethanol, the terminal hydroxyl of polyethylene glycol (PEG) and the lysine ε-amino function in serum albumin also can participate in this reaction in the same manner as water. Thus, from aspirin in ethanol solution, ethyl acetate appears as a product; in polyethylene glycol, a polyethylene glycol acetate is formed; and in a solution containing serum albumin (both *in vitro* and *in vivo*) aspirin produces an acetylated serum albumin. Whitworth et al.<sup>7</sup> reasoned that an aspirin solution, prepared in a PEG solvent containing no free hydroxyl groups, would provide an aspirin solution of improved stability. They used acetylated PEG 400 as a solvent for aspirin and demonstrated that in such a solvent, less than 1% aspirin loss occurred after 30 days at 45°C.

Chloramphenicol decomposition below pH 7 proceeds primarily through hydrolytic cleavage of the amide function.

In the presence of a buffer, the reaction may be represented as

$$-\frac{d[\text{chloramp}]}{dt} = (k_0 + k_1[H^+] + k_2[OH^-] + k_{HB}[HB] + k_{B^-}[B^-])[\text{chloramp}] \quad (77)$$

where [Chloramp] is the concentration of chloramphenicol, and [HB] and [B<sup>-</sup>] are the concentrations of the weak acid and its conjugate base of the buffer species, respectively. In addition to hydrogen and hydroxide-ion catalysis, there is an uncatalyzed (or water) reaction, and there may be general acid-base catalysis, represented above by the buffer species HB and B<sup>-</sup>. In general, the rate of hydroxide-ion-catalyzed hydrolysis of amides is greater than rate of hydronium-ion-catalyzed hydrolysis.

Amides generally are much more stable than esters. Penicillins and cephalosporins are important exceptions to this rule because the amide bond is part of a strained four-membered ring (i.e., β-lactam). The decomposition of these compounds in aqueous solution is catalyzed by hydrogen ion, solvent, hydroxide ion, sugars, and many buffer species. Maximum stability occurs at about pH 7, but β-lactam antibiotics are too unstable to be formulated as solutions. For example, a buffered aqueous solution of penicillin G under refrigeration has a useful life of only about 1 week. Formation of the penicillanic acid by water-catalyzed rearrangement in acidic and neutral solutions is thought to be the first step in the degradation process.<sup>7</sup>

Barbiturate hydrolysis involves hydroxide-ion attack on both the undissociated acid, HP, and the ionized species, P<sup>-</sup>. Hydrogen ion catalyzed hydrolysis is not observed in the pH range of interest in pharmaceutical products. Therefore, the rate equation would take the form of Equation 78.

$$-\frac{d[\text{Barb}]}{dt} = k_1[OH^-][HP] + k_2[OH^-][P^-] \quad (78)$$

Hydrolysis of the amide (peptide) bond also occurs in protein and peptide drugs. This can occur by cleavage of the primary peptide linkage (R-NH-CO-R) between adjacent amino acids

in the peptide chain. Hydrolysis of the free side-chain amide groups of asparagine and glutamine (deamidation) is another degradation pathway for proteins. Insulin and recombinant human growth hormone undergo deamidation in solution. Further discussion of drugs resulting from biotechnology can be found in Chapter 34.

### RACEMIZATION

Many drugs are chiral and racemization is a common mechanism of degradation resulting in loss of biological activity. In proteins, a mixture of the D and L enantiomers is formed by base-catalyzed reaction of the natural L configuration. Acid-catalyzed racemization of epinephrine or base-catalyzed racemization of pilocarpine results in a loss of pharmacological activity.

### OXIDATION

Compounds such as phenols, aromatic amines, aldehydes, ethers, and unsaturated aliphatic compounds are subject to oxidation upon exposure to air or oxidizing chemicals. Epinephrine, ascorbic acid, phenothiazines, and vitamin A are examples of important pharmaceutical products that are oxidized readily. Proteins can undergo oxidative degradation by oxidation of methionine, a thioether, to its corresponding sulf-oxide. Oxidation of the carbon—carbon double bonds in unsaturated fatty acids (e.g., oleic acid) results in the fats and oils tasting rancid.

Of particular concern are oxidations that occur when solutions are exposed to atmospheric oxygen. Such reactions, termed *autoxidation* or *self-oxidation*, are complex reactions that proceed via a free-radical mechanism. A free radical is a highly unstable (highly reactive) species containing an unpaired electron. Autoxidation reactions are autocatalytic in that free-radical reactions generate additional free radicals, causing a chain reaction.

A technique used to protect pharmaceuticals susceptible to autoxidation is to include in the formulation agents that will react readily with free radicals, but that will terminate the chain propagation either by forming relatively stable, resonance-stabilized free radicals or by forming products that do not include additional free radicals.

### PHOTOCHEMICAL DECOMPOSITION

Numerous dyes and drugs are subject to photochemical decomposition. Light-catalyzed oxidations and reductions of photoexcited species are common and are often mechanistically complex reactions involving free-radical intermediates. Pharmaceuticals such as riboflavin, nifedipine, and the phenothiazines are examples of common drugs that are extremely light sensitive.

### INTERACTION BETWEEN COMPONENTS

Because drugs are often combined in solution with buffers, antioxidants, flavoring agents, antimicrobial preservatives, and other drugs, potential interaction between the components of a formulation must be considered in pharmaceutical formulation development. Some obvious interactions, such as the possibility of the reaction of a drug having a primary amino function with an aldehyde, such as vanillin, to produce a Schiff base can be predicted; however, a number of interesting, less well-recognized reactions have been encountered.

In addition to buffer species acting as general acid—base catalysts, as previously indicated, some buffer species undergo specific interactions with drug molecules to form new chemical compounds. The formation of amides in aqueous solution from amines, such as benzocaine, and buffers, such as citric acid, has been observed.

The aromatic function of procaine reacts with glucose to form procaine *N*-glycoside, also, phenylethylamine reacts with dehydroacetic acid to form a Schiff base-type compound. Catechols have been shown to catalyze penicillin hydrolysis.

It has been demonstrated that bisulfite, an agent commonly employed to protect epinephrine against oxidative decomposition, is capable of inducing epinephrine degradation through attack on the chiral side chain.

Although a solution of folic acid alone is stable to light, a combination of riboflavin and folic acid showed a rapid loss of folic acid through formation of a coupled oxidation—reduction system in which riboflavin was photoreduced, with folic acid being used as a reducing substrate and being itself irreversibly oxidized. In the dark and in the presence of oxygen, the riboflavin was regenerated, and, when the solution was again irradiated, the cycle was repeated with further destruction of folic acid. In this case, the riboflavin acts as a photosensitizer in this reaction and would cause the decomposition not only of folic acid, but also of ascorbic acid or any other easily oxidized substrate.

The presence of micellar surfactants and certain high-molecular-weight polymers commonly employed in pharmaceuticals also have been shown to lead to decreased drug stability in some cases. Both nonionic and anionic surfactants, as well as polymers, such as polyvinylpyrrolidone, accelerate the photodecomposition of riboflavin in aqueous solution. Nonionic surfactants also are capable of increasing the rate of hydrolysis of sulfate esters which may be incorporated in or on the micellar surface.

### PHYSICAL INSTABILITY

The introduction of an increasing number of drugs derived from developments in biotechnology necessitates greater awareness of instability occurring as a result of loss of drug activity through structural changes unrelated to disruption of covalent

**Figure 17-12.** Apparent first-order rate of hydrolysis of aspirin as a function of pH. (From Edwards LJ. The hydrolysis of aspirin. A determination of the thermodynamic dissociation constant and a study of the reaction kinetics by ultra-violet spectrophotometry. *Trans Faraday Soc.* 1950; 46: 723–35. Reproduced by permission of the Royal Society of Chemistry.)

bonds. Protein-based drugs may lose activity as a result of a change in conformation (secondary, tertiary, and quaternary structures) that is independent of chemical modification. Conformational changes, which may alter protein drug activity, include denaturation (unfolding), aggregation, surface adsorption, and precipitation. Treatments with potential for inducing such changes include temperature changes, pH extremes, and agitation, foaming resulting from shaking and conditions which may expose drugs, such as proteins, to manufacturing or administering processes that cause shear. Detection of instability of a physical nature generally requires one or more biological assays, or physical assay methods that are sensitive to the critical conformational changes.

## DRUG STABILIZATION

Some drug decomposition reactions, such as photolytic and oxidative reactions, are relatively easy to avoid by protecting the components from light (photodecomposition) or exclusion of oxygen and by use of chain-terminating reagents or free-radical scavengers to minimize free-radical-mediated reactions. Solvolysis reactions, however, cannot be stopped by such procedures, but several techniques may be employed to retard reactions sufficiently to permit the formulation of a suitable drug product. The following approaches may be useful in attempts to retard solvolytic reactions.

### SELECTION OF OPTIMUM pH, BUFFER, AND SOLVENT

Consideration of the mechanism of the reaction and the way in which the reaction rate is influenced by pH, buffer species, and solvent permits the selection of the optimum conditions for drug stability. Often, however, ideal conditions for maximum stability may be unacceptable from the viewpoint of pharmaceutically acceptable formulation or therapeutic efficacy; thus, it may be necessary to prepare a formulation with conditions less than optimum for drug stability. If a suitable compromise between conditions for maximum stability and conditions for a pharmaceutically acceptable formulation cannot be achieved, techniques, such as those described below, may be useful in retarding solvolysis reactions.

### SPECIFIC COMPLEXING AGENTS

The technique of stabilization by forming complexes in solution was introduced by Higuchi and Lachman<sup>9</sup> who demonstrated that the rate of hydrolysis of the ester function of benzocaine was retarded significantly in the presence of caffeine, a reagent with which the benzocaine formed a soluble complex. It was demonstrated further that, in these systems, the complexed drug did not hydrolyze at all and that the observed rate of hydrolysis could be ascribed to the concentration of the free or uncomplexed drug that was in equilibrium with the drug complex.

There are many recognized examples in which drug stabilization occurs by disrupting the kinetic mechanisms of degradation. Boric acid chelation of the catechol function of epinephrine stabilizes epinephrine against attack by bisulfite and sulfite. The complex of povidone (polyvinylpyrrolidone) and iodine was used for many years as a topical antiseptic because of its higher iodine concentration, slow release of iodine from the complex, lower toxicity, and its ability to stabilize and protect the iodine from degradation before application.

### SURFACTANTS

It has been demonstrated that the incorporation of benzocaine into surfactant micelles could retard significantly the rate of ester hydrolysis. Nonionic and anionic surfactants retarded the hydroxide-ion-catalyzed hydrolysis, but cationic surfactants somewhat increased the rate of hydroxide-ion-catalyzed hydrolysis. Similar observations have been reported for a number of drugs that are sufficiently lipophilic to be solubilized by surfactant micelles.

## SUSPENSIONS

If the solubility of a labile drug is reduced and the drug is prepared in a suspension form, the rate at which the drug degrades will be related only to the concentration of dissolved drug rather than to the total concentration of drug in the product. Thus it has been demonstrated that penicillin G procaine suspensions degraded at a rate proportional to the low concentration of penicillin in solution. Because the penicillin in solution was in equilibrium with excess solid penicillin G procaine, the penicillin concentration in solution was constant and the observed order of reaction was apparently zero order.

## REFRIGERATION

Storage below room temperature usually will retard solvolytic reactions. Storage in the frozen state generally is an effective means of retarding degradative reactions. Several antibiotics are sold as frozen solutions in flexible plastic bags. An exception is sodium ampicillin dissolved in 5% dextrose solution, which showed approximately 10% decomposition after 4 h of storage at 5°C and more than 13% loss after storage for the same period in the frozen state at -20°C.

## STABILITY TESTING OF PHARMACEUTICAL PRODUCTS

If a product is to be marketed, it must be stable over relatively long storage times at room temperature or at the actual temperature at which it will be shipped and stored prior to its ultimate use. Thus, the rate of degradation may have to be studied over an undesirably long period of time in order to determine the product's stability under normal storage conditions.

To avoid this undesirable delay in evaluating possible formulations, the manufacturer attempts to predict stability under conditions of room temperature or actual storage conditions by using data for the rate of decomposition obtained at several elevated temperatures. This is accomplished using an Arrhenius plot to predict, from high-temperature data, the rate of product breakdown to be expected at actual lower temperature storage conditions. See Chapter 4.

Prediction based on data obtained at elevated temperatures generally is satisfactory for solution dosage forms. Success is more uncertain when non-homogeneous products are involved. Suspensions of drugs may not provide linear Arrhenius plots because often there is the possibility that the solid phase, which exists at elevated temperature, may not be the same solid phase that exists at room temperature. Such differences in the solubility of the several solid phases may invalidate the usual Arrhenius plots due to a change in mechanism as the phase changes with increase in temperature. These difficulties should be anticipated when polymorphic crystal forms or several different solvates are known to exist for a specific solute. Also, when solid dosage forms (e.g., tablets) are subjected to high temperatures, changes in the quantity of moisture in the product may greatly influence the stability of the product.

Arrhenius plots also suffer limitations when applied to reactions that have relatively low activation energies and, therefore, are not accelerated greatly by an increase in temperature. Where usually it is desirable to determine drug stability by analyzing samples for the amount of intact drug remaining—in instances where there is very little drug decomposition and particularly when it is not convenient to accelerate the reaction by increasing temperature—it sometimes is advantageous to determine initial reaction rates from the determination of the amount of reaction product formed.

Using modern methods of analysis, such as high-performance liquid chromatography (HPLC), it is often possible to measure the rate of formation of a degradation product. By using this technique, very small amounts of degradation (less than 1% loss of parent compound) can be detected, resulting in a more sensitive indication of product stability than can be obtained by analyzing potency.

Because manufacturers are interested primarily in the time required to produce just a few-percent breakdown in their product, it is not uncommon to employ terminology such as  $t_{0.90}$  or  $t_{0.95}$ , which is the time required for the drug to decompose to 90 or 95%, respectively, of original potency.

An Arrhenius-type plot, analogous to that illustrated in Figure 17-4, can be obtained by plotting the natural logarithm of the specific rate constants versus the reciprocal of absolute temperature. The rate constant at the temperature of interest can be determined and applied to the appropriate kinetic model to determine the time required for the product to decrease in potency to 90% of original potency.

COMPLEXES IN PHARMACY 325

In chemistry and chemical processes the word *complex* usually refers to molecules or molecular assemblies formed by combination of *substrates*, *S*, and *ligands*, *L*. Most often complex ( $S_mL_n$ ) formation is a reversible process:

where *m* substrate molecules, associate with *n* ligand molecules to form a complex of *m*:*n* stoichiometry. In this context, *complex formation*, *complexation*, *binding*, *association*, and *chelation* are often synonymous. The substrate and ligand are kept together by relatively strong coordinate covalent bonds or by weak non-covalent forces such as hydrogen bonding, van der Waals forces, electrostatic interactions, dipole forces, charge transfer, release of conformational strain, or hydrophobic interactions. The complex formation changes the physicochemical properties of its constituents, both of the substrate and the ligand, including their aqueous solubility, molar absorptivity, NMR chemical shifts, adsorption to solid surfaces, partitioning behavior, conductivity, chemical reactivity and/or pKa values. By studying such properties, for example of the substrate as a function of the ligand concentration, the complex can be identified and quantitatively described. Furthermore, the methods of chemical kinetics and thermodynamics can be applied to describe the formation and dissociation of a complex. Although most frequently, substrate and ligand molecules are associated by weak chemical forces, there are complexes where bonds are quite strong and formation of some metal complexes are virtually irreversible. Complexes are usually broadly classified into two groups based on the type of S-L bonding involved, namely *coordination complexes* and *molecular complexes*.

**Coordination complexes** consist of ionic substrates, most frequently transition metal ions, with bases or, in other words, products of Lewis acid-base reactions where the metal ion (an acid) accepts a pair of electrons from the ligand (the base) to form a coordinate covalent bond. Examples of such complexes are  $[Ag(NH_3)_2]^+$ ,  $[Co(NH_3)_6]^{3+}$  and  $[Fe(CN)_6]^{4-}$ . Other common types of coordination complexes are organometallic complexes that are complexes formed between organic groups and metal atoms such as vitamin B12 (a porphyrin containing a cobalt atom), and cluster complexes where the central metal ion consists of a three-dimensional cell of several directly bonded metal ions such as triruthenium dodecacarbonyl ( $Ru_3(CO)_{12}$ ):

A **coordination complex** is called a *chelate* if the same substrate (metal ion) binds with two or more sites on a ligand.

**Molecular complexes** consist of non-covalently bound substrates and ligands. These include complexes of relatively small substrates and ligands such as drug-cyclodextrin complexes,

complexes between small substrates and a large ligand such as drug-protein complexes (e.g., plasma protein binding) and complexes between large substrates and a small ligand such as some protein-polyalcohol complexes. Molecular complexes also include molecular dimers, ion-pairs, intramolecular interactions (such as base-base interactions in the DNA helix) and clathrate compounds (cage compounds) where a cage-like lattice of one type of molecules (e.g., hydroquinone molecule) entraps a second type of molecules (e.g., methanol molecule). Pharmaceutical co-crystals can also be considered a type of molecular complex with components subjected to hydrogen bonding and other forces in the crystal lattice. Examples of these types of molecular complexes include isoniazid and 4-aminosalicylic acid where the carboxylic acid function can be shown to interact with the pyridine nitrogen.

The following is a more detailed description of these complexes with several examples of pharmaceutical interest.

### COMPLEX BONDING

Chemical bonding and bonding forces within and between molecules is covered in Chapter 11. The following relates to forces that participate in complex formation.<sup>1,2</sup>

A **coordinate covalent bond** is a covalent bond where both electrons come from the same atom unlike a simple covalent bond which is formed between two atoms with each atom supplying one electron. For example, when silver ions ( $Ag^+$ ) interact with ammonia ( $NH_3$ ) to form the silver-ammonia coordinate complex ( $[Ag(NH_3)_2]^+$ ) both of the electrons forming the covalent bond come from ammonia. However, each of the three H-N covalent bonds in ammonia is formed by one electron from a hydrogen atom and one electron from the ammonia atom.

or

**Coordinate covalent bonds** are sometimes designated by arrows indicating that both electrons are coming from, for example, the nitrogen or by plus and minus signs indicating that the nitrogen end of the bond has become positive because the electron pair has moved away from the nitrogen towards the boron which has thus become negative:

Several different theories have been developed in order to describe coordinate covalent bonding such as *molecular orbital theory* (also called *ligand field theory*) that applies quantum mechanical description of coordinate bonds, *electrostatic theory* where the substrate ions are treated as spherical charges

**Table 18-1. Some examples of the Hard-Soft Classification of Lewis Acids and Bases**

	Acids	Bases
Hard	H <sup>+</sup> , Li <sup>+</sup> , Na <sup>+</sup> , K <sup>+</sup> , Mg <sup>2+</sup> , Ca <sup>2+</sup> , Mn <sup>2+</sup> , Al <sup>3+</sup> , Zn <sup>2+</sup> , AlCl <sub>3</sub> , CO <sub>2</sub>	H <sub>2</sub> O, OH <sup>-</sup> , F <sup>-</sup> , Cl <sup>-</sup> , PO <sub>4</sub> <sup>3-</sup> , SO <sub>4</sub> <sup>2-</sup> , ClO <sub>4</sub> <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , NH <sub>3</sub> , CH <sub>3</sub> COO <sup>-</sup>
Soft	Cu <sup>+</sup> , Ag <sup>+</sup> , Au <sup>+</sup> , Hg <sub>2</sub> <sup>2+</sup> , Hg <sub>2</sub> <sup>2+</sup> , Pd <sup>2+</sup> , Pt <sup>2+</sup> ; I <sub>2</sub> , Br <sub>2</sub>	I <sup>-</sup> , SCN <sup>-</sup> , CN <sup>-</sup> , CO, C <sub>6</sub> H <sub>6</sub>

and the ligands as dipoles, and *valence bond theory*, a quantum mechanical theory wherein the ligand donates a pair of electrons to a vacant orbital associated with the ion.

Another concept that is used to describe coordination complexes is the concept of *hard and soft acids and bases* (HSAB). A *hard acid* is defined as a small Lewis acid (i.e. electron-pair acceptor) atom with high positive charge density and low polarizability whereas a *soft acid* is large and polarizable. A *hard base* has high electronegativity and low polarizability whereas a *soft base* is polarizable (Table 18-1). Polarizability is a measure of the ease with which the electron cloud can be deformed under the influence of a charge field. In general, hard acids bind preferably with hard bases, and soft acids bind preferably with soft bases.

**Non-covalent intermolecular forces** (i.e., between molecules) participating in a complex formation are, in general, relatively weak forces compared to intramolecular forces (i.e., within a molecule) such as covalent bonds. The following types of non-covalent forces are known to participate in complex formations:

**Electrostatic interactions** are the consequence of classical attraction and repulsion effects between charges such as charge-charge, charge-dipole, and dipole-dipole interactions.

**Dispersion force** is a quantum mechanical effect where synchronization of the electronic motion between two molecules results in momentary dipole moments and consequently attraction between the molecules. Dispersion force is also called the *van der Waals force*. However, some authors use the term *van der Waals force* for all non-covalent forces.

**Hydrogen bonding** is an interaction involving formation of hydrogen bond (*H-bond*) between a proton donor (*HA*) and a proton acceptor (*B*):

The *A-H* bond has a covalent character but the *H ... B* bond is predominantly electrostatic. The strength of the hydrogen bond is controlled in part by the acid strength of *HA* and the base strength of *B*, but it is also affected by the solvent.

**Charge-transfer interaction** is a consequence of electron transfer from an electron donor molecule to an electron acceptor molecule. Frequently, charge-transfer complexes involve electron transfer between metal atoms and ligands. However, charge-transfer interactions are also known in other inorganic as well as organic compounds. A well-known charge-transfer complex is the dark blue or purple iodine/starch complex.

**Hydrophobic interaction** results from the tendency of liquid water to exclude non-polar molecules. The water molecules form a “cage” around two or more non-polar molecules keeping them together in a kind of a complex or loosely associated molecules. Hydrophobic interactions are commonly observed during inclusion complex formations where a non-polar moiety of larger molecule enters a somewhat lipophilic cavity.

**Release of conformational strain** is known to participate in formation of cyclodextrin inclusion complexes where the cyclodextrin molecule frequently undergoes significant conformation changes upon complex formation. However, it has been argued that relief of conformational strain is not a driving force for cyclodextrin complex formation.<sup>2</sup>

**Release of high-energy water molecules** from, for example, a cyclodextrin cavity does participate in inclusion complex formation. In aqueous solutions the somewhat lipophilic cyclo-

dextrin cavity is occupied by high-energy water molecules (i.e., water not capable of fulfilling all of its hydrogen-bonding requirements) that are expelled during inclusion complex formation. However, based on some thermodynamic observations it has been argued that the exclusion of water molecules from the cavity is not a driving force of cyclodextrin complex formation.<sup>2</sup> This is based on the fact that although the cavity-bound water molecules are of higher energy (i.e., are enthalpy rich) they have more conformational freedom (i.e., form fewer hydrogen bonds). Consequently, although expulsion of water molecules from the cavity is accompanied by a negative enthalpy change, the free energy change of the overall process is not necessarily negative.

## METAL-ION COORDINATION COMPLEXES

Metal-ion coordination complexes, sometimes simply called metal complexes, consist of a central metal ion bonded to one or more ligands that are electron-pair donors such as a nitrogenous base (e.g., ammonia), an ion (e.g., chloride ion), or an aromatic compound (e.g., ferrocene). The number of bonds between the metal ion and the ligand or ligands is called the *coordination number* of the complex. Metal ions can have more than one coordination number. The maximum number is defined by the size, charge and electronic structure of the metal ion. Coordination numbers are normally between 2 and 9 with the most common coordination numbers being 4 and 6. For example, the anticancer drug cisplatin has a coordination number of 4 (Fig. 18-1).

The *trans* stereoisomer of cisplatin is transplatin (Fig. 18-1). Both of these geometrical isomers have square planar structure, that is, the metal substrate and the four ligand groups all lie in the same plane. Most metal-ion coordination complexes of coordination number 4 have a square planar structure but some are tetrahedral where the central metal ion is in the center of a tetrahedron with each of the four ligands located in the four corners. Most complexes with coordination number 6 are octahedral, that is, the bonds lie along the x, y, and z axes of a coordinate system with the metal ion at the origin. Example of such a complex are the *cis* and *trans* isomers of dichlorotetraamminecobalt(III) chloride (Figure 18-2).

Metal ions that are found within cells form coordination complexes with small molecules such as porphyrins that are themselves bound to proteins. The function of such metalloproteins can be the transport of oxygen or nitric oxide, or can be enzymatic in nature. For example, the heme unit (Figure 18-3) is a coordination complex of iron and a porphyrin that is responsible for binding oxygen in hemoglobin and myoglobin.

A chelate (from Greek word “chelè” meaning “claw”) is formed when a ligand uses more than one donor atom to bind a single metal atom. Such ligands are called chelating agents, chelants, or chelators. Chelates tend to be more stable than comparable complexes containing only one binding site and are used in drug formulations to, for example, bind metal ions that catalyze drug oxidation, thus increasing the shelf-life of the drug product. Examples of such chelating agents include citric acid,

**Figure 18-1.** Cisplatin and transplatin.

**Figure 18-2.** Equivalent ways to draw an octahedral complex.

**Figure 18-3.** Heme, a coordination complex of iron and a porphyrin. Two of the bonds are coordination covalent bonds indicated by arrows.

**Figure 18-4.** Calcium ( $\text{Ca}^{2+}$ ) tetracycline complex (chelate).

tartaric acid and EDTA (ethylenediamine tetraacetic acid). Some drugs can also be chelating agents and bind ions. For instance tetracycline forms hydrophilic chelates with ions such as calcium ( $\text{Ca}^{2+}$ ), iron ( $\text{Fe}^{3+}$ ,  $\text{Fe}^{2+}$ ), aluminium ( $\text{Al}^{3+}$ ), and magnesium ( $\text{Mg}^{2+}$ ), i.e. complexes that possess poor oral bioavailability (Fig. 18-4).<sup>3</sup> Milk and milk products, mineral supplements and antacids containing polyvalent cations ingested simultaneously with tetracycline antibiotics can reduce their oral bioavailability by as much as 90%.<sup>4</sup> Nalidixic acid, ciprofloxacin and other quinolones do also form chelates with polyvalent ions that can reduce their oral bioavailability. The intensity of the effect depends both on the nature of the drug and the cation, as well as on the doses used. The drugs that bind metal ions should be taken either two to three hours after or before ingestion of cation containing products such as dairy products, antacids and mineral supplements.

$\beta$ -Lactam antibiotics form chelates with metal ions such as  $\text{Cu}^{2+}$  (Fig. 18-5). The  $\beta$ -lactam ring is much more susceptible to specific base hydrolysis (i.e., toward  $\text{OH}^-$  attack) when complexed than when uncomplexed. Thus, formation of such chelates can significantly decrease the shelf-life of  $\beta$ -lactam antibiotics.

## MOLECULAR COMPLEXES

Molecular complexes can be classified according to 1) the bonding or interaction between substrate and ligand (e.g.,

**Figure 18-5.** Copper ( $\text{Cu}^{2+}$ ) benzylpenicillin complex (chelate).

electrostatic interaction, charge-transfer, hydrogen bonding and hydrophobic interaction), 2) type of substrate and ligand forming the complex (e.g., small molecule—small molecule, small molecule—macromolecule, enzyme—substrate, drug—receptor and antigen—antibody) or 3) type of structure formed (e.g., self-assembled aggregate, micelle, clathrate, and inclusion complex). Molecular complexes consist of one or more substrates and ligands that are, in general, held together by relatively weak, non-covalent forces. In aqueous solutions, free molecules are most often in dynamic equilibrium with molecules bound within the complex but tightly bound complexes are not unknown. Much of the pioneering work on molecular complexes was published by Takeru Higuchi and coworkers.<sup>5</sup>

**Drug-exciptent interactions** are quite common in pharmaceutical formulations and frequently such interactions are the result of formation of molecular complexes. Formation of such complexes will affect the physicochemical and biological properties of the drug bound to the excipient such as its aqueous solubility, release from the drug formulation and bioavailability.

*Non-ionic water-soluble polymers*, such as polyvinyl pyrrolidone (PVP) and hydroxypropyl methylcellulose (HPMC), are commonly used to enhance viscosity and to form hydrogels. In aqueous solutions, PVP forms coils and is able to bind drug molecules via non-covalent binding, and PVP is known to form complexes with various drugs.<sup>6</sup> PVP binds iodine in the presence of iodide ions (povidone-iodine) and as such is used as antibacterial agent for treatment and prevention of skin or wound infections (Fig. 18-6). Both PVP and HPMC can enhance aqueous solubility of drugs through the formation of water-soluble complexes and have been used as solubility and dissolution enhancers.<sup>7,8</sup>

*Ionic water-soluble polymers*, such as carboxymethylcellulose (CMC), are able to bind drugs. For example, in aqueous solutions CMC forms complexes with some basic drugs such as atenolol, diphenhydramine, lidocaine and propranolol.<sup>9</sup> Gum Arabic and alginates, both of which are anionic polysaccharides, are known to interact with drugs affecting their aqueous solubility and chemical stability. Chitosan (a linear polysaccharide composed of randomly distributed glucosamine) is positively charged at acidic pH and forms nano-sized complexes with negatively charged DNA and RNA. Chitosan has been used in gene delivery.<sup>10</sup> Alginates form drug complexes and have also been used to modify drug delivery.<sup>11</sup>

**Drug-drug interactions** in the form of complexes are also well known. Thus, salicylates form complexes with benzocaine, and the anticancer drugs paclitaxel, doxorubicin, and etoposide have been shown to form dimers and trimers in aqueous solutions as well as etoposide-paclitaxel complexes.<sup>12</sup> Cocaine and morphine form a binary complex in aqueous solutions that

**Figure 18-6.** The iodine—PVP complex.

can affect their pharmacokinetics and biological activity.<sup>13</sup>  $\beta$ -Lactam antibiotics form complexes with aminoglycosides,<sup>14</sup> heparin forms complexes with drugs such as polymyxin B and streptomycin, and caffeine and nicotinamide form water-soluble complexes with a number of drugs and vitamins.<sup>5,15,16</sup>

**Drug-food interactions** can also be due to drug complexation.<sup>17</sup> Dietary fibers reduce oral drug absorption by drug complexation.<sup>18</sup> These material can include psyllium, guar gums, and other carbohydrates such as cyclodextrins. Cholestyramine and related bile acid sequestrates interact with bile acids to reduce their ability to be reabsorbed and thereby accelerating cholesterol elimination. These are strong ion exchange resins which interact with substrates through electrostatic forces to form the desired complexes.

## INCLUSION COMPLEXES

Inclusion complexes are molecular complexes characterized by entrapment of the substrate (guest) in a cage (host) consisting of one or more ligand molecules. Cyclodextrin complexes are examples of guest-host complexes where a single ligand molecule entraps one or more guest molecules. Some other relatively large molecules, such as, water-soluble dextrans, crown ethers and calixarenes, are also capable of forming this type of monomolecular inclusion complex.<sup>19,20</sup> In contrast several small molecules, like hydroquinone, bile acids, thiourea, and urea assemble to form channels (tunnels), clathrates (cages), molecular sandwiches or other types of hydrophilic nanostructures around lipophilic molecules. For example, hydroquinone molecules form a cage like structure around small molecules like methanol through hydrogen bonding of the hydroquinone molecules whereas urea can form channels around straight-chain hydrocarbons and 13-*cis*-retinoic acid.<sup>21,22</sup>

## COMPLEX STABILITY

### STOICHIOMETRY AND BINDING CONSTANTS

The two most important characteristics of complexes are their stoichiometry and the numerical values of their stability constants. If  $m$  substrate molecules (S) associate with  $n$  ligand molecules (L) to form a complex ( $S_mL_n$ ) the following overall equilibrium is attained:

where  $K_{m,n}$  is the stability constant (also known as binding constant, formation constant or association constant) of the substrate-ligand complex. The stability constant can be written as:

$$K_{m,n} = \frac{[S_mL_n]}{[S]^m \cdot [L]^n} \quad (2)$$

where the brackets denote molar concentrations. In general, higher order complexes are formed in a stepwise fashion where a 1:1 complex is formed in the first step and 1:2 (or 2:1) complex in the next step and so on:

Consequently the stability constants can be written as:

$$K_{1,1} = \frac{[SL]}{[S] \cdot [L]} \quad (3)$$

$$K_{1,2} = \frac{[SL_2]}{[SL] \cdot [L]} \quad (4)$$

The **reciprocal values** (e.g.,  $1/K_{1,1}$ ) are known as dissociation constants or instability constants. The physicochemical properties of free substrate molecules are somewhat different from those of the compound bound to the ligand molecules. Likewise, the physicochemical properties of free ligand molecules are different from those of the ligand in the complex. In general, any

methodology that can be used to observe these changes in additive physicochemical properties may be utilized to determine the stoichiometry of the complexes formed and the numerical values of their stability constants. These include changes in solubility, changes in chemical reactivity, changes in UV/VIS absorbance, changes in fluorescence, NMR chemical shifts, changes in substrate retention (e.g., in liquid chromatography), changes in pKa values, potentiometric measurements and effects on substrate permeability through artificial membranes. Furthermore, because complexation will influence the physicochemical properties of the complexation media, methods that monitor these media changes can also be applied to study the complexation. These include measurements of conductivity changes of an aqueous medium, determinations of freezing point depression, viscosity measurements and solution calorimetric titrations. The stoichiometry of the substrate/ligand complexes and the numerical values of their stability constants should be independent of the methodology applied and sometimes that is the case. In some cases, method-dependent differences in the stability constants can be discerned. These inconsistencies can be explained by coexistence of several different types of substrate-ligand complexes in the complexation media and concentration dependent changes in their relative contribution to the overall complexation effect.

The van't Hoff equation is used to explain the effects of temperature on equilibrium constants such as stability constants of complexes:

$$\ln K = \text{Intercept} - \frac{\Delta H^0}{R} \cdot \frac{1}{T} \quad (5)$$

where  $\Delta H^0$  is the standard enthalpy change,  $R$  is the gas constant and  $T$  is the temperature in Kelvin. A plot of  $T^{-1}$  versus  $\ln K$  will give a straight line with slope equal to  $-(\Delta H/R)$ . The standard free energy change ( $\Delta G$ ) for equilibrium processes is calculated from Eq. 6:

$$\Delta G^0 = -R \cdot T \cdot \ln K \quad (6)$$

with the standard free entropy change ( $\Delta S^0$ ) derived from the following relationship:

$$\Delta G^0 = \Delta H^0 - T \cdot \Delta S^0 \quad (7)$$

### DETERMINATION OF BINDING CONSTANTS

Various analytical methods can be applied to obtain the stoichiometry and numerical values of a given substrate-ligand complex. The following are descriptions of just a few common methods that are applied during drug formulation studies. However, it must be emphasized that most of these methods were developed under ideal conditions (e.g., in dilute aqueous solutions) or conditions that rarely can be found in pharmaceutical formulations. Thus, the determined values should be characterized as observed and not exact values (i.e., observed stoichiometry, observed stability constant etc.).

#### The solubility method

The most common application of complexes in pharmaceutical formulations is their usage as solubilizers of poorly soluble drugs. In such cases, the stoichiometry of the substrate-ligand complexes and the numerical values of their stability constants are frequently obtained from phase-solubility diagrams, i.e., plots of substrate solubility vs. ligand concentration. The phase-solubility technique was developed by Higuchi and Connors and it is based on research related to how complexes of different ligands such as caffeine, polyvinylpyrrolidone, and some aromatic acids affects the aqueous solubility of substrates.<sup>5,23,24</sup> Experimentally, an excess of a poorly water-soluble substrate is introduced into several vials to which a constant volume of an aqueous vehicle containing successively higher concentrations of ligand are added. The vials are shaken or otherwise agitated at constant temperature until equilibrium is established. The suspensions are then filtered and the total concentration of dissolved substrate ( $[S]_T$ ) determined based on an appropriate

**Figure 18-7.** Schematic presentation of A- and B-type phase-solubility diagrams with applicable subtypes ( $A_P$ ,  $A_L$ ,  $A_N$ ,  $B_S$ , and  $B_I$ ).

analytical technique. The phase-solubility profile is then constructed by assessing the effect of the ligand concentration on the apparent solubility of the substrate. The phase-solubility method does not give insight as to how the complexes are formed or as to the forces involved. To study these types of effects, only methodologies that monitor physicochemical properties of the included substrate molecule or the ligand molecule can be applied, such as changes in the UV-visible or NMR spectra. Also, due to the coexistence of several different types of substrate–ligand complexes, the stability constants obtained from the phase-solubility profiles are observed constants. Based on the shape of the generated phase-solubility relationships, several types of behaviors can be identified.<sup>25</sup> Phase-solubility diagrams fall into two major types: A and B (Fig. 18-7).

#### A-TYPE PROFILES

In A systems, the apparent solubility of the substrate increase as a function of ligand concentration. Three subtypes have been defined:  $A_L$  profiles indicate a linear increase in solubility as a function of ligand concentration,  $A_P$  systems indicate an isotherm wherein the curve deviates in a positive direction from linearity (i.e., the ligand solubilization is proportionally more effective at higher concentrations) and  $A_N$  relationships indicate a negative deviation from linearity (i.e., the ligand solubilization is proportionally less effective at higher concentrations). Taken as a whole, these isotherms indicate that water-soluble complexes are being formed with solubilities higher than that of the uncomplexed substrate.  $A_L$ -type relationships are first order with respect to ligand and first or higher order with respect to the substrate, that is,  $SL$ ,  $S_2L$ ,  $S_3L$ , and so on. If the slope of the  $A_L$  isotherm is greater than unity, higher order complexes are assumed to be involved in the solubilization. Although a slope of less than one does not exclude the occurrence of higher order complexes, a one-to-one complex is often assumed in the absence of other information.  $A_P$  systems suggest the formation of higher order complexes with respect to the ligand at higher ligand concentrations, for example,  $SL_2$ ,  $SL_3$ , and so on. The stoichiometry of the formed complexes has historically been implied by the extent of curvature of the phase-solubility profile. Thus, an isotherm best fit to a quadratic function suggest the formation of a one-to-two ( $SL_2$ ) complex, one best fit to a cubic function suggests a one-to-three complex ( $SL_3$ ), and so forth.  $A_N$  profiles have several explanations including bulk changes imparted to the solvent by the ligand at various concentrations, that is, the ligand is acting as a chaotrope or kosmotrope or is altering the bulk properties of the media by changing its viscosity, surface tension, or conductivity and/or self-association of the ligand at high concentrations.

Equilibrium constants can be derived from A-type phase-solubility profiles in a number of ways. As discussed previously, the equilibrium constant for a complexation of interest is given by Equation 1. The intrinsic substrate solubility is given as  $S_0$  and a formed complex is represented by  $SL$ :

$$[S] = S_0 \quad (8)$$

$$[S]_T = S_0 + m \cdot [S_m L_n] \quad (9)$$

$$[L]_T = [L] + n \cdot [S_m L_n] \quad (10)$$

where  $[S]$  is the concentration of free substrate (i.e., dissolved substrate that is not bound to ligand),  $[S]_T$  is the total concentration of dissolved substrate (i.e., both free and bound to a water-soluble complex),  $[L]_T$  is the total concentration of ligand in solution and  $[L]$  is the concentration of free ligand (i.e., dissolved ligand molecules that are not forming complex with the substrate). The values for  $[S_m L_n]$ ,  $[S]$  and  $[L]$  can be derived as:

$$[S_m L_n] = \frac{[S]_T - S_0}{m} \quad (11)$$

$$[L] = [L]_T - n \cdot [S_m L_n] \quad (12)$$

where  $S_0$  is the solubility of the substrate in the absence of the  $L$ . For equilibria that are first order with respect to the ligand ( $n = 1$ ), the following equation can be obtained:

$$[S]_T = \frac{m \cdot K \cdot (S_0)^m \cdot [L]_T}{1 + K \cdot (S_0)^m} + S_0 \quad (13)$$

A plot of  $[S]_T$  versus  $[L]_T$  for the formation of  $S_m L$  complex should, therefore, give a straight line with the y-intercept representing  $S_0$  and the slope defined as:

$$\text{Slope} = \frac{m \cdot K \cdot (S_0)^m}{1 + K \cdot (S_0)^m} \quad (14)$$

Therefore, if  $m$  is known, the  $K$  can be calculated, meaning that for one-to-one complexation, that is,  $m = 1$ , the following equation will apply:

$$K_{1:1} = \frac{\text{Slope}}{S_0 \cdot (1 - \text{Slope})} \quad (15)$$

It should be noted that in the circumstance where a series of complexes of the form  $SL + S_2L + \dots + S_m L$  are present, an  $A_L$ -type profile would still be observed and simple phase-solubility analysis would not be able to distinguish between the simple 1:1 (one-to-one) and higher order complexes. If the slope of the isotherm is greater than unity, higher order complexes are indicated and equation 13 can be used with substitution of various trial values of  $m$  to suggest the stoichiometry and magnitude for the equilibrium constant.

Frequently, the y-intercept is not equal to  $S_0$  and this can cause considerable error in the value of  $K$ . A more accurate method for determination of the solubilizing effect of ligands is to determine their complexation efficiency ( $CE$ ), i.e., the concentration ratio between ligand in a complex and free ligand.  $CE$  is calculated from the slope of the phase-solubility diagrams, it is independent of both  $S_0$  and the intercept, and it is more reliable when the influences of different pharmaceutical excipients on the solubilization are being investigated. For 1:1  $SL$  complexes the complexation efficiency ( $CE$ ) can be calculated from the slope of the phase-solubility diagram:

$$CE = \frac{[SL]}{[L]} = S_0 \cdot K_{1:1} = \frac{\text{Slope}}{(1 - \text{Slope})} \quad (16)$$

And the substrate:ligand molar ratio can be calculated from the  $CE$ :

$$S : L \text{ molar ratio} = 1 : \frac{(CE + 1)}{CE} \quad (17)$$

For  $A_P$ -type profiles, the equilibrium constants can also be calculated. Equations 3 and 4 apply for a system in which one

substrate molecules forms a complex with two ligand molecules and the following mass balance equations apply:

$$[S]_T = S_0 + [SL] + [SL_2] \quad (18)$$

$$[L]_T = [L] + [SL] + 2 \cdot [SL_2] \quad (19)$$

Equations 3, 4, 18, and 19 can be combined and converted into the following quadratic relationship:

$$[S]_T = S_0 + K_{1.1} \cdot S_0 \cdot [L] + K_{1.1} \cdot K_{1.2} \cdot S_0 \cdot [L]^2 \quad (20)$$

indicating that a plot of  $[S]_T$  versus  $[L]_T$  (assuming that  $[L] \approx [L]_T$ ) fitted to the quadratic relationship will allow for the estimation of  $K_{1.1}$  and  $K_{1.2}$ . Note that at low L concentrations,  $[L]_T$  is sometimes used as an estimate for  $[L]$ , assuming low CE, meaning that a plot of the ligand concentration versus substrate solubilized can be used to estimate the  $K$  values. A linear form of this equation can also be derived:

$$\frac{[S]_T - S_0}{[L]} = K_{1.1} \cdot S_0 + K_{1.1} \cdot K_{1.2} \cdot S_0 \cdot [L] \quad (21)$$

Theoretically, higher order complexation can be further examined with higher order curve fitting meaning that the same formalism can be used when  $K_{1.3}, K_{1.4}, \dots, K_{1,m}$  values are present (the cubic equation is given as an example):

$$[S]_T = S_0 + K_{1.1} \cdot S_0 \cdot [L] + K_{1.1} \cdot K_{1.2} \cdot S_0 \cdot [L]^2 + K_{1.1} \cdot K_{1.2} \cdot K_{1.3} \cdot S_0 [L]^3 \quad (22)$$

It should be emphasized that frequently the  $K$ -values obtained are apparent values that do not describe the actual process on a molecular level. Coexistence of several different types of ligand complexes and the nonideality of substrate saturated solutions complicate exact determination of the  $K$ -values from phase-solubility diagrams. In addition substrate molecules are known to self-associate in aqueous solution and to interact with other pharmaceutical excipients and because these equilibria will reduce the availability of the substrate for complex formation, this may lead to errors in the  $K$ -value determinations. Although correlation is often found between phase-solubility diagrams and the stoichiometry of substrate-ligand complexes determined by other means such as NMR, some discrepancies can be found in the literature.<sup>26</sup>

The origin of  $A_N$ -type phase-solubility profiles is uncertain. One possibility is ligand enforced structural changes of the aqueous complexation medium. Another possibility is self-association of ligand molecules at higher concentrations.

*B-type profiles* indicate formation of complexes with limited water solubility. Two subclasses have been described including  $B_s$  and  $B_l$  systems (Fig. 18-7).  $B_s$ -type isotherms can be interpreted in the following manner. As the ligand concentration increases, a soluble complex is formed which increases the total solubility of the substrate. At a particular point in this solubilization process, the maximum solubility of the substrate is achieved which is the sum of  $S_0$  plus any substrate solubilized in the form of the ligand complex ( $SL$ ). Additional ligand generates additional complex which precipitates but so long as solid substrate remains, dissolution and complexation can occur to maintain the value of  $[S]_T$ . During this plateau phase, the following equilibrium is assumed to occur:

where  $S_s$  is the solid substrate,  $S_{Aq}$  is the dissolved substrate,  $K$  is the stability constant of the complex,  $(SL)_{Aq}$  is the dissolved complex, and  $(SL)_s$  is the solid complex. At some point, all of the solid substrate will have been consumed in the above described process and further addition of the ligand results in the formation of additional insoluble inclusion complex which precipitates and further depletes the total substrate concentration,  $[S]_T$ . Finally, the solubility observed in the systems is associated with the solubility of the precipitated complex. If the same complex which forms in the ascending portion the phase-solubility profile precipitates in the plateau phase, the increase

in the substrate concentration from  $S_0$  to the plateau should be equal to the intrinsic solubility of the complex.

### The kinetic method

The second most common application of complexes in pharmacy is to influence drug kinetics, usually to decrease drug degradation in pharmaceutical formulations. Complexes are always under kinetic equilibrium in aqueous solutions, i.e., the molecules forming a complex are in equilibrium with free molecules in the solution, where the rate of formation and dissociation of the complex is diffusion controlled. In kinetic studies the stability constant ( $K_{m,n}$  in Equation 1) can be determined from the stabilizing or destabilizing effects of a ligand on a given substrate. If a ligand has for example stabilizing effect on a substrate molecule in aqueous solution, then the rate of disappearance of the substrate will decrease when the substrate-to-ligand concentration ratio is decreased (i.e., at increasing ligand concentration). In the following, we assume that the substrate degradation is first order and that a 1:1  $SL$  complex is being formed. The first-order rate constant for degradation of the free substrate ( $k_f$ ) is determined in the aqueous complexation media when no ligand is present. The first-order rate constant for the degradation of the substrate within the ligand complex ( $k_c$ ) and  $K_{1.1}$  can then be determined from the degradation profile (Fig. 18-8) and the observed first-order rate constant ( $k_{obs}$ ) for the rate of disappearance of the substrate:

$$k_{obs} = k_f \cdot f_f + k_c \cdot f_c \quad (24)$$

where  $f_f$  is the fraction of free substrate and  $f_c$  is the fraction of substrate in complex. If we assume that only a 1:1 substrate-ligand complex ( $SL$ ) is being formed and that the total substrate concentration ( $[S]_T$ ) is the sum of the concentration of free substrate ( $[S]$ ) and the concentration of the complex ( $[SL]$ ) the following equations are obtained:

$$[S]_T = [S] + [SL] \quad (25)$$

$$[L]_T = [L] + [SL] \quad (26)$$

$$K_{1.1} = \frac{[SL]}{[S] \cdot [L]} \quad (27)$$

$$f_f = \frac{[S]}{[S] + [SL]} = \frac{1}{1 + K_{1.1} \cdot [L]} \quad (28)$$

$$f_c = 1 - f_f = \frac{K_{1.1} \cdot [L]}{1 + K_{1.1} \cdot [L]} \quad (29)$$

$$k_{obs} = \frac{k_f + k_c \cdot K_{1.1} \cdot [L]}{1 + K_{1.1} \cdot [L]} \quad (30)$$

$$-\frac{d[S]_T}{dt} = k_{obs} \cdot [S]_T = \left( \frac{k_f + k_c \cdot K_{1.1} \cdot [L]}{1 + K_{1.1} \cdot [L]} \right) \cdot [S]_T \quad (31)$$

If the total ligand concentration is much greater than the total substrate concentration ( $[L]_T \geq 10 \cdot [S]_T$ ) then it can be assumed that  $[L] \approx [L]_T$ :

$$k_{obs} = \left( \frac{k_f + k_c \cdot K_{1.1} \cdot [L]}{1 + K_{1.1} \cdot [L]} \right) \quad (32)$$

Equation 32 can then be rearranged into several different formats including that of the Lineweaver-Burk plot where  $(k_f - k_{obs})^{-1}$  versus  $([L]_T)^{-1}$  will give a straight line in which  $k_c$  can be obtained from the intercept and  $K_{1.1}$  from the slope:

$$\frac{1}{k_f - k_{obs}} = \frac{1}{K_{1.1} \cdot (k_f \cdot k_c)} \cdot \frac{1}{[L]_T} + \frac{1}{k_f - k_c} \quad (33)$$

Alternatively,  $k_c$  and  $K_{1.1}$  can be obtained by simple non-linear fitting of  $k_{obs}$  according to equation 32.

### UV/vis spectroscopic method

It is also possible to determine the value of  $K_{1.1}$  by observing spectrophotometric or spectroscopic changes of the substrate

**Figure 18-8.** Under acidic conditions unionized aspirin forms 1:1 complex with  $\beta$ -cyclodextrin and its derivatives. When cyclodextrin is added to the aqueous aspirin solution the lipophilic aromatic ring will be taken into the cyclodextrin cavity where the ester linkage is more sterically hindered against nucleophilic attack by water molecules than outside it (i.e.,  $k_f > k_c$ ).

**Figure 18-9.** Ultraviolet absorption spectrum of *p*-nitrophenol in the presence of varying concentrations of  $\alpha$ -cyclodextrin. The *p*-nitrophenol concentration is  $1.99 \cdot 10^{-4}$  M, and the cyclodextrin concentration ranges from zero (topmost spectrum) to 0.01 M.

upon binding. Figure 18-9 shows how the ultraviolet spectrum of *p*-nitrophenol changes upon complexation with  $\alpha$ -cyclodextrin. The spectrometric changes which occur are similar to those encountered when a substrate is dissolved in solvents of decreased polarity (e.g., water  $\rightarrow$  dioxane). In the case of cyclodextrin guest-host complexes, the chromophore of the guest (substrate) is transferred from a polar aqueous environment to a less polar environment within the cyclodextrin cavity (ligand). The presence of well-defined isosbestic points is consistent with the assumption of 1:1 stoichiometry.

A wavelength showing significant changes in absorption is selected and the changes in absorption titrated assuming that Beer's law is obeyed:

$$A_0 = \epsilon_s \cdot b \cdot [S]_T \quad (34)$$

where  $A_0$  is the absorbance of a substrate solution when no ligand is present,  $\epsilon_s$  is the molar absorptivity of the substrate,  $b$  is the path length and  $[S]_T$  is the total substrate concentration. In the presence of a ligand the absorbance is:

$$A_L = \epsilon_s \cdot b \cdot [S] + \epsilon_L \cdot b \cdot [L] + \epsilon_{11} \cdot b \cdot [SL] \quad (35)$$

where  $\epsilon_L$  is the absorptivity of the ligand and  $\epsilon_{11}$  is the absorptivity of the complex. Combining equation 35 with the mass

balances  $[S]_T = [S] + [SL]$  and  $[L]_T = [L] + [SL]$  (i.e., Equations 25 and 26) gives:

$$A_L = \epsilon_s \cdot b \cdot [S]_T + \epsilon_L \cdot b \cdot [L]_T + \Delta\epsilon_{11} \cdot b \cdot [SL] \quad (36)$$

where  $\Delta\epsilon_{11} = \epsilon_{11} - \epsilon_S - \epsilon_L$ . If the solution absorbance is measured against reference solution containing same concentration of ligand ( $[L]_T$ ) but no substrate ( $[S]_T = 0$ ) the measured absorbance will be:

$$A = \epsilon_s \cdot b \cdot [S]_T + \Delta\epsilon_{11} \cdot b \cdot [SL] \quad (37)$$

Combining Equations 3 and 37 gives the Benesi-Hildebrand equation:

$$\frac{b}{\Delta A} = \frac{1}{K_{1:1} \cdot [S]_T \cdot \Delta\epsilon_{11}} \cdot \frac{1}{[L]_T} + \frac{1}{[S]_T \cdot \Delta\epsilon_{11}} \quad (38)$$

where  $\Delta A$  is the difference in absorbance in the presence and absence of ligand. Most frequently the  $[S]_T$  is kept constant whereas  $[L]_T$  is varied. Then a plot of  $b/\Delta A$  versus  $1/[L]_T$  should give a straight line for a 1:1 complex with the ratio intercept/slope yielding  $K_{1:1}$ .

### NMR spectrometry

Changes in the NMR spectra of the substrate and/or the ligand (i.e., chemical shifts, coupling constants, nuclear Overhauser effects, and spin-spin and spin-lattice relaxation times) can be used to probe the solution geometry of complexes as well as to give kinetic information on their association and dissociation. If the changes in chemical shift of, for example, the substrate molecule is titrated then a modified Benesi-Hildebrand Equation 38 can be used:

$$\frac{1}{\Delta\delta} = \frac{1}{K_{1:1} \cdot \Delta\delta_{\max}} \cdot \frac{1}{[L]_T} + \frac{1}{[S]_T \cdot \Delta\delta_{\max}}$$

where  $\Delta\delta$  is the change in chemical shift at particular ligand concentration and  $\Delta\delta_{\max}$  is the limiting change in chemical shift at infinite ligand concentration (i.e., when all the substrate molecules in the solutions are bound to the ligand). A plot of  $1/\Delta\delta$  versus  $1/[L]_T$  should give a straight line for a 1:1 complex with the ratio intercept/slope yielding  $K_{1:1}$ .

## CYCLODEXTRINS

Cyclodextrins are cyclic oligosaccharides consisting of ( $\alpha$ -1,4)-linked D-glucopyranose units, with a hydrophilic outer surface and a lipophilic central cavity. The natural  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrins consist of 6, 7, and 8 glucopyranose units, re-

**Figure 18-10.** The structure of  $\beta$ -cyclodextrin.

spectively (Fig. 18-10 and Table 18-2).<sup>25,27,28</sup> The diameters of the central cavities are about 5, 6, and 7 Å for  $\alpha$ -,  $\beta$ -, and  $\gamma$ -cyclodextrin, respectively. Larger cyclodextrins containing more than eight glucopyranose units do exist but are of limited pharmaceutical interest. Although the natural cyclodextrins and their complexes are hydrophilic, their aqueous solubility can be rather limited. This is thought to be due to relative strong binding of the cyclodextrin molecules in the crystal state. Random substitution of the hydroxy groups can result in dramatic improvements in their aqueous solubility. Cyclodextrin derivatives of pharmaceutical interest include the hydroxypropyl derivatives of  $\beta$ - and  $\gamma$ -cyclodextrin, the randomly methylated  $\beta$ -cyclodextrin and sulfobutylether  $\beta$ -cyclodextrin (Table 18-2). The molar degree of substitution (MS) is defined as the average number of substituents that have reacted with one glucopyranose repeat unit. In an aqueous environment, cyclodextrins form inclusion complexes with many lipophilic molecules through a process in which water molecules located inside the central cavity are replaced by either a whole molecule, or more frequently by some lipophilic structure of the molecule (Fig. 18-8). Cyclodextrin complexation of a drug molecule changes the physicochemical properties of the drug, such as its aqueous solubility, chemical stability and ability to permeate biological membranes. Because the cyclodextrin molecule is hydrophilic on the outside the complex formation usually increases the water-solubility of lipophilic water-insoluble drugs. Once included in the cyclodextrin cavity, the drug molecules may be dissociated from the cyclodextrin molecules through complex dilution or competitive binding by some other suitable molecule (e.g., lipids) or, if the complex is located in close approximation to a lipophilic biological membrane (e.g., mucosa), the drug may be transferred to the matrix for which it has the highest affinity. Importantly, because no covalent bonds are formed or broken during the guest-host complex formation, the complexes are

in dynamic equilibrium with free drug and cyclodextrin molecules. In aqueous solutions the rates for formation and dissociation of drug-cyclodextrin complexes are very close to the diffusion-controlled limits and the complexes are continuously being formed and dissociated.<sup>29</sup> For cyclodextrin complexes the value of  $K_{1:1}$  (Equations 1 and 15) is frequently between  $10^1$  and  $10^3 \text{ M}^{-1}$  and  $K_{1:1}$  greater than  $5 \times 10^3 \text{ M}^{-1}$  is rarely observed. The effects of cyclodextrins on drug solubility, bioavailability, chemical stability and delivery through biological membranes have been investigated by a number of research groups.<sup>28,30</sup>

Cyclodextrins enhance drug delivery through biological membranes by increasing drug permeation through the unstirred water layer that is located adjacent to the membrane surface or, in other words, by increasing the availability of dissolved drug molecules juxtaposed to the membrane surface. Cyclodextrins only enhance drug permeation when a water layer is present at the membrane exterior. Such water layers can consist of mucus or an aqueous vehicle such as o/w creams or hydrogels. Cyclodextrins do not enhance drug permeation from vehicles that do not form an unstirred water layer, such as lipophilic ointments and w/o creams. The effect also depends on the physicochemical properties of the drug. Better enhancement is obtained for lipophilic drugs that are poorly soluble in water that form water-soluble complexes with cyclodextrins with stability constants ( $K_{1:1}$ ) that are between about 50 and  $5000 \text{ M}^{-1}$ .<sup>30</sup>

In aqueous solutions free drug molecules are in equilibrium with drug molecules bound in a complex and, thus, the release of drug molecules from cyclodextrin-containing vehicle will depend on the drug/cyclodextrin molar ratio and the  $K_{m:n}$  value (Eq. 1). Furthermore, pharmaceutical excipients will affect the  $K_{m:n}$  value. Thus it is of utmost importance to optimize the drug vehicle with regard to the amount of cyclodextrin. Too much or too little cyclodextrin will result in less than optimal drug bioavailability.

Recently it has been discovered that cyclodextrin molecules and their complexes self-associate in aqueous solutions to form nanoparticles.<sup>31</sup> The general observation is that the aggregate formation increases with increasing cyclodextrin concentration. The anomalously low solubility of  $\beta$ -cyclodextrin is explained by the intensity of nanoparticle formation (i.e., aggregation). The same explanation is valid for the observed peculiarity of aqueous  $\gamma$ -cyclodextrin solutions, which are known to become spontaneously turbid at concentrations of about 1% (w/v) or above. The fraction of molecules participating in nanoparticle formation is often very low. For example, the mass contribution of the nanoparticles in aqueous 12 mM  $\alpha$ -cyclodextrin solution does not exceed 0.8%, that of  $\beta$ -cyclodextrin is only 0.0011% in 10 mM in  $\beta$ -cyclodextrin solution, and that of  $\gamma$ -cyclodextrin is only 0.02% in 12 mM  $\gamma$ -cyclodextrin solution.<sup>32-34</sup> However, formation of cyclodextrin complexes enhances the cyclodextrin aggregation.<sup>35</sup> In some cases the mass contribution of the nanoparticles in aqueous complexation media can be well above 50%. Another interesting feature of cyclodextrin nanoparticles is their shape, such as disks, rods and fibers. Thus, cyclodextrins

**Table 18-2. The natural cyclodextrins and some of their derivatives.**

Cyclodextrin	Synonyms	MS	MW* (Da)	Solubility (mg/ml)
$\alpha$ -Cyclodextrin	alfadex		972.8	130
$\beta$ -Cyclodextrin	betadex		1135	18.4
2-Hydroxypropyl- $\beta$ -cyclodextrin	hydroxypropyl betadex	0.65	1400	> 600
Sulfobutylether $\beta$ -cyclodextrin sodium salt		0.9	2163	> 500
Methylated $\beta$ -cyclodextrin		1.8	1312	> 600
		0.57	1191	200
$\gamma$ -Cyclodextrin	gammadex		1297	249
2-Hydroxypropyl- $\gamma$ -cyclodextrin	hydroxypropylgammadex	0.6	1576	> 600

\*The molecular weights (MW) of the cyclodextrin derivatives will depend on their molar degree of substitution (MS), i.e., the number of substituents per glucopyranose repeat unit.

and cyclodextrin complexes form supramolecular complexes at elevated cyclodextrin concentrations.

Due to their favorable toxicological profile cyclodextrins are frequently preferred to organic solvents during *in vitro/in vivo* evaluation of new chemical entities.

Worldwide there are between 30 and 40 different cyclodextrin-containing drug products on the market and few examples are shown in Table 18-3. In most cases cyclodextrins are used as solubilizers, either to enhance dissolution and oral bioavailability of poorly-soluble drugs in solid dosage forms or to replace organic solvents in parenteral dosage forms. Cyclodextrins are also used to increase both chemical and physical stability of drugs, including both peptide and protein drugs, to reduce drug-drug and drug-excipient interactions and to convert liquids to solid powders. Cyclodextrins can also have some adverse effects. For example, excess cyclodextrin can hamper drug absorption from the gastro-intestinal tract and permeation of drugs through skin and other biological membranes. In fact, cyclodextrins have been used to prevent permeation of topically applied sunscreen agents into skin and to reduce absorption of fat from the gastrointestinal tract.

## COMPLEXES IN PHARMACY

### APPLICATION TO DRUG DELIVERY

Complexation may affect physicochemical and biopharmaceutical properties of drugs, such as aqueous solubility, chemical stability, dissolution rate, partition coefficient, permeability, rate of absorption, bioavailability, biological activity, volatility and physical state (e.g., converting liquid drug into solid drug complex). Pharmaceutical formulators sometimes apply

complexation agents in their formulation design. For example, cyclodextrins and their derivatives are commonly applied functional pharmaceutical excipients with products containing these materials associated with numerous therapeutic categories and administration routes (Table 18-3). These materials are present in formulations intended for parenteral (intravenous, intramuscular, intracavernosal), oral, sublingual, buccal, nasal, ophthalmic, and dermal use. Parenteral use of cyclodextrins include drug products intended to deliver prostaglandins with examples including prostaglandin E1 formulated with  $\alpha$ -cyclodextrin ( $\alpha$ CD) (alprostadil alfadex). This formulation is used in the treatment of various vascular complications including Buerger's disease. More recently, the material has been shown to be of benefit in male erectile dysfunction when administered intracavernosally. Studies have found that it is useful in patients who do not respond to oral sildenafil (Viagra®, Pfizer) treatment. Although  $\beta$ -cyclodextrin ( $\beta$ CD) is contraindicated parenterally, its derivatives can be safely administered using the oral route. 2-Hydroxypropyl- $\beta$ -cyclodextrin (HP $\beta$ CD) is available in several intravenous products including in the Sporanox® IV solution (itraconazole) product. Itraconazole is a triazole-type drug which exerts its effect by inhibiting fungal P450 and inhibiting the biosynthesis of ergosterol, an essential component of the fungal membrane. The compound is noteworthy in that it was the first approved orally bioavailable agent with significant clinical activity against both candidiasis and *Aspergillus spp.*, the two most common human fungal pathogens. Intravenous use of itraconazole is indicated for empiric therapy of idiopathic fever as well as for blastomycosis (pulmonary and extra-pulmonary), histomycosis (pulmonary and disseminated, non-meningeal) and aspergillosis (pulmonary and non-pulmonary). Cyclodextrins were enabling in this

**Table 18-3. Examples of cyclodextrin-containing drug products.**

Drug/Cyclodextrin	Therapeutic usage	Formulation	Trade Name
<i><math>\alpha</math>-Cyclodextrin (<math>\alpha</math>CD)</i>			
Alprostadil	To treat erectile dysfunction	IV solution	Caverject Dual
<i><math>\beta</math>-Cyclodextrin (<math>\beta</math>CD)</i>			
Cetirizine	Antihistamine drug	Chewing tablets	Cetirizin
Dexamethasone	Anti-inflammatory steroid	Ointment, tablets	Glymesason
Ethinylestradiol and drospirenone	Birth control	Tablets	Yaz
Iodine	Throat disinfection	Solution	Mena-Gargle
Nicotine	Nicotine replacement product	Sublingual tablets	Nicorette
Nimesulide	Non-steroidal anti-inflammatory drug	Tablets	Nimedex
Omeprazole	To treat gastroesophageal reflux	Tablets	Omebeta
Piroxicam	Non-steroidal anti-inflammatory drug	Tablets, suppository	Brexin
Tiaprofenic acid	Non-steroidal anti-inflammatory drug	Tablets	Surgamyl
<i>2-Hydroxypropyl-<math>\beta</math>-cyclodextrin (HP<math>\beta</math>CD)</i>			
Indomethacin	Non-steroidal anti-inflammatory drug	Eye drop solution	Indocid
Itraconazole	Antifungal agent	Oral and i.v. solutions	Sporanox
Mitomycin	Anticancer agent	IV infusion	MitoExtra
<i>Sulfobutylether <math>\beta</math>-cyclodextrin sodium salt (SBE<math>\beta</math>CD)</i>			
Aripiprazole	Antipsychotic drug	IM solution	Abilify
Maropitant	Anti-emetic drug (motion sickness in dogs)	Parenteral solution	Cerenia
Voriconazole	Antifungal agent	IV solution	Vfend
Ziprasidone mesylate	Antipsychotic drug	IM solution	Geodon
<i>Randomly methylated <math>\beta</math>-cyclodextrin (RM<math>\beta</math>CD)</i>			
Cloramphenicol	Antibacterial agent	Eye drop solution	Clorocil
<i><math>\gamma</math>-Cyclodextrin (<math>\gamma</math>CD)</i>			
Tc-99 Teboroxime	Diagnostic aid, cardiac imaging	IV solution	CardioTec
<i>2-Hydroxypropyl-<math>\gamma</math>-cyclodextrin (HP<math>\gamma</math>CD)</i>			
Diclofenac sodium salt	Non-steroidal anti-inflammatory drug	Eye drop solution	Voltaren Ophtha
Tc-99 Teboroxime	Diagnostic aid, cardiac imaging	IV solution	CardioTec

product due to their solubilizing effect on itraconazole which has an estimated aqueous solubility at neutral pH of about 1 ng/mL. The formulation contains 40% w/v HP $\beta$ CD and increases the solubility of itraconazole to 10 mg/mL (or approximately 100,000-fold). Based on i.v. doses of itraconazole between 200 and 400 mg and the formulation containing 10 mg/mL itraconazole in a 40% HP $\beta$ CD solution, the i.v. dose of HP $\beta$ CD is between 8 and 16 g/day. Another widely used  $\beta$ -cyclodextrin derivative is the sulfobutylether  $\beta$ -cyclodextrin sodium salt (SBE $\beta$ CD). This anionic excipient is found in a number of parenteral products including the intravenous formulation for voriconazole (Vfend, Pfizer) as well as intramuscular preparations for ziprasidone (Geodon, Zeldox, Pfizer) and aripiprazole (Abilify, BMS). In the case of voriconazole, the cyclodextrin solubilizes the antifungal such that its solubility increases from 0.2 mg/mL at pH 3 in the absence of cyclodextrin to 10 mg/mL using 15% w/v SBE $\beta$ CD. Based on standard injection doses of the API, 3.5 to 7 g of the cyclodextrin are administered. 2-Hydroxypropyl- $\gamma$ -cyclodextrin (HP $\gamma$ CD) is also available in an approved intravenous product.

Oral use of cyclodextrins includes products containing  $\alpha$ CD,  $\beta$ CD, and HP $\beta$ CD. An oral formulation has been developed and marketed for itraconazole. This dosage form provides for increased and more consistent oral bioavailability of itraconazole relative to other solid formulation in various subpopulations with a fraction absorbed of 85% and oral bioavailability of 55%. Based on oral doses of 200 mg itraconazole, the dose of HP $\beta$ CD is 8 g/day. This formulation also allowed the effective treatment of esophageal candidiasis. Solid oral dosage forms containing  $\beta$ CD include tablets containing ethinylestradiol and drospirenone (Yaz®, Bayer), piroxicam (Brexin®, Chiesi) and prostaglandin E2 (Prostarmon E®, Ono). Cyclodextrins are also used to enhance drug absorption from suppositories as well as to increase the bioavailability of drug in eye drops and nasal sprays.<sup>28,30</sup>

Complexation does not always improve the physicochemical and biopharmaceutical properties of drugs and, as previously mentioned, some *incompatibilities* (i.e., drug-drug and drug-excipient interactions) as well as drug-food interactions are the results of unwanted drug complexation.

Other complexing agents commonly used in drug formulations are, for example, EDTA and citric acid for complexation of metal ions. Metal ions catalyze various drug degradation pathways such as oxidation. However, the complex bound metal ions are inactive. Polyalcohols, such as sorbitol, are added as stabilizers to lyophilized protein drugs. The polyalcohols form complexes with proteins and prevent their self-aggregation.

## COMPLEXES IN PHARMACEUTICAL ANALYSIS

Complexation is an essential aspect of many types of bioanalysis. Determination of metal ions is frequently based on metal ion coordination complexes. *Complexometric* (chelometric) titration is often based on EDTA complexation of metal ions. Spectrophotometric (i.e., colorimetric) determinations of metal ions are sometimes based on complex formations. Recently, complexes have been applied in *chiral chromatography*. Cyclodextrins have found numerous applications in this regard in part due to their ability to interact with compounds by complexation as well as their molecular recognition abilities. These properties have allowed cyclodextrin to aid in chiral analysis in gas and high performance liquid chromatography as well as capillary electrophoresis and NMR assessments. Chromatographically, cyclodextrins can be added to the mobile phase or bound to the stationary phase with both approaches being widely exploited. Cyclodextrins are chiral sugars and can be useful adjuncts in circular dichroism measurements due to their ability to induce chirality in non-chiral substrates. Furthermore, cyclodextrins can increase fluorescence quantum yield by shielding the excited singlet state in the central cavity thus protecting it from quenching and related effects. *Phosphorescence* can likewise be allowed in solution by providing

pseudo-ordered state within the cyclodextrin cavity in which the triplet state can relax.

## DRUG-PROTEIN BINDING

After a drug has been absorbed into plasma, or after it has been injected into the blood circulation, the drug molecules are carried by the blood circulation to the target tissue within the body where they bind to receptors. The drug molecules are also carried to the eliminating organs such as the liver and kidneys. Blood plasma and the various body tissues contain proteins that are able to form complexes with drugs. Formation of such complexes is reversible and is normally referred to as drug-protein binding. Irreversible drug-protein binding is usually a consequence of covalent binding of drug molecules to proteins, not complexation, and may account for certain types of adverse effects such as allergy, carcinogenicity, teratogenicity or tissue toxicity. Drug-protein binding does affect the ability of drug molecules to permeate biological membranes and their ability to interact with enzymes and receptors. Only unbound drug molecules permeate membrane barriers and interact with drug receptors or undergo metabolism and glomerular filtration, and, thus, drug-protein binding will affect the drug pharmacokinetics.

Plasma protein binding is the result of complex formation between drug molecules and plasma proteins, such as human serum albumin (HSA), lipoprotein, glycoprotein, and  $\alpha$ -,  $\beta$ -, and  $\gamma$ -globulin, of which HSA is the most important and most studied. HSA consists of 585 amino acid residues having calculated molecular weight of 66.47 kDa. Normal plasma concentration of HSA is between 35 and 55 mg/ml but it varies with age, exercise, stress and disease. One of the functions of HSA is to act as a transporter for poorly soluble drugs. However, HSA is very non-specific complexing agent that besides drugs binds water, various cations, fatty acids and thyroid hormones. Also plasma  $\alpha_1$ -acid-glycoprotein ( $\alpha$ -AGP) has been shown to bind a variety of drugs. Other plasma proteins play a smaller role in drug-protein binding.<sup>36,37</sup> In general, weak bonds such as hydrophobic bonds, van der Waals dispersion forces, hydrogen bonds, and ionic interactions are involved in the protein binding of drugs. Each protein molecule may possess several binding sites (i.e. bind several drug molecules) and, thus Equation 1 is not precisely applicable but it can be used to explain the basis of binding of drug ( $D$ ) to a protein ( $P$ ) to form a drug-protein complex ( $PD$ ):

If one drug molecule is bound to one protein molecule then (see Equations 28 and 29 for comparison):

$$r = \frac{\text{concentration of bound drug}}{\text{total concentration of protein}} = \frac{[PD]}{[PD] + [P]} \quad (41)$$

$$= \frac{[PD]}{[P]_r} = \frac{K \cdot [D]}{1 + K \cdot [D]}$$

where  $K$  is the binding constant or the equilibrium constant of the complex formation and  $[D]$  is the concentration of free drug. However, because each protein has  $n$  number of independent binding sites we get:

$$r = \frac{n \cdot K \cdot [D]}{1 + K \cdot [D]} \quad (42)$$

Then the large protein molecule may contain more than one type of binding sites:

$$r = \frac{n_1 \cdot K_1 \cdot [D]}{1 + K_1 \cdot [D]} + \frac{n_2 \cdot K_2 \cdot [D]}{1 + K_2 \cdot [D]} + \dots \quad (43)$$

where  $n_1$  is the number of binding sites of type 1 with binding constant  $K_1$ ,  $n_2$  is the number of binding sites of type 2 with binding constant  $K_2$ , and so on. If only one type of binding site exists then Equation 42 can be converted to:

$$\frac{1}{r} = \frac{1}{n \cdot K} \cdot \frac{1}{[D]} + \frac{1}{n} \quad (44)$$

Plotting  $1/r$  against  $1/[D]$  will give a straight line where the value of  $K$  is obtained from the slope and the number of binding sites ( $n$ ) from the intercept. The concentration of free drug can be determined by dialysis. The fraction of bound drug ( $\beta$ ) is expressed as:

$$\beta = \frac{\text{concentration of bound drug}}{\text{total concentration of drug}} = \frac{[PD]}{[PD] + [D]} \quad (45)$$

$$= \frac{n \cdot K \cdot [P]_T}{1 + K \cdot [D] + n \cdot K \cdot [P]_T}$$

The plasma protein binding is non-linear and, thus, the fraction of drug bound is dependent on the concentration of both drug and protein. However, at very low free drug concentrations ( $[D]$ )  $\beta$  becomes essentially independent of drug concentration but  $\beta$  increases with increasing protein concentration ( $[P]_T$ ). Drugs with high  $K$  value may saturate the protein resulting in a decrease in  $\beta$  with increasing drug concentration. Drugs with relatively high  $\beta$  values are susceptible to drug-drug interactions due to competitive drug protein binding.

*Enzymes* are proteins that catalyze reactions and like all proteins, enzymes are long, linear chains of amino acids that fold to produce a three-dimensional structure. Enzymes ( $E$ ) form an intermediate complex ( $ES$ ) with the substrate which is then converted to product upon release of the enzyme:

$K$  is the binding constant or the equilibrium constant of the complex formation and  $k_2$  is the rate constant for the catalyzed reaction. Enzymes can be highly specific catalyzing only certain class of chemical reactions or even only one particular reaction. Enzyme catalysis is covered in Chapter 17.

*Drug receptors* ( $R$ ) are most often, but not always, proteins that interact with the drug molecules ( $D$ ) to form a drug-receptor complex ( $DR$ ) (see Chapter 38):

The complex formation changes the receptor that consequently leads to a biological activity and pharmacological response and/or adverse toxic effects. The forces involved in drug-receptor binding are the same as responsible for drug-protein binding such as ionic interactions, hydrogen bonds van der Waals dispersion forces and hydrophobic bonds. Formation of irreversible covalent bonds between drug and receptor leads to long-lasting effects.

## COMPLEXES IN THERAPEUTICS

Complexes are very common in biological systems. As mentioned above drugs interact with proteins, including enzymes and receptors, through complex formations. For example, biological activity of some antimicrobial and antineoplastic agents is based on complex formation with DNA base-pairs. Molecular complexes in biological systems include DNA base-pairing and folding of proteins. Charge-transfer interactions play an important role in some membrane-transport processes. Metal ion coordination complexes are important parts of many biologically active compounds.<sup>38</sup> Examples of such compounds are hemoglobin (iron), cytochrome (iron), carboxypeptidase A (zinc), carbonic anhydrase (zinc), superoxide dismutase (zinc and copper), vitamin B<sub>12</sub> (cobalt), chlorophyll (magnesium), and urease (nickel).

### INTRODUCTION

Very often it is desirable or necessary in the development of pharmaceutical dosage forms to produce multiphase dispersions by mixing together two or more ingredients that are not mutually miscible and capable of forming homogeneous solutions. Examples of such dispersions include:

- Suspensions (solid in liquid)
- Emulsions (liquid in liquid)
- Foams (vapor in liquids)

Because these systems are not homogeneous and thermodynamically stable, over time they will show some tendency to separate on standing. By doing so, this produces the minimum possible surface area of contact between phases. Thus, suspended particles agglomerate and sediment, emulsified droplets cream and coalesce, and the bubbles dispersed in foams collapse to produce unstable and nonuniform dosage forms. One way to prevent or slow down this natural tendency for further phase separation is to add materials that can accumulate at the interface to provide some type of energy barrier to aggregation and coalescence. Such materials are said to exhibit *surface activity* or to act as *surface-active agents*.

In this chapter the fundamental physical chemical properties of molecules situated at interfaces will be discussed so that the reader can gain a better understanding of how problems involving interfaces can be resolved in designing pharmaceutical dosage forms by the use of surface-active agents.

### INTERFACIAL FORCES AND ENERGETICS

In the bulk portion of each phase, molecules are attracted to each other equally in all directions, such that no resultant forces are acting on any one molecule. The strength of these forces determines whether a substance exists as a vapor, liquid, or solid at a particular temperature and pressure.

At the boundary between phases, however, molecules are acted upon unequally because they are in contact with other molecules exhibiting different forces of attraction. For example, the primary intermolecular forces in water are due to hydrogen bonds, whereas those responsible for intermolecular bonding in hydrocarbon liquids, such as mineral oil, are due to London dispersion forces.

Thus, molecules situated at the interface experience interaction forces dissimilar to those experienced in each bulk phase. In liquid systems such unbalanced forces can be satisfied by spontaneous movement of molecules from the interface into the bulk phase. This leaves fewer molecules per unit area at the interface (greater intermolecular distance) and reduces the actual contact area between dissimilar molecules.

Any attempt to reverse this process by increasing the area of contact between phases—that is, bringing more molecules into

the interface—causes the interface to resist expansion and behave as though it is under a tension everywhere in a tangential direction. The force of this tension per unit length of interface generally is called the *interfacial tension*, except when dealing with the air–liquid interface, where the terms *surface* and *surface tension* are used.

To illustrate the presence of a tension in the interface, consider an experiment in which a circular metal frame with a looped piece of thread loosely tied to it is dipped into a liquid. When the frame is removed and exposed to the air, a film of liquid will be stretched entirely across the circular frame, as when one uses such a frame to blow soap bubbles. Under these conditions (Figure 19-1A) the thread will remain collapsed. If a heated needle is used to puncture and remove the liquid film from within the loop (Figure 19-1B), the loop will stretch spontaneously into a circular shape.

The result of this experiment demonstrates the spontaneous reduction of interfacial contact between air and the liquid remaining; indeed, it illustrates that a tension causing the loop to remain extended exists parallel to the interface. The circular shape of the loop indicates that the tension in the plane of the interface exists at right angles or normal to every part of the looped thread. The total force on the entire loop divided by the circumference of the circle, therefore, represents the tension per unit distance of surface, or the surface tension.

Just as work is required to extend a spring under tension, work should be required to reverse the process seen in Figure 19-1A and B, thus bringing more molecules to the interface. This may be seen quantitatively by considering an experiment in which tension and work may be measured directly. Assume that we have a rectangular wire with one movable side (Figure 19-2). Assume further that by dipping this wire into a liquid, a film of liquid will form within the frame when it is removed and exposed to the air. As seen earlier in Figure 19-1, when it comes in contact with air, the liquid surface will tend to contract with a force  $F$  as molecules leave the surface for the bulk. To keep the movable side in equilibrium, an equal force must be applied to oppose this tension in the surface. The surface tension  $\gamma$  of

**Figure 19-1.** A circular wire frame with a loop of thread loosely tied to it: (A) a liquid film on the wire frame with a loop in it; (B) the film inside the loop is broken. (From Semat H. *Fundamentals of Physics*, 3rd edn. New York: Holt Rinehart Winston, 1957.)

**Figure 19-2.** A movable wire frame containing a film of liquid being expanded with a force  $F$ .

the liquid may be defined as  $F/2l$ , where  $2l$  is the distance of surface over which  $F$  is operating. The factor 2 arises out of considering two surfaces, top and bottom. Upon expansion of the surface by a very small distance,  $\Delta x$ , the work done ( $W$ ) is

$$W = F\Delta x \quad (1)$$

and, therefore,

$$W = \gamma 2l\Delta x \quad (2)$$

Since

$$\Delta A = 2l\Delta x \quad (3)$$

where  $\Delta A$  is the change in area due to the expansion of the surface, it may be concluded that

$$W = \gamma\Delta A \quad (4)$$

Thus, the work required to create a unit area of surface, known as the *surface free energy/unit area*, is equivalent to the surface tension of a liquid system—the greater the area of interfacial contact between phases, the greater the free-energy increase for the total system. Because a prime requisite for equilibrium is that the free energy of a system be at a minimum, it is not surprising to observe that phases in contact tend to reduce area of contact spontaneously.

Liquids, being mobile, may assume spherical shapes (smallest interfacial area for a given volume), as when ejected from an orifice into air or when dispersed into another immiscible liquid. If a large number of drops are formed, further reduction in area can occur by having the drops coalesce, as when a foam collapses or when the liquid phases making up an emulsion separate.

In the centigrade-gram-second (cgs) system, surface tension is expressed in units of dynes per centimeter (dyne/cm), while surface free energy is expressed in  $\text{erg}/\text{cm}^2$ . Because an  $\text{erg}$  is a dyne-cm, both sets of units are equivalent. In the SI (international units) system, surface tension is expressed in  $\text{mN}/\text{m}$  and surface free energy in  $\text{mJ}/\text{m}^2$ .

Values for the surface tension of a variety of liquids are given in Table 19-1, and interfacial tension values for various liquids against water are given in Table 19-2. Other combinations of immiscible phases could be given, but most heterogeneous systems encountered in pharmacy usually contain water. Values for these tensions are expressed for a particular temperature. Because an increased temperature increases the thermal energy of molecules, the work required to bring molecules to the interface should be less, and thus the surface and interfacial tension will be reduced. For example, the surface tension of water is 76.5 dynes/cm at  $0^\circ\text{C}$  and 63.5 dynes/cm at  $75^\circ\text{C}$ .

As would be expected from the discussion so far, the relative values for surface tension should reflect the nature of intermolecular forces present, hence the relatively large values for mercury (metallic bonds) and water (hydrogen bonds) and the lower values for benzene, chloroform, carbon tetrachloride, and the  $n$  alkanes.

Benzene, with  $\pi$  electrons, exhibits a higher surface tension than the alkanes of comparable molecular weight, but increasing the molecular weight of the alkanes (and hence intermolecular

**Table 19-1.** Surface Tension of Various Liquids at  $20^\circ\text{C}$

Substance	Surface Tension (dyne/cm)
Mercury	476
Water	72.8
Glycerin	63.4
Oleic acid	32.5
Benzene	28.9
Chloroform	27.1
Carbon tetrachloride	26.8
1-Octanol	26.5
Hexadecane	27.4
Dodecane	25.4
Decane	23.9
Octane	21.8
Heptane	19.7
Hexane	18.0
Perfluoroheptane	11.0
Nitrogen (at $75^\circ\text{K}$ )	9.4

**Table 19-2.** Interfacial Tension of Various Liquids Against Water at  $20^\circ\text{C}$

Substance	Interfacial Tension (dyne/cm)
Decane	52.3
Octane	51.7
Hexane	50.8
Carbon tetrachloride	45.0
Chloroform	32.8
Benzene	35.0
Mercury	428
Oleic acid	15.6
1-Octanol	8.51

attraction) increases their surface tension closer to that of benzene. The lower values for the more nonpolar substances, perfluoroheptane and liquid nitrogen, demonstrate this point even more strongly.

Values of interfacial tension should reflect the differences in chemical structure of the two phases involved—the greater the tendency to interact, the less the interfacial tension. The 20-dyne/cm difference between air–water tension and that at the octane–water interface reflects the small, but significant, interaction between octane molecules and water molecules at the interface. This is seen also in Table 19-2 by comparing the values for octane and octanol, oleic acid and the alkanes, or chloroform and carbon tetrachloride. In each case the presence of chemical groups capable of hydrogen bonding with water markedly reduces the interfacial tension, presumably by satisfying the unbalanced forces at the interface. These observations strongly suggest that molecules at an interface arrange themselves, or orient, so as to minimize differences between bulk phases.

That this phenomenon occurs even at the air–liquid interface is seen when one notes the relatively low surface-tension values of very different chemical structures, such as the  $n$  alkanes, octanol, oleic acid, benzene, and chloroform. Presumably, in each case the similar nonpolar groups are oriented toward the air, with any polar groups oriented away toward the bulk phase. This tendency for molecules to orient at an interface is a basic factor in interfacial phenomena and will be discussed more fully in succeeding sections.

**Figure 19.3.** Adipic acid crystal showing various faces. (From Michaels AS. Modification of growth rate and habit of adipic acid crystals with surfactants. *J Phys Chem* 1961; 65: 1730.)

Solid substances, such as metals, metal oxides, silicates, and salts, all containing polar groups exposed at their surface, may be classified as *high-energy solids*, whereas nonpolar solids, such as carbon, sulfur, glyceryl tristearate, polyethylene, and polytetrafluoroethylene (Teflon), may be classified as *low-energy solids*. It is of interest to measure the surface free energy of solids; however, the lack of mobility of molecules at the surface of solids prevents the observation and direct measurement of a surface tension. It is possible to measure the work required to create new solid surface by cleaving a crystal and measuring the work involved. However, this work not only represents free energy due to exposed groups but also takes into account the mechanical energy associated with crystal fracture (i.e., plastic and elastic deformation and strain energies due to crystal structure and imperfections in that structure).

Also contributing to the complexity of a solid surface is the heterogeneous behavior as a result of the exposure of different crystal faces, each having a different surface free energy/unit area. For example, adipic acid,  $\text{HOOC}(\text{CH}_2)_4\text{COOH}$ , crystallizes from water as thin, hexagonal plates with three different faces, as shown in Figure 19-3. Each unit cell of such a crystal contains adipic acid molecules, oriented such that the hexagonal planes (faces) contain exposed carboxyl groups, while the sides and edges (A and B faces) represent the side view of the carboxyl and alkyl groups and, thus, are quite nonpolar. Indeed, interactions involving these different faces reflect the differing surface free energies.<sup>2</sup>

Other complexities of solid surfaces include roughness and porosity.<sup>3</sup> Even in the absence of chemical contamination, such as that occurring during recrystallization, surface energy changes in a solid can be induced by unit operations such as milling, resulting in an altered pattern of drug dissolution.<sup>4,5</sup> In view of all these potential complications that are difficult to quantify, surface free energy values for solids, when reported, should be regarded as average values, often dependent on the method used and not necessarily the same for other samples of the same substance.

Table 19-3 lists some average values of  $\gamma_{sv}$  for a variety of solids, ranging in polarity from Teflon to copper, obtained by various indirect techniques.

Solid	$\gamma_{sv}$ (dyne/cm)
Teflon	19.0
Paraffin	25.5
Polyethylene	37.6
Polymethyl methacrylate	45.4
Nylon	50.8
Indomethacin	61.8
Griseofulvin	62.2
Hydrocortisone	68.7
Sodium Chloride	155
Copper	1300

## ADHESIONAL AND COHESIONAL FORCES

Of prime importance to those dealing with heterogeneous systems is the question of how two phases will behave when brought in contact with each other. It is well known, for instance, that some liquids, when placed in contact with other liquid or solid surfaces, will remain retracted in the form of a drop (known as a *lens*), while other liquids may exhibit a tendency to spread and cover the surface of this liquid or solid.

Based upon concepts developed to this point, it is apparent that the individual phases will exhibit a tendency to minimize the area of contact with other phases, thus leading to phase separation. On the other hand, the tendency for interaction between molecules at the new interface will offset this to some extent and give rise to the spontaneous spreading of one substance over the other.

In essence, therefore, phase affinity is increased as the forces of attraction between different phases (*adhesional forces*) become greater than the forces of attraction between molecules of the same phase (*cohesional forces*). If these adhesional forces become great enough, miscibility will occur and the interface will disappear. The present discussion is concerned only with systems of limited phase affinity, where an interface still exists.

A convenient approach used to express these forces quantitatively is work of adhesion and work of cohesion. The *work of adhesion*,  $W_a$ , is defined as the free energy/cm<sup>2</sup> required to separate two phases at their boundary and is equal but opposite in sign to the free energy/cm<sup>2</sup> released when the interface is formed. In an analogous manner, the *work of cohesion* for a pure substance,  $W_c$ , is the work/cm<sup>2</sup> required to produce two new surfaces, as when separating different phases, but now both surfaces contain the same molecules. This is equal and opposite in sign to the free energy/cm<sup>2</sup> released when the same two pure liquid surfaces are brought together and eliminated.

By convention, when the work of adhesion between two substances, A and B, exceeds the work of cohesion for one substance (e.g., B), spontaneous spreading of B over the surface of A should occur with a net loss of free energy equal to the difference between  $W_a$  and  $W_c$ . If  $W_c$  exceeds  $W_a$ , no spontaneous spreading of B over A can occur. The difference between  $W_a$  and  $W_c$  is known as the *spreading coefficient*,  $S$ . Only when  $S$  is positive will spreading occur.

The values for  $W_a$  and  $W_c$  (and hence  $S$ ) may be expressed in terms of surface and interfacial tensions, when one considers that upon separation of two phases, A and B,  $\gamma_{AB}$  ergs of interfacial free energy/cm<sup>2</sup> (interfacial tension) are lost but that  $\gamma_A$  and  $\gamma_B$  erg/cm<sup>2</sup> of energy (surface tensions of A and B) are gained; upon separation of bulk-phase molecules in an analogous manner,  $2\gamma_A$  or  $2\gamma_B$  erg/cm<sup>2</sup> will be gained. Thus,

$$W_a = \gamma_A + \gamma_B - \gamma_{AB} \quad (5)$$

and

$$W_c = 2\gamma_A \text{ or } 2\gamma_B \quad (6)$$

for B spreading on the surface of A. Therefore,

$$S_B = \gamma_A + \gamma_B - \gamma_{AB} - 2\gamma_B \quad (7)$$

or

$$S_B = \gamma_A - (\gamma_B + \gamma_{AB}) \quad (8)$$

Using Equation 8 and the values of surface and interfacial tension given in Tables 19-1 and 19-2, the spreading coefficient can be calculated for three representative substances—decane, benzene, and oleic acid—on water at 20°C.

$$\text{Decane: } S = 72.8 - (23.9 + 52.3) = -3.4$$

$$\text{Benzene: } S = 72.8 - (28.9 + 35.0) = 8.9$$

$$\text{Oleic Acid: } S = 72.8 - (32.5 + 15.6) = 24.7$$

As expected, relatively nonpolar substances such as decane exhibit negative values of spreading coefficient, whereas the more-polar materials yield positive values—the greater the polarity of the molecule, the more positive the value of  $S$ .

The importance of the cohesive energy of the spreading liquid may be noted also by comparing the spreading coefficients for hexane on water and water on hexane.

$$S_{H/W} = 72.8 - (18.0 + 50.8) = 10.0$$

$$S_{W/H} = 18.0 - (72.8 + 50.8) = -105.6$$

Here, despite the fact that both liquids are the same, the high cohesion and air-liquid tension of water prevents spreading on the low-energy hexane surface, while the very low value for hexane allows spreading on the water surface. This also is seen when comparing the positive spreading coefficient of hexane to the negative value for decane on water.

To see whether spreading does or does not occur, a powder such as talc or charcoal can be sprinkled over the surface of water such that it floats; then, a drop of each liquid is placed on this surface. As predicted, decane will remain as an intact drop, while hexane, benzene, and oleic acid will spread out, as shown by the rapid movement of solid particles away from the point where the liquid drop was placed originally.

An apparent contradiction to these observations may be noted for hexane, benzene, and oleic acid when more of each substance is added: lenses now appear to form even though initial spreading occurred. Thus, in effect, a substance does not appear to spread over itself.

It is now established that the spreading substance forms a monomolecular film that creates a new surface that has a lower surface free energy than pure water. This arises because of the apparent orientation of the molecules in such a film so that their most hydrophobic portion is oriented toward the spreading phase. It is the lack of affinity between this exposed portion of the spread molecules and the polar portion of the remaining molecules that prevents further spreading. This may be seen by calculating a final spreading coefficient where the new surface tension of water plus monomolecular film is used. For example, the presence of benzene reduces the surface tension of water to 62.2 dyne/cm so that the final spreading coefficient is

$$S = 62.2 - (28.9 + 35.0) = -1.7$$

The lack of spreading exhibited by oleic acid should be reflected in an even more negative final spreading coefficient, for the very polar carboxyl groups should have very little affinity for the exposed alkyl chain of the oleic acid film. Spreading so as to form a second layer with polar groups exposed to the air also would seem very unlikely, thus leading to the formation of a lens.

## WETTING PHENOMENA

In the experiment described above, it was shown that talc or charcoal sprinkled onto the surface of water floats, despite the fact that their densities are much greater than that of water. In order for immersion of the solid to occur, the liquid must displace air and spread over the surface of the solid; when liquids

**Figure 19.4.** Forces acting on a nonwetting liquid drop exhibiting a contact angle of. (From Zisman WA. Relation of the equilibrium contact angle to liquid and solid constitution. *Adv Chem Ser* 1964; 43: 1.)

cannot spread over a solid surface spontaneously, and, therefore,  $S$ , the spreading coefficient, is negative, we say that the solid is not wetted.

An important parameter reflecting the degree of wetting is the angle made by the liquid with the solid surface at the point of contact (Figure 19-4). By convention, when wetting is complete, the contact angle is  $0^\circ$ ; in nonwetting situations it theoretically can increase to a value of  $180^\circ$ , where a spherical droplet makes contact with solid at only one point.

To express contact angle in terms of solid-liquid-air equilibria, one can balance forces parallel to the solid surface at the point of contact between all three phases (see Figure 19-4), as expressed in

$$\gamma_{SV} = \gamma_{SL} + \gamma_{LV} \cos \theta \quad (9)$$

where  $\gamma_{SV}$ ,  $\gamma_{SL}$ , and  $\gamma_{LV}$  represent the surface free energy/unit area of the solid-air, solid-liquid and liquid-air interfaces, respectively. Although difficult to use quantitatively because of uncertainties with  $\gamma_{SV}$  and  $\gamma_{SL}$  measurements, conceptually the equation, known as the Young equation, is useful because it shows that the loss of free energy due to elimination of the air-solid interface by wetting is offset by the increased solid-liquid and liquid-air area of contact as the drop spreads out.

The  $\gamma_{LV} \cos \theta$  term arises as the horizontal vectorial component of the force acts along the surface of the drop, as represented by  $\gamma_{LV}$ . Factors tending to reduce  $\gamma_{LV}$  and  $\gamma_{SL}$ , therefore, will favor wetting, while the greater the value of  $\gamma_{SV}$ , the greater the chance for wetting to occur. This is seen in Table 19-4 for the wetting of a low-energy surface, paraffin (hydrocarbon), and a higher energy surface, nylon (polyhexamethylene adipamide). Here, the lower the surface tension of a liquid, the smaller the contact angle on a given solid, and the more polar the solid, the smaller the contact angle with the same liquid.

With Equation 9 in mind and looking at Figure 19-5, it is now possible to understand how the forces acting at the

**Table 19-4. Contact Angle on Paraffin and Nylon for Various Liquids of Differing Surface Tension**

Substance	Surface Tension (dyne/cm)	Contact Angle ( $^\circ$ )	
		Paraffin	Nylon
Water	72.8	105	70

Decane	23.9	7	spreads
Nonane	22.9	spreads	spreads

**Figure 19.5.** Forces acting on a nonwetable solid at the air+liquid+solid interface: contact angle  $\theta$  greater than  $90^\circ$ .

solid–liquid–air interface can cause a dense, nonwetted solid to float if  $\gamma_{SL}$  and  $\gamma_{LV}$  are large enough, relative to  $\gamma_{SV}$ .

The significance of reducing  $\gamma_{LV}$  was first developed empirically by Zisman<sup>6</sup> when he plotted  $\cos \theta$  versus the surface tension of a series of liquids and found that a linear relationship, dependent on the solid, often was obtained. When such plots are extrapolated to  $\cos$  equal to 1, or  $0^\circ$  contact angle, a value of surface tension required to just cause complete wetting is obtained. Doing this for a number of solids, it was shown that this surface tension (known as the critical surface tension,  $\gamma_c$ ) parallels expected solid surface energy  $\gamma_{SV}$ —the lower  $\gamma_c$ , the more nonpolar the surface.

Table 19-5 indicates some of these  $\gamma_c$  values for different surface groups, indicating such a trend. Thus, water with a surface tension of about 72 dyne/cm will not wet polyethylene ( $\gamma_c = 31$  dyne/cm), but heptane, with a surface tension of about 20 dyne/cm, will. Likewise, Teflon (polytetrafluoroethylene) ( $\gamma_c = 19$ ) is not wetted by heptane but is wetted by perfluoroheptane with a surface tension of 11 dyne/cm.

One complication associated with the wetting of high-energy surfaces is the lack of wetting after the initial formation of a monomolecular film, caused by the spreading substance. As in the case of oleic acid spreading on the surface of water, the remaining liquid retracts because of the low-energy surface produced by the oriented film. This phenomenon, often called *autophobic behavior*, is an important factor in many systems of pharmaceutical interest because many solids, expected to be wetted easily by water, may be rendered hydrophobic if other molecules dissolved in the water can form these monomolecular films at the solid surface.

## CAPILLARITY

Because water shows a strong tendency to spread out over a polar surface such as clean glass (contact angle equal to  $0^\circ$ ),

**Table 19-5. Critical Surface Tensions of Various Polymeric Solids**

**Figure 19.6.** Capillary rise for a liquid exhibiting  $0^\circ$  contact angle. (From Semat H. *Fundamentals of Physics*, 3rd edn. New York: Holt Rinehart Winston, 1957.)

one would expect to observe a meniscus forming when water is contained in a glass vessel such as a pipet or buret. This behavior is accentuated dramatically if a fine-bore capillary tube is placed into the liquid (Figure 19-6). Not only will the wetting of the glass produce a more highly curved meniscus, but the level of the liquid in the tube will be appreciably higher than the level of the water in the beaker.

The spontaneous movement of a liquid into a capillary or narrow tube due to surface forces is defined as *capillarity* and is responsible for a number of important processes involving the penetration of liquids into porous solids. In contrast to water in contact with glass, if the same capillary is placed into mercury (contact angle on glass:  $130^\circ$ ), not only will the meniscus be inverted (Figure 19-7), but the level of the mercury in the capillary will be lower than in the beaker. In this case one does not expect mercury or other *nonwetting* liquids to penetrate pores easily unless external forces are applied.

To examine more closely the factors giving rise to the phenomenon of capillarity, consider the case of a liquid that rises to a height,  $h$ , above the bulk liquid in a capillary having a radius  $r$ . As shown in Figure 19-6, if the contact angle of water on glass is  $0$ , a force  $F$  will act upward and vertically along the circle of liquid–glass contact. Based upon the definition of surface tension, this force will be equal to the surface tension  $\gamma$  multiplied by the circumference of the circle,  $2\pi r$ . Thus,

$$F = \gamma 2\pi r \quad (10)$$

This force upward must support the column of water, and because the mass  $m$  of the column is equal to the density  $d$  multiplied by the volume of the column,  $\pi r^2 h$ , the force  $W$  opposing the movement upward will be

$$W = mg = \pi r^2 dgh \quad (11)$$

where  $g$  is the gravity constant.

Equating the two forces at equilibrium gives

$$\pi r^2 dgh = \gamma 2\pi r \quad (12)$$

**Figure 19.7.** Capillary fall for a liquid exhibiting a contact angle,  $\theta$ , that is greater than  $90^\circ$ . (From Semat H. *Fundamentals of Physics*, 3rd edn. New York: Holt Reinhart Winston, 1957.)

**Figure 19.8.** Capillary rise for a liquid exhibiting a contact angle,  $\theta$ , that is greater than  $0^\circ$  but less than  $90^\circ$ . (From Semat H. *Fundamentals of Physics*, 3rd edn. New York: Holt Rinehart Winston, 1957.)

so that

$$h = \frac{2\gamma}{rdg} \quad (13)$$

Thus, the greater the surface tension and the finer the capillary radius, the greater the rise of liquid in the capillary.

If the contact angle of liquid is not  $0$  (Figure 19-8), the same relationship may be developed, except the vertical component of  $F$ , which opposes the weight of the column, is  $F \cos \theta$  and, therefore

$$h = \frac{2\gamma \cos \theta}{rdg} \quad (14)$$

This indicates the very important fact that if  $\theta$  is less than  $90^\circ$  but greater than  $0^\circ$ , the value of  $h$  will decrease with increasing contact angle until at  $90^\circ$  ( $\cos \theta = 0$ ),  $h = 0$ . Above  $90^\circ$ , values of  $h$  will be negative, as indicated in Figure 19-7 for mercury. Thus, based on these equations it may be concluded that capillarity will occur spontaneously in a cylindrical pore even if the contact angle is greater than  $0^\circ$ , but it will not occur at all if the contact angle becomes  $90^\circ$  or more. In solids with irregularly shaped pores, the relationships between parameters in Equation 14 will be the same, but they will be more difficult to quantify because of nonuniform changes in pore radius throughout the porous structure.

## PRESSURE DIFFERENCES ACROSS CURVED SURFACES

From the preceding discussion of capillarity, another important concept follows. In order for the liquid in a capillary to rise spontaneously, it must develop a higher pressure than the lower level of the liquid in the beaker. However, because the system is open to the atmosphere, both surfaces are in equilibrium with the atmospheric pressure. To be raised above the level of liquid in the beaker and produce a hydrostatic pressure equal to  $hgd$ , the pressure just below the liquid meniscus, in the capillary,  $P_1$ , must be less than that just below the flat liquid surface,  $P_0$ , by  $hgd$ , and therefore,

$$P_0 - P_1 = hgd \quad (15)$$

Because, according to Equation 14,

$$h = \frac{2\gamma \cos \theta}{rdg}$$

then

$$P_0 - P_1 = \frac{2\gamma \cos \theta}{r} \quad (16)$$

For a contact angle of  $0^\circ$ , where the radius of the capillary is the radius of the hemisphere making up the meniscus,

$$P_0 - P_1 = \frac{2\gamma}{r} \quad (17)$$

The consequences of this relationship (known as the Laplace equation) are important for any curved surface when  $r$  becomes very small and is  $\gamma$  relatively significant. For example, a spherical

droplet of air formed in a bulk liquid, and having a radius  $r$ , will have a greater pressure on the inner concave surface than on the convex side, as expressed in Equation 17. Direct measurement of the pressure difference ( $P_0 - P_1$ ) for an air bubble of known radius allows the determination of the surface tension of either a pure liquid or a solution of surface active substance. Both static (constant radius) and dynamic (radius changing in a cyclic fashion as a function of time) measurements have been employed. The latter treatment, known as the pulsating bubble method, has been very useful in the study of some of the biophysical properties and associated disease states of pulmonary surfactant, a mixture of surface active materials lining the small airways of the mammalian lung.<sup>7</sup> One of the less appreciated advantages of this method for measuring surface tension is the need for only a very small sample size, typically on the order of  $50 \mu\text{L}$ .

Another direct consequence of what Equation 17 expresses is the fact that very small droplets of liquid, having highly curved surfaces, will exhibit a higher vapor pressure,  $VP$ , than are observed over a flat surface of the same liquid at  $VP'$ . Equation 18, called the *Kelvin equation*, expresses the ratio of  $VP/VP'$  to droplet radius  $r$ , and surface tension  $\gamma$ :

$$\log \frac{P}{P'} = \frac{2\gamma M}{2.303RT\rho r} \quad (18)$$

where  $M$  is the molecular weight,  $R$  is the gas constant in  $\text{erg}/\text{mol}/\text{degree}$ ,  $T$  is temperature, and  $\rho$  is the density in  $\text{g}/\text{cm}^3$ . Values for the ratio of vapor pressures are given in Table 19-6 for water droplets of varying size. Such ratios indicate why it is possible for very fine water droplets in clouds to remain uncondensed, despite their close proximity to one another.

This same behavior may be seen when measuring the solubility of very fine solid particles, for both vapor pressure and solubility are measures of the escaping tendency of molecules from a surface. Indeed, the equilibrium solubility of extremely small particles has been shown to be greater than the usual value noted for coarser particles; the greater the surface energy and smaller the particles, the greater this effect.

## ADSORPTION

### VAPOR ADSORPTION ON SOLID SURFACES

It was suggested earlier that a high surface or interfacial free energy may exist at a solid surface if the unbalanced forces at the surface and the area of exposed groups are quite great.

Substances such as metals, metal oxides, silicates, and salts—all containing exposed polar groups—may be classified as high-energy or hydrophilic solids; nonpolar solids, such as carbon, sulfur, polyethylene, or Teflon (polytetrafluoroethylene), may be classified as low-energy or hydrophobic solids (see Table 19-3). Whereas liquids satisfy their unbalanced surface forces by changes in shape, pure solids (which exhibit negligible surface mobility) must rely on reaction with molecules, either in the

**Table 19-6.** Ratio of Observed Vapor Pressure ( $P$ ) to Expected Vapor Pressure ( $P'$ ) of Water at  $25^\circ\text{C}$  With Varying Droplet Size

$P/P'$	Droplet Size (0 m)
1.001	1
1.01	0.1
1.1	0.01
2.0	0.005
3.0	0.001
4.2	0.00065
5.2	0.00060

**Figure 19.9.** Adsorption isotherms for ammonia on charcoal. (From Titoff Z. Die Adsorption von Gasen durch Kohle. *Z Phys Chem Leipzig* 1910; 74: 641–678.)

vapor state or in a solution that comes in contact with the solid surface to accomplish this.

Vapor adsorption is the simplest model demonstrating how solids reduce their surface free energy in this manner. Depending on the chemical nature of the adsorbent (solid) and the adsorbate (vapor), the strength of interaction between the two species may vary from strong specific chemical bonding to interactions produced by the weaker, more nonspecific London dispersion forces. Ordinarily, these latter forces are those responsible for the condensation of relatively nonpolar substances, such as  $N_2$ ,  $O_2$ ,  $CO_2$ , or hydrocarbons.

When chemical reaction occurs, the process is called *chemisorption*; when dispersion forces predominate, the term *physisorption* is used. Physisorption occurs at temperatures approaching the liquefaction temperature of the vapor; for chemisorption, temperatures depend on the particular reaction involved. Water-vapor adsorption to various polar solids can occur at room temperature through hydrogen-bonding, with binding energies intermediate to physisorption and chemisorption.

To study the adsorption of vapors onto solid surfaces, one must measure the amount of gas adsorbed/unit area or unit mass of solid, at different pressures of gas. Because such studies usually are conducted at constant temperature, plots of volume

**Figure 19.10.** Typical plot for multilayer physical adsorption of a vapor on a solid surface.

adsorbed versus pressure are known as *adsorption isotherms*. If the physical or chemical adsorption process is monomolecular, the adsorption isotherm should appear similar to those shown in Figure 19-9. Adsorption significantly increases with increasing pressure, followed by a leveling off, which is due either to a saturation of available specific chemical groups, as in chemisorption, or to the entire available surface being covered by physically adsorbed molecules. Adsorption reduction with increasing temperature occurs because the adsorption process is exothermic. In the case of physical adsorption at low temperatures after adsorption levels off, often a marked increase in adsorption occurs, presumably due to multilayered adsorption. In this case vapor molecules essentially condense upon themselves as the liquefaction pressure of the vapor is approached. Figure 19-10 illustrates one type of isotherm generally seen with multilayered physisorption.

To have a quantitative understanding of the adsorption process and to be able to compare different systems, two factors must be evaluated. It is important to know the capacity of the solid or the maximum amount of adsorption under a given set of conditions and the affinity of a given substance for the solid surface—how readily does it adsorb for a given amount of pressure? In effect, the second term is the equilibrium constant for the process. For many systems vapor-adsorption data may fit a very general, but somewhat empirical, equation, the Freundlich equation:

$$V_a = kp^n \quad (19)$$

where  $V_a$  is the volume of gas adsorbed,  $p$  is the gas pressure, and  $k$  and  $n$  are constants, reflecting adsorption affinity and capacity.

A significant theoretical improvement along these lines was the theory of *monomolecular adsorption*, proposed by Langmuir. He postulated that for adsorption to occur, a solid must contain uniform adsorption sites, each capable of holding a single gas molecule. Molecules colliding with the surface may bounce off elastically, or they may remain in contact for a period of time. It is this contact over a period of time that Langmuir termed *adsorption*.

Two major assumptions were made in deriving the adsorption equation:

Only those molecules striking an empty site can be adsorbed; hence, only monomolecular adsorption occurs.

The forces of interaction between adsorbed molecules are negligible and, therefore, the probability of a molecule adsorbing onto or desorbing from any site is independent of the surrounding sites.

With these assumptions and applying the kinetic theory of gases, it can be shown that

$$V_a = (V_m k' p) / (1 + k' p) \quad (20)$$

where  $V_m$  is the volume of gas covering all of the adsorption sites with a single layer of molecules, and  $k'$  is a constant that reflects the affinity of the gas for the solid.

A test of fit to this equation can be made by expressing it in linear form.

$$\frac{p}{V_a} = \frac{1}{V_m k'} + \frac{p}{V_m} \quad (21)$$

The value of  $k'$  is, in effect, the equilibrium constant and may be used to compare affinities of different substances for the solid surface. The value of  $V_m$  is valuable because it indicates the maximum number of sites available for adsorption. In the case of physisorption, the maximum number of sites is actually the total surface area of the solid; therefore, the value of  $V_m$  can be used to estimate surface area if the volume and area/molecule of vapor are known.

Since physisorption most often involves some multilayered adsorption, an equation based on the Langmuir equation, the B.E.T. equation, normally is used to determine  $V_m$  and solid surface areas. Equation 22 is the B.E.T. equation:

$$V_a = \frac{V_m c p}{(p_0 - p) [1 + (C - 1)(p/p_0)]} \quad (22)$$

where  $c$  is a constant and  $p_0$  is the vapor pressure of the adsorbing substance.<sup>9</sup> Experimentally, the most widely used vapor for this purpose is nitrogen, which adsorbs nonspecifically on most solids near its boiling point at 195°C and appears to occupy about 16 Å<sup>2</sup>/molecule on a solid surface.

### ADSORPTION FROM SOLUTION

By far one of the most important aspects of interfacial phenomena encountered in pharmaceutical systems is the tendency for substances dissolved in a liquid to adsorb to various interfaces. Adsorption from solution is generally more complex than that from the vapor state because of the influence of the solvent and any other solutes dissolved in the solvent. Although such adsorption generally is limited to one or two molecular layers at most, the presence of other molecules often makes the interpretation of adsorption mechanisms much more difficult than for chemisorption or physisorption of a vapor. Because monomolecular adsorption from solution is so widespread at all interfaces, we will first discuss the nature of monomolecular films and then return to a discussion of adsorption from solution.

### INSOLUBLE MONOMOLECULAR FILMS

It was suggested above that molecules exhibiting a tendency to spread out at an interface might be expected to orient so as to reduce the interfacial free energy produced by the presence of the interface. Direct evidence for molecular orientation has been obtained from studies dealing with the spreading on water of insoluble polar substances containing long hydrocarbon chains, such as fatty acids.

In the late 19th century Pockels and Rayleigh showed that a very small amount of olive or castor oil, when placed on the surface of water, spreads out, as discussed above. If the amount of material was less than could physically cover the entire surface, only a slight reduction in the surface tension of water was noted. However, if the surface was compressed between barriers, as shown in Figure 19-11, the surface tension was reduced considerably.

Devaux extended the use of this technique by dissolving small amounts of solid in volatile solvents and dropping the solution onto a water surface. After assisting the water-insoluble molecules to spread, the solvent evaporated, leaving a surface film containing a known amount of solute.

Compression and measurement of surface tension indicated that a maximum reduction of surface was reached when the number of molecules/unit area was reduced to a value corresponding to complete coverage of the surface. This suggested that a monomolecular film forms and that surface tension is reduced upon compression because contact between air and water is reduced by the presence of the film molecules. Beyond the point of closest packing, the film apparently collapses very much as a layer of corks floating on water would be disrupted when laterally compressed beyond the point of initial physical contact.

Using a refined quantitative technique based on these studies, Langmuir<sup>11</sup> spread films of pure fatty acids, alcohols, and

**Figure 19.11.** Insoluble monomolecular film compressed between a fixed barrier  $B$  and a movable barrier  $A$ . (Osipow L.I. *Surface Chemistry: Theory and Applications*. New York: Reinhold, 1962.)

esters on the surface of water. Comparing a series of saturated fatty acids, differing only in chain length, he found that the area/molecule at collapse was independent of chain length, corresponding to the cross-sectional area of a molecule oriented in a vertical position (see Figure 19-11). He further concluded that this molecular orientation involved association of the polar carboxyl group with the water phase and the nonpolar alkyl chain out toward the vapor phase.

In addition to the evidence for molecular orientation, Langmuir's work with surface films revealed that each substance exhibits film properties which reflect the interactions between molecules in the surface film. This is seen best by plotting the difference in surface tension of the clean surface  $\gamma_0$  and that of the surface covered with the film  $\gamma$ , versus the area/molecule  $A$  produced by film compression (total area/the number of molecules). The difference in surface tension is called the surface pressure,  $\pi$ , and thus

$$\pi = \gamma_0 - \gamma \quad (23)$$

Figure 19-12 depicts such a plot for a typical fatty acid monomolecular film. At areas greater than 50 Å<sup>2</sup>/molecule, the molecules are far apart and do not cover enough surface to reduce the surface tension of the clean surface to any extent, and thus the lack of appreciable surface pressure. Because the molecules in the film are quite free to move laterally in the surface, they are said to be in a two-dimensional *gaseous* or *vapor* state.

As the intermolecular distance is reduced upon compression, the surface pressure rises because the air-water surface is being covered to a greater extent. The rate of change in  $\gamma$  with  $A$ , however, will depend on the extent of interaction between film molecules—the greater the rate of change, the more “condensed” the state of the film.

In Figure 19-12, from 50 to 30 Å<sup>2</sup>/molecule, the curve shows a steady increase in  $\pi$ , representative of a two-dimensional “liquid” film, where the molecules become more restricted in their freedom of movement because of interactions. Below 30 Å<sup>2</sup>/molecule, the increase in  $\pi$  occurs over a narrow range of  $A$ , characteristic of closest packing and a two-dimensional “solid” film.

Any factor tending to increase polarity or bulkiness of the molecule—such as increased charge, number of polar groups, reduction in chain length, or the introduction of aromatic rings, side chains, and double bonds—should reduce molecular interactions. On the other hand, the longer the alkyl chain and the less bulky the polar group, the closer the molecules can approach and the stronger the extent of interaction in the film.

### SOLUBLE FILMS AND ADSORPTION FROM SOLUTION

If a fatty acid exhibits highly gaseous film behavior on an aqueous surface, a relatively small change in  $\pi$  with  $A$  over a

**Figure 19.12.** A surface pressure–area curve for an insoluble monomolecular film: Region  $A$ , gaseous film; Region  $B$ , liquid film; Region  $C$ , solid film; Region  $D$ , film collapse.

considerable range of compression should be expected. Indeed, for short-chain compounds, such as lauric acid (12 carbons) or decanoic acid, not only is the change small with decreasing  $A$ , but at a point just before the expected closest packing area, the surface pressure becomes constant without any collapse.

If lauric acid is converted to the laurate ion, or if a shorter chain acid such as octanoic acid is used, spreading on water and compression of the surface produces no increase in  $\pi$ . These results illustrate that the more polar the molecule (hence, the more *gaseous* the film), the higher the area/molecule where a constant surface pressure occurs. This behavior may be explained by assuming that polar molecules form monomolecular films when spread on water, but that, upon compression, they are caused to enter the aqueous bulk solution rather than to remain as an intact, insoluble film. The constant surface pressure with increased compression arises because a constant number of molecules/unit area remain at the surface in equilibrium with dissolved molecules. The extent of such behavior will be greater for substances exhibiting weaker intermolecular interaction and greater water solubility.

Starting from the other direction, it can be shown that short-chain acids and alcohols (when dissolved in water) reduce the surface tension of water, thus producing a surface pressure, just as with insoluble films (see Equation 23). That dissolved molecules are accumulating at the interface in the form of a monomolecular film is suggested from the similarity in behavior to systems where lightly soluble molecules are spread on the surface. For example, compressing the surface of a solution containing "surface-active" molecules has no effect on the initial surface pressure, whereas increasing bulk-solution concentration tends to increase surface pressure, presumably by shifting the equilibrium between surface and bulk molecules.

At this point one may ask, why should water-soluble molecules leave an aqueous phase and accumulate or *adsorb* at an air-solution interface? Because any process will occur spontaneously if it results in a net loss in free energy, such must be the case for the process of adsorption. A number of factors will produce such a favorable change in free energy:

- The presence of the oriented monomolecular film reduces the surface free energy of the air-water interface.
- The hydrophobic group on the molecule is in a lower state of energy at the interface, where it no longer is as surrounded by water molecules, than when it is in the bulk-solution phase.
- Increased interaction between film molecules also will contribute to this process.

A further reduction in free energy occurs upon adsorption because of the gain in entropy associated with a change in water structure. Water molecules in the presence of dissolved alkyl chains are more highly organized or *ice-like* than they are as a pure bulk phase; hence, the entropy of such structured water is lower than that of bulk water.

The process of adsorption requires that the ice-like structure *melt* as the chains go to the interface, and thus an increase in the entropy of water occurs. The adsorption of molecules dissolved in oil can occur, but it is not influenced by water structure changes, and hence, only the first factors mentioned are important here.

It is very rare that significant adsorption can occur at the hydrocarbon-air interface because little loss in free energy comes about by bringing hydrocarbon chains with polar groups attached to this interface. On the other hand, at oil-water interfaces, the polar portions of the molecule can interact with water at the interface, leading to significant adsorption.

Thus, whereas water-soluble fatty acid salts are adsorbed from water to air-water and oil-water interfaces, their undissociated counterparts, the free fatty acids, which are water insoluble, form insoluble films at the air-water interface, are not adsorbed from oil solution to an oil-air interface but show

significant adsorption at the oil-water interface when dissolved in oil.

From this discussion it is possible also to conclude that adsorption from aqueous solution requires a lower solute concentration to obtain the same level of adsorption if the hydrophobic chain length is increased or if the polar portion of the molecule is less hydrophilic. On the other hand, adsorption from nonpolar solvents is favored when the solute is quite polar.

Because soluble or adsorbed films cannot be compressed, there is no simple, direct way to estimate the number of molecules/unit area coming to the surface under a given set of conditions. For relatively simple systems it is possible to estimate this value by application of the Gibbs equation, which relates surface concentration to the surface-tension change produced at different solute activities. The derivation of this equation is beyond the scope of this discussion, but it arises from a classical thermodynamic treatment of the change in free energy when molecules concentrate at the boundary between two phases. The equation may be expressed as

$$\Gamma = -\frac{a}{RT} \frac{d\gamma}{da} \quad (24)$$

where  $\Gamma$  is the moles of solute adsorbed/unit area,  $R$  is the gas constant,  $T$  is the absolute temperature, and  $d\gamma$  is the change in surface tension, with a change in solute activity,  $da$ , at activity  $a$ .

For dilute solutions of nonelectrolytes, or for electrolytes when the Debye-Hückel equation for activity coefficient is applicable, the value of  $a$  may be replaced by solute concentration,  $c$ . Because the term  $dc/c$  is equal to  $d \ln c$ , the Gibbs equation is often written as

$$\Gamma = -\frac{1}{RT} \frac{d\gamma}{d \ln c} \quad (25)$$

In this way the slope of a plot of  $\gamma$  versus  $\ln c$  multiplied by  $1/RT$  should give  $\Gamma$  at a particular value of  $c$ .

Figure 19-13 depicts typical plots for a series of water-soluble surface-active agents differing only in the alkyl chain length. A greater reduction of surface tension occurs at lower concentrations for longer chain-length compounds. In addition, there are greater slopes with increasing concentration, indicating more adsorption (Equation 25), and an abrupt leveling of surface tension at higher concentrations. This latter behavior reflects the self-association of surface-active agent to form micelles, which exhibit no further tendency to reduce surface tension. The topic of micelles will be discussed later in Chapter 20.

If one plots the values of surface concentration,  $\Gamma$  versus concentration  $c$ , for substances adsorbing to the vapor-liquid and liquid-liquid interfaces, using data such as those given in Figure 19-13, one generally obtains an adsorption isotherm shaped like those in Figure 19-9 for vapor adsorption. Indeed, it can be

**Figure 19.13.** The effect of increasing chain length on the surface activity of a surfactant at the air-aqueous solution interface (each curve differs from the preceding or succeeding by two methylene groups, with A, the longest chain, and D, the shortest).

shown that the Langmuir equation (Equation 20) can be fitted to such data when written in the form

$$\Gamma = \frac{\Gamma_{\max} k'c}{1 + k'c} \quad (26)$$

where  $\Gamma_{\max}$  is the maximum surface concentration attained with increasing concentration and  $k'$  is related to  $k$  in Equation 20. Combining Equations 24 and 26 leads to a widely used relationship between surface-tension change  $\pi$  (see Equation 23), and solute concentration  $c$ , known as the Szyszkowski equation.

$$\Pi = \Gamma_{\max} RT \ln(1 + k'c) \quad (27)$$

### MIXED FILMS

It would seem reasonable to expect that the properties of a surface film could be varied greatly if a mixture of surface-active agents were in the film. As an example, consider that a mixture of short- and long-chain fatty acids would be expected to show a degree of *condensation* varying from the gaseous state, when the short-chain substance is used in high amount, to a highly condensed state, when the longer chain substance predominates. Thus, each component in such a case would operate independently by bringing a proportional amount of film behavior to the system.

More often, the ingredients of a surface film do not behave independently but rather interact to produce a new surface film. An obvious example would be the combination of organic amines and acids, which are charged oppositely and would be expected to interact strongly. In addition to such polar-group interactions, chain-chain interactions strongly favor mixed condensed films. An important example of such a case occurs when a long-chain alcohol is introduced along with an ionized long-chain substance. Together the molecules form a highly condensed film, despite the presence of a high number of like charges. Presumably this occurs, as seen in Figure 19-14, by arranging the molecules so that ionic groups alternate with alcohol groups; however, if chain-chain interactions are not strong, the ionic species often will be displaced by the more nonpolar un-ionized species and will "desorb" into the bulk solution.

On the other hand, sometimes the more soluble surface-active agent produces surface pressures in excess of the collapse pressure of the insoluble film and displaces it from the surface. This is an important concept because it is the underlying principle behind cell lysis by surface-active agents and some drugs, and behind the important process of detergency.

### ADSORPTION FROM SOLUTION ON TO SOLID SURFACES

Adsorption to solid surfaces from solution may occur if the dissolved molecules and the solid surface have chemical groups capable of interacting. Nonspecific adsorption also will occur if the solute is surface active and if the surface area of the solid is high. This latter case would be the same as occurs at the vapor-liquid and liquid-liquid interfaces. As with adsorption to liquid interfaces, adsorption to solid surfaces from solution generally leads to a monomolecular layer, often described by the Langmuir equation in the form:

$$x/M = [(x/M)mk^*c]/(1 + k^*c) \quad (28)$$

where  $x$  is the amount of adsorbed solute,  $M$  is the total weight of solid,  $x/M$  is the amount of solute adsorbed per unit weight

**Figure 19.14.** A mixed monomolecular film; a long-chain ion; a long-chain non-ionic compound.

of solid at concentration  $c$ ,  $k^*$  is a constant, and  $(x/M)m$  is the amount of solute per unit weight covering the surface with a complete monolayer. However, as Giles<sup>12</sup> has pointed out, the variety of combinations of solutes and solids, and hence the variety of possible mechanisms of adsorption, can lead to a number of more complex isotherms. In particular, adsorption of surfactants and polymers, of great importance in a number of pharmaceutical systems, still is not understood well on a fundamental level and may in some situations even be multilayered.

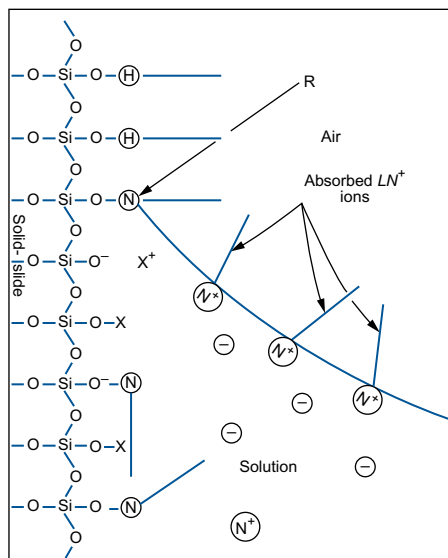

Adsorption from solution may be measured by separating solid and solution and either estimating the amount of adsorbate adhering to the solid or the loss in concentration of adsorbate from solution. In view of the possibility of solvent adsorption, the latter approach really only gives an apparent adsorption. For example, if solvent adsorption is great enough, it is possible to end up with an increased concentration of solute after contact with the solid; here, the term *negative adsorption* is used.

Solvent not only influences adsorption by competing for the surface, but as discussed in connection with adsorption at liquid surfaces, the solvent will determine the escaping tendency of a solute; for example, the more polar the molecule, the less the adsorption that occurs from water. This is seen in Figure 19-15, where adsorption of various fatty acids from water onto charcoal increases with increasing alkyl chain length or nonpolarity. It is difficult to predict these effects, but, in general, the more chemically unlike the solute and solvent and the more alike the solid surface groups and solute, the greater the extent of adsorption. Another factor that must be kept in mind is that charged solid surfaces, such as polyelectrolytes, will strongly adsorb oppositely charged solutes. This is similar to the strong specific binding seen in gas chemisorption, and it is characterized by significant monolayer adsorption at very low concentrations of solute. See Figure 19-16 for an example of such adsorption.

Adsorption onto activated charcoal has been shown to be extremely useful in the emergency treatment of acute overdosage of a variety of drugs taken by the oral route.<sup>15</sup> Overall effectiveness of commercially available activated-charcoal suspensions as an antidote in oral poisonings appears to be directly related to the total charcoal surface area.<sup>16</sup> Drug adsorption to charcoal tends to follow the Langmuir model as well as the Freundlich model. In addition, a drug that is un-ionized at gastric pH will

**Figure 19.15.** The relation between adsorption and molecular weight of fatty acids. (Data from Weiser HB. *A Textbook of Colloid Chemistry*. New York: Elsevier, 1949.)

**Figure 19.16.** The adsorption of a cationic surfactant, LN, onto a negatively charged silica or glass surface, exposing a hydrophobic surface as the solid is exposed to air. (From TerMinassianSaraga L. *Chemisorption and dewetting of glass and silica. Adv Chem Ser* 1964; 43: 232–49.)

adsorb to charcoal to a greater extent than will the ionized form of the drug, probably because of less repulsive interactions in the adsorbed state of neutral molecules. Great care must be exercised in the formulation of activated-charcoal suspensions because pharmaceutical adjuvants employed in suspensions have the potential to adsorb to the charcoal and block sites for drug adsorption.

## SURFACE-ACTIVE AGENTS

Throughout the discussion so far, examples of surface-active agents (surfactants) have been restricted primarily to fatty acids and their salts. It has been shown that both a hydrophobic portion (alkyl chain) and a hydrophilic portion (carboxyl and carboxylate groups) are required for their surface activity, the relative degree of polarity determining the tendency to accumulate at interfaces. It now becomes important to look at some of the specific types of surfactants available and to see what structural features are required for different pharmaceutical applications.

The classification of surfactants is quite arbitrary, but one based on chemical structure appears best as a means of introducing the topic. It is generally convenient to categorize surfactants according to their polar portions because the nonpolar portion usually is made up of alkyl or aryl groups. The major polar groups found in most surfactants may be divided as follows: anionic, cationic, amphoteric, and nonionic. As shall be seen, the last group is the largest and most widely used for pharmaceutical systems, so that it will be emphasized in the discussion that follows.

### TYPES

#### Anionic Agents

The most commonly used anionic surfactants are those containing carboxylate, sulfonate, and sulfate ions. Those containing carboxylate ions are known as soaps and generally are prepared by the saponification of natural fatty acid glycerides in alkaline solution. The most common cations associated with soaps are sodium, potassium, ammonium, and triethanolamine; the chain length of the fatty acids ranges from 12 to 18.

The extent of solubility in water is influenced greatly by the length of the alkyl chain and the presence of double bonds. For

example, sodium stearate is quite insoluble in water at room temperature, whereas sodium oleate under the same conditions is quite water soluble.

Multivalent ions, such as calcium and magnesium, produce marked water insolubility, even at lower alkyl chain lengths; thus, soaps are not useful in hard water that is high in content of these ions. Soaps, being salts of weak acids, are subject also to hydrolysis and the formation of free acid plus hydroxide ion, particularly when in more concentrated solution.

To offset some of the disadvantages of soaps, a number of long alkyl chain sulfonates, as well as alkyl aryl sulfonates such as sodium dodecylbenzene sulfonate, may be used; the sulfonate ion is less subject to hydrolysis and precipitation in the presence of multivalent ions. A popular group of sulfonates, widely used in pharmaceutical systems, are the dialkyl sodium sulfosuccinates, particularly sodium bis (2-ethylhexyl)sulfosuccinate, best known as Aerosol OT or docusate sodium. This compound is unique in that it is soluble both in oil and water and, hence, forms micelles in both phases. It reduces surface and interfacial tension to low values and acts as an excellent wetting agent in many types of solid dosage forms (Table 19-7).

A number of alkyl sulfates are available as surfactants, but by far the most popular member of this group is sodium lauryl sulfate, which is used widely as an emulsifier and solubilizer in pharmaceutical systems. Unlike the sulfonates, *sulfates* are susceptible to pH-dependent hydrolysis, leading to the formation of the long-chain alcohol.

#### Cationic Agents

A number of long-chain cations, such as amine salts and quaternary ammonium salts, often are used as surface-active agents when dissolved in water; however, their use in pharmaceutical preparations is limited to that of antimicrobial preservation rather than as surfactants. This arises because the cations adsorb so readily at cell membrane structures in a nonspecific manner, leading to cell lysis (e.g., hemolysis), as do anionics to a lesser extent. It is in this way that they act to destroy bacteria and fungi.

Since anionic and nonionic agents are not as effective as preservatives, one must conclude that the positive charge of these compounds is important; however, the extent of surface activity has been shown to determine the amount of material needed for a given amount of preservation. Quaternary ammonium salts are preferable to free amine salts because they are not subject to effect by pH in any way; however, the presence of organic anions, such as dyes and natural polyelectrolytes, is an important source of incompatibility, and such a combination should be avoided.

#### Amphoteric Agents

The major groups of molecules falling into the amphoteric category are those containing carboxylate or phosphate groups

**Table 19-7. Effect of Aerosol OT Concentration on the Surface Tension of Water and The Contact Angle of Water With Magnesium Stearate**

Concentration (M $\times 10^6$ )	$\gamma_{SV}$	$\theta(^{\circ})$
1.0	60.1	120
3.0	49.8	113
5.0	45.1	104
8.0	40.6	89
10.0	38.6	80
12.0	37.9	71
15.0	35.0	63
20.0	32.4	54
25.0	29.5	50

such as the anion, and amino or qua-ternary ammonium groups such as the cation. The former group is represented by various polypeptides, proteins, and the alkyl betaines; the latter group consists of natural phospholipids, such as the lecithins and cephalins. In general, long-chain amphoteric, which exist in solution in zwitterionic form, are more surface active than are ionic surfactants having the same hydrophobic group because, in effect, the oppositely charged ions are neutralized. However, when compared to nonionics, they appear somewhere between ionic and nonionic.

### Proteins

Considering the rapidly growing importance of proteins as therapeutic agents, the unique surface characteristics of these biological macromolecules deserve some special attention. Therapeutic proteins have been shown to be extremely surface active, and they adsorb to clinically important surfaces, such as glass bottles and syringes, sterile filters, and plastic IV bags and administration sets; the result is treatment failures. In general, proteins can adsorb to a whole variety of surfaces, both hydrophobic and hydrophilic. From the standpoint of the surface, protein adsorption appears to be maximized when the electrical charge of the surface is opposite that of the protein or when the surface is extremely hydrophobic. From the standpoint of the protein, the extent of adsorption depends on the molecular weight, the number of hydrophobic side chains, and the relative distribution of cationic and anionic side chains. The effect of ionic strength is usually to enhance adsorption by shielding adjacent proteins from repulsive electrical interactions. Adsorption is also maximized when the pH of the protein solution is equal to the pI (isoelectric point) of the molecule, again due to minimized electrical repulsion.

When different proteins compete for adsorption sites on a single surface, the effect of molecular weight becomes most striking. Early in the adsorption process the protein with the smaller molecular weight, which can diffuse to the surface more rapidly, initially occupies the interface. After some time, it is found that the larger molecular weight protein has displaced the smaller protein since the larger molecule has more possible interaction points with the surface and, thus, greater total energy of interaction.

The most important consequence of therapeutic protein adsorption is the loss of bioactivity, the reasons for which include loss of therapeutic agent by irreversible adsorption to the surface, possible structural changes in the protein induced by the interface, and surface-associated aggregation and precipitation of the protein. Each of these consequences is related to the structure adopted by the protein in the interfacial region. The native three-dimensional structure of a protein in solution is the result of a complex balance between attractive and repulsive forces. Surface can easily disrupt the balance of forces in proteins residing in the interfacial region and cause the molecule to undergo a change, unfolding from the native to the extended configuration. Because it is unlikely that the extended configuration will refold back to the native state upon release from the interface, the protein is considered to be denatured. Like other polymers, the unfolding of the protein at the interface is thought to minimize the contact of apolar amino acid side chains with water.

In addition, electrical interactions, both within the protein and between the protein and the surface, strongly modulate the configuration assumed at the interface. Motion of the interface, such as comes about during shaking of a solution, appears to accelerate the surface-associated denaturation. Some proteins appear to be rather vulnerable to surface-induced structural alterations, whereas others are very resistant. Algorithms for predicting those proteins most vulnerable to the structure-damaging effects of interfaces are not yet available. Empirical observations suggest that those proteins easily denatured in solution by elevated temperatures may also be most sensitive to interfacial denaturation.

The best defense against untoward effects on the structure of proteins induced by surfaces appears to be prevention of adsorption. Research in the field of biomaterials has shown that surfaces that are highly hydrophilic are less likely to serve as sites for protein adsorption. Steric hindrance of adsorption by bonding hydrophilic polymers, such as polyethylene oxide, to a surface also appears to be successful in minimizing adsorption. Formulations of proteins intended for parenteral administration frequently contain synthetic surfactants to preserve bioactivity. The specific molecular mechanism of protection is not understood and can involve specific blocking of adsorption to the interface or enhanced removal from the interface before protein unfolding can occur. In support of the former mechanism is the observation that surfactants most successful at protecting proteins from interfacial denaturation contain long polyethylene oxide chains capable of blocking access of the protein to the surface.

### Phospholipids

All lecithins contain the L-glycerophosphocholine skeleton esterified to two long-chain fatty acids (often oleic, palmitic, stearic, and linoleic). Typically, for pharmaceutical use, lecithins are derived from egg yolk or soybean. Although possessing a polar zwitterionic *head* group, the twin hydrocarbon *tails* result in a surfactant with very low water solubility in the monomer state. With the exception of the skin, phospholipids make up a vast majority of the lipid component of cell membranes throughout the body. As a result, the biocompatibility of lecithin is high, accounting for the increasing popularity of use in formulations intended for oral, topical, and intravenous use. Egg yolk lecithins are used extensively as the main emulsifying agent in the fat emulsions intended for intravenous use.

The ability of the lecithins to form a tough but flexible film between the oil and water phases is responsible for the excellent physical stability shown in the IV fat emulsions. In aqueous media phospholipids are capable of assembling into concentric bilayer structures, known as liposomes. The therapeutic advantage of such a lipid assembly for drug delivery depends upon the encapsulation of the active ingredient either within the interior aqueous environment or within the hydrophobic region of the bilayer. Deposition of the liposome within the body appears to be dependent upon a number of factors, including the composition of the phospholipids employed in the bilayer and the diameter of the liposome.

The unique surface properties of phospholipids are critical to the function of the pulmonary system. Pulmonary surfactant is a mixture of phospholipids and other associated molecules secreted by type II pneumocytes. In the absence of pulmonary surfactant (as in a neonate born prematurely), the high surface energy of the pulmonary alveoli and airways can be diminished only by physical collapse of these structures and resulting elimination of the air-water interface. As a consequence of airway collapse, the lung fails to act as an organ of gas exchange. Pulmonary surfactant maintains the morphology and function of the alveoli and airways by markedly decreasing surface energy through decreasing the surface tension of the air-water interface.

The most prevalent component of pulmonary surfactant, dipalmitoylphosphatidylcholine (DPPC), is uniquely responsible for forming the very rigid surface film necessary to reduce the surface tension of the interface to a value near 0. Such an extreme reduction in surface tension is most critical during the process of exhalation of the lung, where the air-water interfacial area is decreasing. Although DPPC does form the rigid film, in the absence of additives, it is unable to respread over an expanding interface typical of a lung during the inhalation phase. An anionic phospholipid, phosphatidylglycerol, in conjunction with a surfactant-associated protein, SP-C, appears to aid the respreading of DPPC and to maintain mechanical stability of the interface. A truly remarkable feature is that pulmonary surfactant is able to carry out the cycle of reducing surface tension

to near 0 during exhalation and then re-expanding over the interface during inhalation at whatever rate is necessary by the respiratory pattern.

Commercially available pulmonary surfactant replacement preparations contain DPPC as the primary ingredient. Agents that aid in the respreading of DPPC may differ, depending upon the source of the surface-active material.

### Nonionic Agents

The major class of compounds used in pharmaceutical systems are the nonionic surfactants, for their advantages with respect to compatibility, stability, and potential toxicity are quite significant. It is convenient to divide these compounds into those that are relatively water insoluble and those that are quite water soluble. The major types of compounds making up this first group are the long-chain fatty acids and their water-insoluble derivatives. These include

- Fatty alcohols, such as lauryl, cetyl (16 carbons), and stearyl alcohols
- Glyceryl esters, such as the naturally occurring mono-, di-, and triglycerides
- Fatty acid esters of fatty alcohols and other alcohols, such as propylene glycol, polyethylene glycol, sorbitan, sucrose, and cholesterol. Included also in this general class of nonionic water-insoluble compounds are the free steroidal alcohols, such as cholesterol.

To increase the water solubility of these compounds and to form the second group of nonionic agents, polyoxyethylene groups are added through an ether linkage with one of their alcohol groups. The list of derivatives available is much too long to cover completely, but a few general categories will be given.

The most widely used compounds are the polyoxyethylene sorbitan fatty acid esters, found in pharmaceutical formulations that are to be used both internally and externally. Closely related compounds include polyoxyethylene glyceryl and steroidal esters, as well as the comparable polyoxypropylene esters. It is also possible to have a direct ether linkage with the hydrophobic group, as with a polyoxyethylene-stearyl ether or a polyoxyethylene-alkyl phenol. These ethers offer advantages because, unlike the esters, they are quite resistant to acidic or alkaline hydrolysis.

Besides the classification of surfactants according to their polar portion, it is useful to have a method that categorizes them in a manner that reflects their interfacial activity and their ability to function as wetting agents, emulsifiers, and solubilizers. Variation in the relative polarity or nonpolarity of a surfactant significantly influences its interfacial behavior, so some measure of polarity or nonpolarity should be useful as a means of classification.

One such approach assigns a hydrophile-lipophile balance (HLB) number for each surfactant; although the method was developed by a commercial supplier of one group of surfactants, it has received widespread application.

The HLB value, as originally conceived for nonionic surfactants, is merely the percentage weight of the hydrophilic group divided by 5 in order to reduce the range of values. On a molar basis, therefore, a 100% hydrophilic molecule (polyethylene glycol) would have a value of 20. Thus, an increase in polyoxyethylene chain length increases polarity and, hence, the HLB value; at constant polar chain length, an increase in alkyl chain length or number of fatty acid groups decreases polarity and the HLB value. One immediate advantage of this system is that, to a first approximation, one can compare any chemical type of surfactant to another type when both polar and nonpolar groups are different.

Values of HLB for nonionics are calculable on the basis of the proportion of polyoxyethylene chain present; however, to determine values for other types of surfactants, it is necessary to compare physical chemical properties reflecting polarity with those surfactants having known HLB values.

Relationships between HLB and phenomena, such as water solubility, interfacial tension, and dielectric constant have been used. Those surfactants exhibiting values greater than 20 (e.g., sodium lauryl sulfate) demonstrate hydrophilic behavior in excess of the polyoxyethylene groups alone. Refer to Chapter 21 for further information.

## Colloidal Dispersions

Bill J. Bowman, RPh, PhD; Clyde M. Ofner III, PhD; Hans Schott, PhD and Yvonne Perrie, PhD

DEFINITIONS AND CLASSIFICATIONS 343

PROPERTIES OF COLLOIDAL DISPERSIONS 345

LYOPHILIC DISPERSIONS 355

LYOPHOBIC DISPERSIONS 356

ASSOCIATION COLLOIDS 361

PHARMACEUTICAL APPLICATIONS OF COLLOIDAL SYSTEMS 365

The British chemist Thomas Graham applied the term “colloid” (derived from the Greek word for glue) about 1850 to polypeptides such as albumin and gelatin, to polysaccharides such as acacia, starch, and dextrin, and to inorganic compounds such as gelatinous metal hydroxides and Prussian blue (ferric ferrocyanide). Contemporary colloid and surface chemistry deals with an unusually wide variety of industrial and biological systems.

Within the field of pharmacy, the colloidal systems we commonly come across include some protein and polymer solutions, micellar systems, liquid crystals and emulsions, suspensions, aerosols, foams and other drug delivery systems that fall within the colloidal size range. In some instances, what was formally referred to as colloidal systems have been replaced by the term nanotechnology (structures that have one or more dimension between approximately 1 and 100 nm).

### DEFINITIONS AND CLASSIFICATIONS

#### COLLOIDAL SYSTEMS AND INTERFACES

Except for high-molecular-weight polymers, most soluble substances can be prepared as either low-molecular-weight solutions, colloidal dispersions, or coarse suspensions, depending upon the choice of dispersion medium and dispersion technique. Colloidal dispersions consist of at least two phases: one or more dispersed or internal phases, and a continuous or external phase called the *dispersion medium* or *vehicle*. Colloidal dispersions are distinguished from solutions and coarse dispersions by the particle size of the dispersed phase, not its composition. Whilst somewhat arbitrary, colloidal dispersions can be characterized as containing particles in the size range of between approximately 1 nm and 1 micrometer, however a smaller size range of up to 500 nm is also quoted. Thus, blood, cell membranes, micelles, thinner nerve fibers, milk, rubber latex, fog, and beer foam are colloidal systems. Some materials, such as emulsions and suspensions of most organic drugs, are coarser than true colloidal systems but exhibit similar behavior. Even though serum albumin, acacia, and povidone form true or molecular solutions in water, the size of the individual solute molecules places such solutions in the colloidal range (particle size >1 nm).

In general, there are several features that distinguish colloidal dispersions from coarse suspensions and emulsions. Colloidal particles are usually too small for visibility in a light microscope, because at least one of their dimensions measures 1 micrometer or less. They are, however, often visible in an ultramicroscope, and almost always in an electron microscope. Conversely, coarse suspended particles are usually visible to the naked eye and always in a light microscope. In addition, colloidal particles, as opposed to coarse particles, pass through ordinary filter paper but are retained by dialysis or ultrafiltration membranes. Also, unlike coarse particles, colloidal particles diffuse very slowly and undergo little or no sedimentation or creaming. Brownian motion (see Diffusion and Sedimentation below) maintains the dispersion of the colloidal internal phases.

An appreciable fraction of atoms, ions, or molecules of colloidal particles are located in the boundary layer between the particle and the dispersion medium. The boundary layer between a particle and air is commonly referred to as a *surface*, whereas the boundary layer between a particle and a liquid or solid is commonly referred to as an *interface*. The ions or molecules within the particle and within the medium are surrounded on all sides by similar ions or molecules and have balanced force fields; however, the ions or molecules at surfaces or interfaces are subjected to unbalanced forces of attraction. Consequently, a surface free-energy component is added to the total free energy of colloidal particles and becomes important as the particles become smaller and a greater fraction of their atoms, ions, or molecules are located in the surface or interfacial region. As a result, the solubility of very fine solid particles and the vapor pressure of very small liquid droplets are greater than the corresponding values for coarse particles and drops of the same materials.

#### Specific Surface Area

Decreasing particle size increases the surface-to-volume ratio, expressed as the *specific surface area* ( $A_{sp}$ ). Specific surface area can be expressed as the area ( $A$ ,  $\text{cm}^2$ ) per unit volume ( $V$ ,  $\text{cm}^3$ ) or per unit mass ( $M$ , grams). For a sphere,  $A = 4\pi r^2$  and  $V = 4/3\pi r^3$ , then  $A_{sp}$  is:

$$A_{sp} = \frac{A}{V} = \frac{4\pi}{4/3\pi r^3} = \frac{3 \text{ cm}^2}{r \text{ cm}^3} = \frac{3}{r} \text{ cm}^{-1} \quad (1)$$

For density ( $d$ ) of the material expressed as  $\text{g}/\text{cm}^3$ , the specific surface area is:

$$A_{sp} = \frac{A}{M} = \frac{A}{Vd} = \frac{4\pi r^2}{4/3\pi r^3 d} = \frac{3 \text{ cm}^2}{rd \text{ g}} \quad (2)$$

Table 20-1 illustrates the effect of comminution on the specific surface area of a material initially consisting of one sphere

**Table 20-1. Effect of Comminution on the Specific Surface Area of a Volume of  $4/3 \text{ cm}^3$ , Divided into Uniform Spheres of Radius  $R$**

Number of Spheres	$R$	$A_{sp} \text{ cm}^2/\text{cm}^3$

<b><math>10^{21}</math></b>	<b>1 nm</b>	<b><math>3 \times 10^7</math></b>
$10^{23}$	0.1 nm	$3 \times 10^8$

Shaded region corresponds to colloidal particle-size range.

having a 1-cm radius. The specific surface area increases as the material is broken into a larger number of smaller and smaller spheres. Activated charcoal and kaolin are solid adsorbents having specific surface areas of about  $6 \times 10^6$  cm<sup>2</sup>/g and  $10^4$  cm<sup>2</sup>/g, respectively. One gram of activated charcoal has a surface area equal to approximately 700 square meters because of its extensive porosity and internal voids.

### PHYSICAL STATES OF DISPERSED AND CONTINUOUS PHASES

A useful classification of colloidal systems is based upon the state of matter of the dispersed phase and the dispersion medium (i.e., whether they are solid, liquid, or gaseous).<sup>1,2</sup> Common examples and various combinations are shown in Table 20-2. The terms *sols* and *gels* are often applied to colloidal dispersions of a solid in a liquid or gaseous medium. Sols tend to have a lower viscosity and are fluid. If the solid particles form bridged structures possessing some mechanical strength, the system is then called a gel. Prefixes typically designate the dispersion medium. For example, hydrosol (or hydrogel), alcocol (or alcogel), and aerosol (or aerogel) designate water, alcohol, and air, respectively.

### INTERACTION BETWEEN DISPERSED PHASES AND DISPERSION MEDIUMS

Ostwald originated another useful classification of colloidal dispersions based on the affinity or interaction between the dispersed phase and the dispersion medium.<sup>2</sup> This classification refers mostly to solid-in-liquid dispersions. Colloidal dispersions are divided into the two broad categories, *lyophilic* and *lyophobic*. Some soluble, low-molecular-weight substances have molecules with both tendencies and associate in solution, forming a third category called *association colloids*.

#### Lyophilic Dispersions

The system is said to be *lyophilic* (solvent-loving) if there is considerable attraction between the dispersed phase and the liquid vehicle (i.e., extensive solvation). The system is said to be *hydrophilic* if the dispersion medium is water. Due to the presence of high concentrations of hydrophilic groups, solids such as bentonite, starch, gelatin, acacia, and povidone swell, disperse, or dissolve spontaneously in water to the greatest degree possible without breaking covalent bonds. Hydrophilic colloids often contain ionized groups that dissociate into highly

hydrated ions (e.g., carboxylate, sulfonate, and alkylammonium ions) and/or organic functional groups that bind water through hydrogen bonding (e.g., hydroxyl, carbonyl, amino, and imino groups).

Hydrophilic colloidal dispersions can be further subdivided as:

- *True solutions*: water-soluble polymers (e.g., acacia and povidone)
- *Gelled solutions, gels, or jellies*: polymers present at sufficiently high concentrations and/or at temperatures where their water solubility is low, such as relatively concentrated solutions of gelatin and starch (which set to gels upon cooling) and methylcellulose (which gels upon heating)
- *Particulate dispersions*: solids that do not form molecular solutions but remain as discrete though minute particles (e.g., bentonite and microcrystalline cellulose)

*Lipophilic* or *oleophilic* substances have a strong affinity for oils. Oils are nonpolar liquids consisting mainly of hydrocarbons having few polar groups and low dielectric constants. Examples include mineral oil, benzene, carbon tetrachloride, vegetable oils (e.g., cottonseed or peanut oil), and essential oils (e.g., lemon or peppermint oil). Oleophilic colloidal dispersions include polymers such as polystyrene and unvulcanized or gum rubber dissolved or dispersed in benzene, magnesium, or aluminum stearate dissolved or dispersed in cottonseed oil, and activated charcoal, which forms sols or particulate dispersions in all oils.

#### Lyophobic Dispersions

The dispersion is said to be *lyophobic* (solvent-hating) when there is little attraction between the dispersed phase and the dispersion medium. *Hydrophobic* dispersions consist of particles that are only hydrated slightly or not at all, because water molecules prefer to interact with one another instead of solvating the particles. Therefore, such particles do not disperse or dissolve spontaneously in water. Examples of materials that form hydrophobic dispersions include organic compounds consisting largely of hydrocarbon portions with few, if any, hydrophilic functional groups (e.g., cholesterol and other steroids); some nonionized inorganic substances (e.g., sulfur); and oleophilic materials such as polystyrene or gum rubber, organic lipophilic drugs, paraffin wax, magnesium stearate, and cottonseed or soybean oils. Materials such as sulfur, silver chloride, and gold

**Table 20-2. Classification of Colloidal Dispersions According to State of Matter**

Disperse Phase	Dispersion Medium (Vehicle)		
	Solid	Liquid	Gas
Solid	Zinc Oxide Paste USP, toothpaste (dicalcium phosphate or calcium carbonate with aqueous sodium carboxymethylcellulose binder), and pigmented plastics (titanium dioxide in polyethylene)	<b>Sols:</b> Bentonite Magma NF, Trisulfapyrimidines Oral Suspension USP, Alumina and Magnesia Oral Suspension USP, Tetracycline Oral Suspension USP, Betamethasone Valerate Lotion USP, and Ophthalmic Suspension USP	<b>Solid aerosols:</b> Epinephrine Bitartrate Inhalation Aerosol USP, Isoproterenol Sulfate Inhalation Aerosol USP, smoke, and dust
Liquid	Absorption bases (aqueous medium in Hydrophilic petrolatum USP), emulsion bases (oil in Hydrophilic Ointment USP, Lanolin USP), and butter	<b>Emulsions:</b> Mineral Oil Emulsion USP, Benzyl Benzoate Lotion USP, and soybean oil in water for parenteral nutrition, milk, and mayonnaise	<b>Liquid aerosols:</b> Metaproterenol Sulfate Inhalation Aerosol USP, Povidone Iodine Topical Aerosol USP, mist, and fog
Gas	Solid foams (foamed plastics and rubbers) and pumice	Foams, carbonated beverages, and effervescent salts in water.	No colloidal dispersions

form hydrophobic dispersions without being lipophilic. There is no sharp dividing line between hydrophilic and hydrophobic dispersions. For example, gelatinous hydroxides of polyvalent metals (e.g., aluminum and magnesium hydroxide) and clays (e.g., bentonite and kaolin) possess some characteristics of both.<sup>2</sup> Common *lipophobic* dispersions include water-in-oil (W/O) emulsions, which are essentially lyophobic dispersions in lipophilic vehicles.

### Association Colloids

Organic compounds that contain large hydrophobic moieties on the same molecule with strongly hydrophilic groups are said to be *amphiphilic*. The individual molecules are generally too small to be in the colloidal size range, but they tend to associate into larger aggregates when dissolved in water or oil. These compounds are designated *association colloids*, because their aggregates are large enough to qualify as colloidal particles. Examples include surfactant molecules that associate into micelles above their critical micelle concentration (CMC) and phospholipids that associate into cellular membranes and liposomes, which have been used for drug delivery.

## PROPERTIES OF COLLOIDAL DISPERSIONS

### PARTICLE SHAPE

Particle shape depends upon the chemical and physical nature of the dispersed phase and the method employed to prepare the dispersion (preparation methods are described in later sections of this chapter). Primary particles exist in a wide variety of shapes, and their aggregation produces an even wider variety of shapes and structures. Preparation methods such as mechanical comminution and precipitation generally produce randomly shaped particles unless the precipitating solids possess pronounced crystallization habits or the solids being ground possess strongly developed cleavage planes. For example, micronized particles of sulfonamides and other organic powders, as well as precipitated aluminum hydroxide gels, typically have irregular random shapes. An exception is bismuth subnitrate; hydrolyzing bismuth nitrate solutions with sodium carbonate precipitates lath-shaped particles. In addition, precipitated silver chloride particles show their cubic nature under the electron microscope. Lamellar or plate-like solids often preserve their lamellar shape during mechanical comminution, because milling and micronization break up the stacks of thin plates, in addition to fragmenting plates in the lateral dimensions. In these materials, the molecular cohesion between layers is much weaker than the cohesion within layers. Examples of such materials include graphite, mica, and kaolin (Figure 20-1). In a like manner, macroscopic asbestos and cellulose fibers consist of bundles of microscopic and submicroscopic fibrils that have very small diameters. Mechanical comminution splits these bundles into their component fibrils as well as cutting them shorter. Figure 20-2 shows the individual, needle- or rod-shaped cellulose crystallites formed after breaking up the aggregated bundles of *microcrystalline cellulose*. These crystallites average 0.3 micrometers in length and 0.02 micrometers in width, which places them in the colloidal size range. Microcrystalline cellulose is a fibrous thickening agent and tablet additive made by the controlled hydrolysis of cellulose.

Except in the special cases of clay and cellulose just mentioned, regular-shaped particles are typically produced by condensation rather than disintegration methods. For example, *colloidal silicon dioxide* is a white powder consisting of submicroscopic spherical particles of rather uniform size (i.e., narrow particle size distribution). It is manufactured by high-temperature, vapor-phase hydrolysis of silicon tetrachloride in an oxygen-hydrogen flame (i.e., a flame produced by burning hydrogen in a stream of oxygen). It is commonly referred to as fumed or pyrogenic silica because of this manufacturing process. Different grades are produced by different reaction conditions.

**Figure 20-1.** Transmission electron micrograph of a well-crystallized, fine-particle kaolin. Note hexagonal shape of the clay platelets. (Courtesy of John L. Brown, Engineering Experiment Station, Georgia Institute of Technology.)

**Figure 20-2.** Transmission electron micrograph of Avicel RC-591 thickening-grade microcrystalline cellulose. The needles are individual cellulose crystallites; some are aggregated into bundles. (Courtesy of FMC Corporation; Avicel is a registered trademark of FMC Corporation.)

Figure 20-3 shows the relatively large, single spherical particles of colloidal silicon dioxide. Their average diameter of 50 nm corresponds to the comparatively small specific surface area of 50 m<sup>2</sup>/g. Smaller spherical particles have a larger specific surface area. For example, the grade with the smallest average diameter, 5 nm, has a specific surface area of 380 m<sup>2</sup>/g. The finer

**Figure 20-3.** Transmission electron micrograph of Aerosil OX 50, ground and dusted on. The spheres are translucent to the electron beam, causing overlapping portions to be darker as a result of an increased thickness. The suffix 50 indicates the specific surface area in m<sup>2</sup>/g. (Courtesy of Degussa AG, Hanau, Germany; Aerosil is a registered trademark of Degussa.)

**Figure 20-4.** Transmission electron micrograph of Aerosil 130, ground and dusted on. The spheres are fused together into chain-like aggregates. The suffix 130 indicates the specific surface area in m<sup>2</sup>/g. (Courtesy of Degussa AG, Hanau, Germany; Aerosil is a registered trademark of Degussa.)

grade particles tend to sinter or grow together into chain-like aggregates resembling pearl necklaces during the manufacturing process (Figure 20-4). *Latexes* of polymers, such as latex-based paints, are aqueous dispersions prepared by emulsion polymerization. Their particles are spherical, because polymerization of the solubilized liquid monomers takes place inside spherical surfactant micelles. Some *clays* grow as plate-like particles possessing straight edges and hexagonal angles (e.g., bentonite and kaolin) (Figure 20-1). Other clays have lath-shaped (nontronite) or rod-shaped particles (attapulgite).<sup>3</sup>

Emulsification produces spherical droplets to minimize the oil-water interfacial area. Cooling an emulsion below the melting point of the dispersed phase freezes the dispersed particles in a spherical shape. For instance, paraffin may be emulsified in 80°C water and then cooled to room temperature to produce a hydrosol containing spherical particles. Sols of viruses and globular proteins, which are hydrophilic, contain compact particles possessing definite geometric shapes. For example, the poliomyelitis virus is spherical, the tobacco mosaic virus is rod-shaped, and the serum albumins and globulins are prolate ellipsoids of revolution (football-shaped).

### DIFFUSION AND SEDIMENTATION

The molecules of a gas or liquid are engaged in a perpetual and random thermal motion causing collisions with one another and with the container wall billions of times per second. Each collision changes the direction and the velocity of these molecules. The continuous motion of molecules of a dispersion medium randomly buffets any dissolved molecules and suspended colloidal particles. The random bombardment imparts an erratic movement called *brownian motion* to solutes and particles.

This phenomenon is named after the botanist Robert Brown, who first observed it under the microscope in an aqueous pollen suspension. The brownian motion of colloidal particles magnifies the random movements of molecules in the liquid or gaseous suspending medium and represents a three-dimensional random walk.

Suspended colloidal particles and solute molecules undergo both rotational and translational brownian movements. For translational motion, Einstein derived the equation:

$$\bar{x} = \sqrt{2Dt} \quad (3)$$

where  $x$  is the mean displacement in the  $x$ -direction in time  $t$ , and  $D$  is the *diffusion coefficient*. Einstein also showed that for spherical particles of radius  $r$ , under conditions valid for Stokes' law and Einstein's law of viscosity:

$$D = \frac{RT}{6\pi\eta rN} \quad (4)$$

where  $R$  is the gas constant,  $T$  is the absolute temperature,  $N$  is Avogadro's number, and  $\eta$  is the viscosity of the suspending medium.

A common measure of the mobility of a dissolved molecule or suspended particle in a liquid medium is the diffusion coefficient. At room temperature, using units of cm<sup>2</sup>/s, the value of sucrose in water is  $4.7 \times 10^{-6}$  and the value of serum albumin in water is  $6.1 \times 10^{-7}$ . Diffusion is a slow process on a macroscopic scale. Using the value of  $1 \times 10^{-7}$  cm<sup>2</sup>/s, brownian motion causes a particle to move in one direction an average distance of 1 cm in 58 days, 1 mm in 14 hours, or 1 micrometer in 0.05 seconds. As seen in the above equation, smaller molecules diffuse faster

in a given medium. The radius of a sucrose molecule is smaller than that of a serum albumin molecule; the calculated values are 0.44 nm and 3.5 nm, respectively (assuming a spherical shape). Steroids have only slightly higher molecular weights than sucrose; however, their diffusion coefficients in petrolatum-based absorption bases are in the range of  $10^{-10}$  to  $10^{-8}$  cm<sup>2</sup>/s. These much smaller diffusion coefficients are caused by the much higher vehicle viscosity. Passive diffusion (driven by a concentration gradient and carried out through brownian motion) is important in the release of drugs from topical preparations and in the gastrointestinal absorption of drugs.

Brownian motion and convection currents maintain dissolved molecules and small colloidal particles in suspension indefinitely. This is true for all intrinsically stable systems when dissolution or dispersion occurs spontaneously and the corresponding free energy change is negative (see equation 5 below). In meta-stable or *diuturna* (i.e., durable, lasting) dispersions, brownian motion prevents sedimentation and may extend their life for years.

As particle size or  $r$  increases, brownian motion decreases as seen by the  $x$  proportionality to  $r^{-1/2}$ . Larger particles have a greater tendency than smaller particles of the same material to settle to the bottom of the dispersion, provided the densities of the dispersed phase,  $dP$ , and the liquid vehicle,  $dL$ , are sufficiently different (sedimentation, when  $dP > dL$ ). On the other hand, larger particles will rise to the top of the dispersion when  $dP < dL$ . This is known as creaming. The Stokes equation reflects the rate of *sedimentation/creaming*; it is expressed as:

$$h = \frac{2(d_p - d_l)r^2gt}{9\eta} \quad (5)$$

where  $h$  is the height (or distance) that a spherical particle moves in time  $t$ , and  $g$  is the acceleration of gravity. The equation illustrates that this rate is proportional to  $r^2$ . Consequently, as brownian motion diminishes with increasing particle size, the tendency of particles to sediment or cream is increased. At a critical radius, the distance,  $h$ , that a particle settles/creams equals the mean displacement,  $x$ , due to brownian motion over the same time interval,  $t$ , and therefore, the two are equal.<sup>4</sup> Intravenous vegetable oil emulsions have little tendency to cream, because their mean droplet size, approximately 0.2 micrometers, is smaller than the critical radius. In most pharmaceutical suspensions, sedimentation prevails.

## LIGHT SCATTERING

The optical properties of a medium are determined by its refractive index. Light will pass through the medium undeflected when the refractive index is uniform throughout. However, when there are discrete variations in the refractive index from the presence of particles or caused by small-scale density fluctuations, part of the passing light will be scattered in all directions. When a narrow beam of sunlight is admitted through a small hole into a darkened room, bright flashing points reveal the presence of the minute dust particles suspended in the air. A beam of light striking a particle polarizes the atoms and molecules of that particle and induces dipoles, which act as secondary sources and re-emit weak light of the same wavelength as the incident light. This phenomenon is called *light scattering*. The scattered radiation propagates in all directions away from the particle. In a bright room, the light scattered by the dust particles is too weak to be noticeable.

Colloidal particles suspended in a liquid also scatter light. When an intense, narrowly defined beam of light is passed through a suspension, its path becomes visible because of the light scattered by the particles in the beam. This *Tyndall beam* is characteristic of colloidal systems and becomes most visible when viewed against a dark background in a direction perpendicular to the incident beam. The magnitude of the turbidity or opalescence depends upon the nature, size, and concentration of the dispersed particles. For example, when clear mineral oil

is dispersed in an equal volume of a clear, aqueous surfactant solution, the resultant emulsion is milky white and opaque as a result of light scattering. However, microemulsions containing emulsified droplets that are only about 40 nm in diameter (i.e., much smaller than the wavelength of visible light) are transparent and clear to the naked eye.

The concentration of inorganic and organic colloidal dispersions and of bacterial suspensions can be measured by their Tyndall effect or turbidity. Turbidity,  $\tau$ , is defined by an equation analogous to Beer's law for the absorption of light,<sup>1,2</sup> namely:

$$\tau = \frac{1}{l} \ln \frac{I_0}{I_t} \quad (6)$$

where  $I_0$  and  $I_t$  are the intensities of the incident and transmitted light beams, and  $l$  is the length of the dispersion through which the light passes. The concentration of dispersed particles can be measured in two ways using turbidity. In *turbidimetry* a spectrophotometer or photoelectric colorimeter is used to measure the intensity of the light transmitted in the incident direction. If the dispersion is less turbid, the intensity of light scattered at 90 degrees to the incident beam is measured with a *nephelometer*. Both methods require careful standardization, using suspensions that contain known amounts of particles similar to those being studied. The turbidity of hydrophilic colloidal systems such as aqueous solutions of gums, proteins, and other polymers is far weaker than that of lyophobic dispersions. These solutions appear clear to the naked eye; however, their turbidity can be measured with a photoelectric cell/photomultiplier tube and used to determine the molecular weight of the solute.

The theory of light scattering was developed in detail by Lord Rayleigh. For white, nonabsorbing nonconductors or dielectrics like sulfur and insoluble organic compounds, the equation obtained for spherical particles whose radius is small compared to the wavelength of light ( $\lambda$ ) is<sup>1,2</sup>:

$$I_s = I_0 \frac{4\pi^2 n_0^2 (n_1 - n_0)}{\lambda^4 d^2 c} (1 + \cos^2 \theta) \quad (7)$$

$I_0$  is the intensity of the unpolarized incident light;  $I_s$  is the intensity of light scattered in a direction making an angle,  $\theta$ , with the incident beam and measured at a distance,  $d$ . The scattered light is largely polarized. The concentration,  $c$ , is expressed as the number of particles per unit volume. The refractive indices,  $n_1$  and  $n_0$ , refer to the dispersion and the dispersion medium, respectively. Because the intensity of scattered light is inversely proportional to the fourth power of the wavelength, blue light ( $\lambda \approx 450$  nm) is scattered much more strongly than red light ( $\lambda \approx 650$  nm). Colloidal dispersions of colorless particles appear blue when the incident white light is viewed in scattered light (i.e., in lateral directions such as 90 degrees to the incident beam). Loss of the blue rays due to preferential scattering leaves the transmitted light yellow or red. Preferential scattering of blue radiation sideways accounts for the blue color of the sky, sea, cigarette smoke, and diluted milk, and for the yellow-red color of the rising and setting sun viewed head-on.

The particles in pharmaceutical suspensions, emulsions, and lotions are generally larger than the wavelength of light,  $\lambda$ . When the particle size exceeds  $\lambda/20$ , destructive interference between the light scattered by different portions of the same particle lowers the intensity of the scattered light and changes its angular dependence. Rayleigh's theory was extended to large and strongly absorbing and conducting particles by German physicist Gustav Mie and to nonspherical particles by German physicist Richard Gans.<sup>1,2</sup> It is possible to determine the average particle size and even the particle size distribution of colloidal dispersions and coarser suspensions by means of turbidity measurements using appropriate precautions in experimental techniques and interpretations.

## Dynamic Light Scattering

Light scattered by a moving particle undergoes a Doppler shift; its frequency increases slightly when the particle moves toward the photodetector and decreases slightly when it moves away. This shift is so small that it can only be detected by very intense, strictly monochromatic laser light. Because they are engaged in random brownian motion, a set of colloidal particles scatters light with a broadened frequency. Smaller particles diffuse faster than larger ones and therefore produce greater Doppler broadening. If the particles are spherical and monodisperse, and their concentration is so dilute that they neither attract nor repel one another, the frequency broadening can be used to estimate the particle diffusion coefficient,  $D$ . As noted above, the diffusion coefficient is inversely proportional to the particle radius. The measured radius is actually the hydrodynamic radius ( $r_H$ ), which comprises the particle plus its attached water of hydration. The technique is called *dynamic or quasi-elastic light scattering*. The technique is also called *photon correlation spectroscopy* (PCS), because it counts and correlates the number of scattered photons over very short time intervals. For polydisperse spherical colloidal particles, it estimates the particle size distribution.<sup>2,5</sup> Particles that are asymmetric rather than spherical and/or extensively hydrated have a larger  $r_H$  and hence smaller  $D$  value than unsolvated spherical particles with the same dry volume. It is not possible to separate the effect of hydration upon  $r_H$ , and  $D$  from the effect of asymmetry by PCS alone; either hydration or particle shape must be determined by other means.<sup>1,2,5</sup>

In a related technique that uses a *fiber-optic Doppler anemometer*, a laser beam is carried into the interior of a colloidal dispersion via a fiber-optic cable. Particles in the small volume of dispersion around the immersed tip scatter light with the Doppler frequency shift back into the same fiber to the detector. This method is suitable for concentrated dispersions that are opaque to the laser beam and would have to be diluted extensively for conventional dynamic light scattering measurements.<sup>6</sup>

## VISCOSITY

Most lyophobic dispersions have viscosities only slightly greater than that of the liquid vehicle. This holds true even at comparatively high volume fractions of the disperse phase unless the particles form continuous network aggregates throughout the vehicle, in which case yield stresses are observed. By contrast, the apparent viscosities of lyophilic dispersions, especially of polymer solutions, are several orders of magnitude greater than the viscosity of the solvent or vehicle even at concentrations of only a few percent solids. Lyophilic dispersions are also generally much more pseudoplastic or shear-thinning than lyophobic dispersions.

## GEL FORMATION

The flexible chains of dissolved polymers interpenetrate and entangle because of the constant brownian motion of their segments. The chains constantly writhe and change their conformations. Each chain is encased in a sheath of solvent molecules that solvate its functional groups. For example, water molecules are hydrogen-bonded to the hydroxyl groups of polyvinyl alcohol, hydroxyl groups, and ether linkages of polysaccharides, ether linkages of polyethylene oxide or PEG, amide groups of polypeptides and povidone, and carboxylate groups of anionic polyelectrolytes. This envelope of water of hydration prevents chain segments that are in close proximity from touching and attracting one another through interchain hydrogen bonds and van der Waals forces as they do in the solid state. The free solvent between the chains' solvation sheaths acts as a lubricant allowing the solvated chains to slip past one another when the solution flows. However, any factor that lowers the hydration of dissolved macromolecules will reduce or thin out the sheath of hydration separating adjacent chains. When hydration is low,

contiguous chains tend to attract one another through secondary valence forces such as hydrogen bonds and van der Waals forces, which establish weak and reversible crosslinks between the chains at their points of contact or entanglement, thus bringing about phase separation or precipitation. Hydrophobic bonding is an important contribution to the interchain attraction between polypeptide chains even in solution.

Most water-soluble polymers have a higher solubility in hot water than in cold water and tend to precipitate upon cooling because the sheaths of hydration surrounding adjacent chains become too sparse to prevent interchain attraction. Cooling dilute solutions tends to separate them into a solvent phase and a viscous liquid phase that contains practically the entire amount of polymer but still a large excess of solvent. This process is called *simple coacervation*, and the polymer-rich liquid phase is referred to as a *coacervate*.<sup>7</sup> If the polymer solution is concentrated enough and/or the temperature is low enough, cooling causes the formation of a continuous network of precipitating chains attached to one another through weak crosslinks that consist of interchain hydrogen bonds and van der Waals forces at the points of mutual contact. Segments of regularly sequenced polymer chains will associate laterally into crystalline bundles or crystallites. However, irregular chain structures, such as those found in random copolymers, randomly substituted cellulose ethers and esters, and highly branched polymers like acacia, will prevent crystallization during precipitation from solution. In these cases chain entanglements provide the sole temporary crosslinks. A network of associated polymer chains immobilizes the solvent, which may result in the separation of gelatinous precipitates or highly swollen flocs, and in the case of more concentrated polymer solutions, may even cause the solution to set to a gel.

The most important factors causing phase separation, precipitation, and gelation of polymer solutions are the chemical nature of the polymer and the solvent, temperature, polymer concentration, and polymer molecular weight. Lower temperatures, higher concentrations, and higher molecular weights promote *gelation* and produce stronger gels. For a typical *gelatin*, 10 percent solutions acquire yield values and begin to gel at about 25°C, 20 percent solutions gel at about 30°C, and 30 percent solutions gel at about 32°C. The gelation is reversible, and the gels liquefy when heated above these temperatures. Regardless of concentration, gelation is rarely observed above 34°C, and therefore, gelatin solutions do not gel at body temperature (i.e., 37°C). Agar and pectic acid solutions set to gels at only a few percent of solids. Unlike most water-soluble polymers, methylcellulose, hydroxypropyl cellulose, and polyethylene oxide are more soluble in cold water than in hot water. Therefore, their solutions tend to gel upon heating (i.e., *thermal gelation*) instead of cooling.

When dissolving powdered polymers in water, temporary gel formation often slows dissolution considerably. As water diffuses into loose clumps of the powder, their exterior frequently turns to a cohesive gel of solvated particles encasing the remaining dry powder. Such globs of gel dissolve very slowly because of their high viscosity and the low diffusion coefficients of the polymers. For large-scale dissolution, it is helpful to disperse the polymer powder in water at temperatures where the solubility of the polymer is lowest before it can agglomerate into lumps of gel. Most polymer powders, such as sodium carboxymethylcellulose, are dispersed with high shear in *cold* water before the particles can hydrate and swell into sticky gel grains that agglomerate into lumps. Once the powder is well dispersed, the mixture is heated with moderate shear to about 60°C for the quickest dissolution. Because methylcellulose hydrates more slowly in hot water, the powder is dispersed with high shear in one-fifth to one-third of the required amount of water heated to 80°C to 90°C. Once the powder is finely dispersed, the remaining amount of water is added cold, or even as ice, and moderate stirring causes prompt dissolution. For maximum clarity, fullest hydration, and highest viscosity, the solution should be cooled to 0°C to 10°C

for about an hour. Alternatively, the polymer powder may be prewetted with a water-miscible organic solvent (e.g., ethyl alcohol or propylene glycol) that does not swell the polymer. The solvent should be added in a proportion of three to five parts of solvent to one part of polymer. If other nonpolymeric, powdered adjuvants are to be incorporated into the solution, they are dry-blended with the polymer powder and should comprise only one-quarter or less of the blend for the best results.

Large increases in the concentration of polymer solutions may lead to precipitation and gelation. One way of effectively increasing the concentration of aqueous polymer solutions is to add inorganic salts. The salts will bind part of the water in the solution so as to become hydrated. Competition for water of hydration dehydrates the polymer molecules and precipitates them. This phenomenon is called **salting out** and may cause the polymer to separate as a concentrated, viscous liquid solution, a simple coacervate, or a solid gel. Because of its high solubility in water, ammonium sulfate is often used to precipitate and separate proteins from dilute solutions. However, salting out is reversible and subsequent addition of water redissolves the precipitated polymers and liquefies their gels.

### Hofmeister or Lyotropic Series

The effectiveness of electrolytes to cause salting out depends upon their extent of hydration. The *Hofmeister or lyotropic series* arranges ions in order of increasing hydration and increasing effectiveness in salting out hydrophilic colloids. The series for monovalent and divalent cations are:

and

The Hofmeister series governs many colloidal phenomena, including the effect of salts upon the temperature of gelation, the swelling of aqueous gels, and the viscosity of hydrosols, and the permeability of membranes toward salts. The series is observed in many phenomena involving small atoms or ions and true solutions, including the ionization potential and electronegativity of metals; the heats of hydration of cations; the size of hydrated cations; the viscosity, surface tension, and infrared spectra of salt solutions; and the solubility of gases in salt solutions. This series also arranges cations in order of increasing ease in displacement from cation-exchange resins based on the smaller hydrated species size (e.g.,  $\text{K}^+$  displaces  $\text{Na}^+$  and  $\text{Li}^+$ ). Adsorption in the Stern layer of particles (see below) also illustrates the series. The lithium ion is more extensively hydrated, and therefore,  $\text{Li}^+$  (aq), including the hydration shell, is larger than  $\text{Cs}^+$  (aq). Because of its smaller size, the hydrated cesium ion can approach a negative particle's surface more closely than the hydrated lithium ion. Moreover, because of its greater electron cloud, the  $\text{Cs}^+$  ion is more polarizable than the  $\text{Li}^+$  ion. Therefore, the  $\text{Cs}^+$  ion is more strongly adsorbed in the Stern layer.

For anions, in order of decreasing effectiveness in salting out, the lyotropic series is

Iodides and thiocyanates, and to a lesser extent bromides and nitrates, actually tend to increase the solubility of polymers in water (i.e., salt them in).<sup>1,2</sup> These large polarizable anions reduce the extent of hydrogen bonding among water molecules and thereby make more of the hydrogen-bonding capacity of water available to the solute. Most salts, except for nitrates, bromides, perchlorates, iodides, and thiocyanates, raise the temperature of precipitation or gelation of most hydrophilic

colloidal solutions. Exceptions among hydrophilic colloids are methylcellulose, hydroxypropyl cellulose, and polyethylene oxide, whose gelation temperatures or gel melting points are lowered by salting out.

Most hydrophilic sols require electrolyte concentrations of 1 M or higher to induce precipitation or gelation. In addition, hydrophilic colloids disperse or dissolve spontaneously in water, and their sols are intrinsically stable. Therefore, the polymer can be redissolved by removing the coagulating salt through dialysis or by adding more water. Whenever hydrophilic colloidal dispersions undergo irreversible precipitation or gelation, chemical reactions are involved. Neither dilution with water, heating, nor attempts to remove the gelling or precipitating agent by washing or dialysis will liquefy these gels.

Most of the hydrophilic and water-soluble polymers mentioned previously are only slightly soluble or insoluble in alcohol. Addition of alcohol to their aqueous solutions may cause precipitation or gelation, because it lowers the dielectric constant of the medium and tends to dehydrate the hydrophilic solute. Alcohol also lowers the concentrations at which electrolytes salt out hydrophilic colloids. Therefore, alcohol is often referred to as a nonsolvent or precipitant. However, the addition of alcohol to an aqueous polymer solution may cause coacervation (i.e., the separation of a concentrated viscous liquid phase) rather than precipitation or gel formation. Sucrose also competes for water of hydration with hydrophilic colloids and may cause phase separation. However, most hydrophilic sols tolerate substantially higher concentrations of sucrose than of electrolytes or alcohol. Lower viscosity grades of a given polymer are usually more resistant to the effects of electrolytes, alcohol, and sucrose than grades having higher viscosities and molecular weights.

The gelation temperature or gel point of gelatin is highest at its isoelectric point, where the attachment of adjacent chains through ionic bonds between carboxylate ions and alkylammonium, guanidinium, or imidazolium groups is most extensive. Because carboxyl groups are not ionized in strongly acidic media such as gastric juices, interchain ionic bonds are practically nonexistent in this environment and interchain attraction is limited to hydrogen bonds and van der Waals forces. Therefore, the combination of an acidic pH that is considerably below the isoelectric point and a temperature of 37°C completely prevents the gelation of gelatin solutions. Conversely, if a polymer owes its solubility to the ionization of these weakly acid groups, reducing the pH of its solution below 3 may lead to precipitation or gelation. This is observed with carboxylated polymers such as many gums, sodium carboxymethylcellulose, and carbomer. Adjusting the media to higher pH values returns the carboxyl groups to their ionized state and reverses the gelation or precipitation. However, gelation temperatures typically depend more upon temperature and concentration than pH.<sup>8,9</sup>

Hydrogen carboxymethylcellulose swells and disperses but does not dissolve in water. Only the sodium, potassium, ammonium, and triethanolammonium salts of carboxylated polymers are well soluble in water. In the case of carboxymethylcellulose, salts with heavy-metal cations (e.g., silver, copper, mercury, lead) and trivalent cations (e.g., aluminum, chromic, ferric) are practically insoluble. Salts with divalent cations, especially of the alkaline earth metals, have borderline solubilities. Generally, higher degrees of substitution tend to increase the tolerance of carboxymethylcellulose toward salts.

When inorganic salts of heavy or trivalent cations are mixed with alkali metal salts of carboxylated polymers in solution, precipitation or gelation occurs due to metathesis. For instance, if a soluble copper salt is added to a solution of sodium carboxymethylcellulose, the double decomposition can be schematically written as:

$R_1$  and  $R_2$  represent two carboxymethylcellulose chains, which are crosslinked by a chelated copper ion. Dissociation of the cupric carboxylate complex is negligible.

## ELECTRIC PROPERTIES

### Origin of Electric Charges

Particles can acquire charges from several sources. In *proteins*, one end group of the polypeptide chain and any aspartic and glutamic acid units contribute carboxylic acid groups, which are ionized into negatively charged carboxylate ions in neutral to alkaline media. The other chain end group and any lysine units contribute amino groups, while arginine units contribute guanidine groups, and histidine units contribute imidazole groups. The nitrogen atoms of these groups become protonated in neutral to acid media. These covalently attached anions and cations confer a negative and positive charge to the molecule, respectively. Therefore, proteins may be referred to as *polyelectrolytes* (polymeric electrolytes or salts). However, they are not the only organic polymers that contain ionic groups, and thus, many substances can be considered to be polyelectrolytes. For example, natural polysaccharides of vegetable origin such as acacia, tragacanth, alginic acid, and pectin contain carboxylic acid groups, which are ionized in neutral to alkaline media. Agar and carrageenan, as well as the animal polysaccharides heparin and chondroitin sulfate, contain sulfate groups, which are strongly acidic and ionize even in acid media. Cellulosic polyelectrolytes include *sodium carboxymethylcellulose*, while synthetic carboxylated polymers include *carbomer*, a copolymer of acrylic acid.

Counterions are required for electroneutrality of the ionizing groups on polyelectrolytes. Counterions dissociate from ionogenic functional groups and can be replaced by other ions of like charge. For example, in neutral and alkaline media,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Mg}^{2+}$  are among the counterions neutralizing the negative charges of the carboxylate groups, and if hydrochloric acid was used to make the medium acidic and to supply the protons,  $\text{Cl}^-$  is present to neutralize any of the cationic groups mentioned previously. These counterions are not an integral part of the protein particle but are located in its immediate vicinity. Alternatively, at a specific intermediate pH value (4.5–7 for most proteins), the carboxylate anions and the alkylammonium, guanidinium, and imidazolium cations on the same molecule neutralize each other exactly. There is no need for counterions, because the ionized functional groups are in exact balance. At this pH value, called the *isoelectric point*, the protein particle or molecule is neutral; its electrical charge is neither negative nor positive, but zero.<sup>2</sup>

Most inorganic particulate compounds are also charged. *Aluminum hydroxide*,  $\text{Al}(\text{OH})_3$ , can be dissolved by acids and alkalis to form aluminum ions,  $\text{Al}^{3+}$ , and aluminate ions,  $\text{Al}(\text{OH})_4^-$ , respectively. In neutral or weakly acid media (i.e., acid concentrations too low to cause dissolution), an aluminum hydroxide particle has some positive charges attributed to  $\text{Al}^{3+}$  valences that have not been completely neutralized. Figure 20-5A represents a portion of the surface of an aluminum hydroxide particle that has one such positive charge neutralized by a  $\text{Cl}^-$  counterion.

In weakly alkaline media (i.e., base concentrations too low to transform the aluminum hydroxide particles completely into aluminate and dissolve them), the aluminum hydroxide particles bear some negative charges due to the presence of a few aluminate groups. Figure 20-5B represents a portion of the surface of an aluminum hydroxide particle that has one such negative group neutralized by a  $\text{Na}^+$  counterion. At a pH of 8.5 to 9.1 there are neither  $\text{Al}(\text{OH})_2^+$  nor  $\text{Al}(\text{OH})_4^-$  ions on the particle surface but only neutral  $\text{Al}(\text{OH})_3$  molecules.<sup>10,11</sup> Therefore, the particles have no charge and do not need counterions for charge neutralization. This pH is considered to be the isoelectric point. In the case of inorganic particulate compounds such as aluminum hydroxide, it also is called the *zero point of charge*.

**Figure 20-5.** Schematic representation of a portion of the surface of an aluminum in a neutral or weakly acid media (A) or a weakly alkaline media (B).

*Bentonite* clay is a lamellar aluminum silicate. Each lattice layer consists of a sheet of hydrated alumina sandwiched between two silica sheets. Isomorphous replacement of  $\text{Al}^{3+}$  by  $\text{Mg}^{2+}$  or of  $\text{Si}^{4+}$  by  $\text{Al}^{3+}$  confers net negative charges to the thin clay lamellas in the form of cation-exchange sites resembling silicate ions built into the lattice. The counterions producing electroneutrality are usually  $\text{Na}^+$  (in sodium bentonite) or  $\text{Ca}^{2+}$  (in calcium bentonite).

*Silver iodide* sols can be prepared by the reaction:

In the bulk of the silver iodide particles, there is a 1:1 stoichiometric ratio of  $\text{Ag}^+$  ions to  $\text{I}^-$  ions. If the above reaction is carried out with an excess of silver nitrate, there will be more  $\text{Ag}^+$  ions than  $\text{I}^-$  ions in the surface layer of the particles. The particles will then be positively charged, and the counterions surrounding them will be  $\text{NO}_3^-$ . If the reaction is carried out using an exact stoichiometric 1:1 ratio of silver nitrate to sodium iodide or with an excess of sodium iodide, the surface of the particles will contain more  $\text{I}^-$  ions than  $\text{Ag}^+$  ions.<sup>1,2</sup> The particles will then be negatively charged, and the counterions surrounding them will be  $\text{Na}^+$ .

An additional mechanism through which particles acquire electric charges is by the adsorption of ions,<sup>1,2,12</sup> including ionic surfactants. This is discussed in more detail in a later section (Stabilization of Colloidal Systems).

### Electric Double Layers

As described previously, the surface layer of a silver iodide particle prepared using an excess of sodium iodide contains more  $\text{I}^-$  ions than  $\text{Ag}^+$  ions; in contrast, the bulk of the particle contains the two ions in an equimolar proportion. The aqueous solution in which such particles are suspended contains relatively high concentrations of  $\text{Na}^+$  and  $\text{NO}_3^-$ , a lower concentration of  $\text{I}^-$ , and traces of  $\text{H}^+$ ,  $\text{OH}^-$ , and  $\text{Ag}^+$ . The negatively charged particle surface attracts positive ions from the solution and repels negative ions. Therefore, the solution immediately surrounding the particle surface contains a much higher concentration of  $\text{Na}^+$  (counterions) and a much lower concentration of  $\text{NO}_3^+$  ions than in the bulk solution. A number of  $\text{Na}^+$  ions equal to the number of excess  $\text{I}^-$  ions in the surface (i.e., the number of  $\text{I}^-$  ions in the surface layer minus the number of  $\text{Ag}^+$  ions in the surface layer) and equivalent to the net negative surface charge of a particle are pulled toward its surface. These counterions tend to approach the particle surface as closely as their hydration spheres permit (Helmholtz double layer); however, thermal agitation of the water molecules tends to disperse them throughout the solution. Consequently, the layer of counterions surrounding the particle is spread out. The  $\text{Na}^+$

ion concentration is highest in the immediate vicinity of the negative surface, where the ions form a compact layer called the Stern layer. The  $\text{Na}^+$  ion concentration decreases with distance from the surface, throughout a diffuse layer called the Gouy-Chapman layer. Therefore, the sharply defined, negatively charged particle surface is surrounded by a cloud of  $\text{Na}^+$  counterions required for electroneutrality. The combination of the two layers of oppositely charged ions constitutes an electric double layer, which is illustrated in the top part of Figure 20-6.

The electric potential of a plane is equal to the work required to bring a unit electric charge from infinity (in this case, from the bulk of the solution) to that plane against electrostatic forces. If the plane is the surface of a particle, the potential is called surface or  $\psi_0$  potential, which measures the total potential of the double layer (Figure 20-5). This is the thermodynamic potential that operates in galvanic cells. Upon moving away from the particle surface toward the bulk solution in the direction of the horizontal axis, the potential drops rapidly across the Stern layer because the  $\text{Na}^+$  ions in the immediate vicinity of the particle surface screen  $\text{Na}^+$  ions that are farther removed in the diffuse part of the double layer from the effect of the negative surface charge. The decrease in potential across the Gouy-Chapman layer is more gradual. As the composition of the diffuse double layer gradually approaches that of the bulk liquid, where the anion concentration equals the cation concentration, the potential asymptotically approaches zero. In view of this

**Figure 20-6.** Electric double layer at the surface of a silver iodide particle (upper part) and the corresponding potentials (lower part). The distance from the particle surface, plotted on the horizontal axis, refers to both the upper and lower portions of the figure.

indefinite end point, the thickness of the diffuse double layer ( $\delta$ ) is arbitrarily defined as the distance over which it takes the potential at the boundary between the Stern and Gouy-Chapman layers to drop to 0.37 (equal to  $1/e$ ) of its value (Figure 20-6).<sup>1,2,5,12</sup> The thickness of double layers usually ranges from 1 to 100 nm and decreases as the concentration of electrolytes in solution increases. This occurs more rapidly for higher valence counterions. The value of  $\delta$  is approximately equal to the reciprocal of the Debye-Hückel theory parameter ( $\kappa$ ).

The electrokinetic or zeta potential ( $\zeta$ -potential) has practical importance, because it can be measured experimentally. In aqueous dispersions, organic particles containing polar functional groups, and even relatively hydrophobic inorganic particles, are surrounded by a layer of water of hydration, which is associated with the particles through ion-dipole and dipole-dipole interactions. When a particle moves, this shell of water and all of the ions located inside it move along with the particle. Conversely, if water or an aqueous solution flows through a fixed bed of these solid particles, the hydration layer surrounding each particle remains attached to it. The electric potential at the plane of shear or slip separating the bound water from the free water is the  $\zeta$ -potential. It does not include the Stern layer and includes only the part of the Gouy-Chapman layer that lies outside the hydration shell (Figure 20-6).

### Stabilization by Electrostatic Repulsion

When two uncharged hydrophobic particles are in close proximity, they attract each other by van der Waals secondary valences, mainly London dispersion forces. For individual atoms and molecules, these forces decrease with the seventh power of the distance between them. In the case of two particles, every atom of one particle attracts every atom of the other particle. Because the attractive forces are nearly additive, they decay much less rapidly with interparticle distance, approximately with the second or third power of the distance between them. Therefore, whenever two particles approach each other closely, the attractive forces take over and cause them to adhere. Coagulation occurs as the primary particles aggregate into increasingly larger secondary particles or flocs. If the dispersion consists of two kinds of particles, one having positive and the other negative charges, the electrostatic attraction between such oppositely charged particles is superimposed on the attraction by van der Waals forces and coagulation is accelerated. If the dispersion contains only one kind of particle with the same surface charge and charge density (the most common case), then electrostatic repulsion tends to prevent the particles from approaching closely enough to come within the effective range of each other's van der Waals attractive forces. This stabilizes the dispersion against interparticle attachments or coagulation. The electrostatic repulsive energy has a range in the order of  $\delta$ .

A quantitative theory of the interaction between lyophobic disperse particles was worked out independently by Derjaguin and Landau in the USSR and by Verwey and Overbeek in the Netherlands in the early 1940s.<sup>1,2,5</sup> The so-called DLVO theory (after the surnames of the four authors just mentioned) predicts and explains many, but not all, experimental data; its refinement to account for discrepancies is ongoing. The DLVO theory is summarized in Figure 20-7, where curve WA represents the van der Waals attractive energy, which decreases approximately by the second power of the interparticle distance, and curve ER represents the electrostatic repulsive energy, which decreases exponentially with interparticle distance. Because of the combination of these two opposing effects, attraction predominates at small and large distances; whereas repulsion may predominate at intermediate distances. Negative energy values indicate attraction, and positive values indicate repulsion. The resultant curve *DPBAS*, obtained by algebraic addition of curves WA and ER, gives the total, net energy of interaction between two particles.

Interparticle attraction depends mainly upon the chemical nature and particle size of the dispersed material. Once these

have been selected, the attractive energy between particles is fixed and cannot be readily altered. Electrostatic repulsion depends upon the  $\psi_0$  potential, or the density of the surface charge, and upon the thickness of the double layer, both of which govern the magnitude of the  $\zeta$ -potential. Thus, dispersion stability correlates to some extent with this potential. The  $\zeta$ -potential can be widely adjusted using additives, especially ionic surfactants, water-miscible solvents, and electrolytes. If the absolute value of the  $\zeta$ -potential is small, the resultant potential energy is negative and van der Waals forces of attraction predominate over electrostatic repulsion at all interparticle distances. Such sols coagulate rapidly.

The two identical particles, whose interaction is depicted in Figure 20-7, have a large (positive or negative)  $\zeta$ -potential, resulting in an appreciable positive or repulsive potential energy at intermediate distances. However, brownian motion, convection currents, sedimentation, or stirring of the dispersion will eventually put them on a collision course. As the two particles approach each other, the two counterion atmospheres begin to interpenetrate or overlap at point A, corresponding to the distance,  $d_A$ . This produces a net repulsive (positive) energy because of the work involved in distorting the diffuse double layers and pushing water molecules and counterions aside. If the particles continue to approach each other, the repulsion between their surface charges increases the net potential energy of interaction to its maximum positive value at B, where most of the intervening water and counterions have been displaced. If the height of the potential energy barrier  $B$  exceeds the kinetic energy of the approaching particles, they will not come any closer to each other than the distance  $d_B$  and will then move away from each other. A net positive potential energy of about  $25 kT$  units usually suffices to keep them apart and renders the dispersion stable ( $k$  is the Boltzmann constant and  $T$  is absolute temperature). At  $T = 298$  K, the required potential energy for stabilization corresponds to  $1 \times 10^{-12}$  erg or  $1 \times 10^{-5}$  J. The kinetic energy of a particle is of the order of  $kT$ .

**Figure 20-7.** Curves representing the van der Waals energy of attraction (WA), the energy of electrostatic repulsion (ER), and the net energy of interaction (DPBAS) between two identical charged particles, as a function of the interparticle distance.

On the other hand, if the kinetic energy of the approaching particles exceeds the potential energy barrier  $B$ , the particles will continue to approach each other past  $d_B$ , where the van der Waals forces of attraction become increasingly more important compared to the electrostatic repulsion. Therefore, the net potential energy of particle interaction decreases to zero and then becomes negative. This now pulls the particles closer together. When the particles touch, at a distance,  $d_P$ , the net energy has acquired a large negative value of  $P$ . This deep minimum in potential energy corresponds to a very stable situation in which the particles adhere. Because it is unlikely that enough kinetic energy can be supplied to the particles or that their  $\zeta$ -potential can be increased sufficiently to cause them to climb out of the potential energy well  $P$ , they are permanently attached to each other. When most or all of the primary particles agglomerate into secondary particles by this process, the sol coagulates. Any closer approach of the two particles than the touching distance  $d_P$  will cause a very rapid rise in potential energy along  $PD$  because the solid particles would interpenetrate each other and cause atomic orbitals to overlap (Born repulsion).

### Coagulation of Hydrophobic Dispersions

The height of the potential energy barrier and the range over which the electrostatic repulsion is effective (or the thickness of the double layer) determine the stability of hydrophobic dispersions. Both factors are reduced by the addition of electrolytes. The transition between a coagulating and a stable sol is gradual and depends upon the time of observation. Therefore, standardized conditions must be used to classify a sol as either coagulated or coagulating, or stable (i.e., fully dispersed).

To determine the coagulating concentration of a given electrolyte for a given sol, a series of test tubes is filled with equal portions of the sol. Identical volumes of electrolyte solutions having increasing concentrations are added to the test tubes with vigorous stirring. After a rest period of a certain duration (e.g., 2 hours), the mixtures are agitated again. After an additional, shorter rest period (e.g., 30 minutes) they are inspected for signs of coagulation. The tubes are then classified into two groups – one showing no signs of coagulation and the other showing at least some signs such as visible flocs. Alternatively, they can be classified into one group showing complete coagulation and another showing none or incomplete coagulation, such as some deflocculated colloid left in the supernatant. In either case, the separation between the two classes is quite sharp. The intermediate agitation breaks the weakest interparticle bonds and brings smaller particles into contact with larger ones, thus sharpening the distinction between coagulation and stability. After repeating the experiment with a narrower range of electrolyte concentrations, the coagulation value ( $ccv$ ) of the electrolyte (i.e., the lowest concentration at which the electrolyte coagulates the sol) is established with good reproducibility.<sup>1,2</sup>

Typical  $ccv$ 's for a silver iodide sol prepared with an excess of iodide are listed in Table 20-3. The following conclusions can be drawn from the left half of Table 20-3:

1. The  $ccv$  does not depend upon the valence of the anion. For example, nitrate and sulfate salts of the same metal have nearly identical  $ccv$ 's.
2. The differences between the  $ccv$ 's of cations having the same valence are relatively minor. However, there is a slight but significant trend of decreasing  $ccv$  with increasing atomic number in both the alkali and the alkaline earth metal groups. Arranging these cations in order of decreasing  $ccv$  produces the Hofmeister or lyotropic series in decreasing size of hydrated species. For monovalent cations, the lyotropic series is described above. The atomic weight of cesium is 19 times greater than that of lithium, but the  $Cs^+$  ion in aqueous solution is less hydrated and therefore smaller than the hydrated  $Li^+$  ion. It is also more polarizable. Therefore, the  $Cs^+$  ion can approach the surface of a negatively charged particle

suspended in water more closely and is more extensively adsorbed. This reduces its *ccv*, making cesium salts more effective coagulants than lithium salts for negatively charged hydrosols.

- The coagulation values depend primarily upon the valence of the counterions, decreasing by one to two orders of magnitude for each unit increase in the valence of the counterions (Schulze-Hardy rule). According to the DLVO theory, the coagulation values vary inversely with the sixth power of the valence of the counterions. For mono-, di-, and trivalent counterions, they should be in the ratio:

$$\frac{1}{1^6} : \frac{1}{2^6} : \frac{1}{3^6} \text{ or } 100 : 1.6 : 0.14$$

The mean *ccv*'s for the mono-, di-, and trivalent counterions in Table 20-3 are 141, 2.45, and 0.068 mmol/L, respectively. This results in a ratio of 100:1.7:0.05, which is in satisfactory agreement with the DLVO theory.

The following conclusions can be drawn from the right half of Table 20-3:

- The cations on the right side of Table 20-3 constitute obvious exceptions to the preceding conclusions.  $\text{Ag}^+$  is a potential-determining counterion (i.e., those whose concentration determines the surface potential). When silver nitrate is added to the negatively charged silver iodide dispersion, some of its silver ions are incorporated into the negatively charged surface of the particles. This lowers the magnitude of the particle's surface charge by reducing the excess of  $\text{I}^-$  ions in the surface. Therefore, silver salts are exceptionally effective coagulating agents because they reduce the magnitude of both the  $\psi_0$ -potential and the  $\zeta$ -potential. Indifferent salts, which only reduce the  $\zeta$ -potential, require much higher salt concentrations for comparable reductions in this potential. The other potential-determining ion of silver iodide is the  $\text{I}^-$  ion. Alkali iodides have *ccv*'s higher than 141 mmol/L because they supply iodide ions that enter the surface layer of the silver iodide particles and increase its excess of  $\text{I}^-$  ions over  $\text{Ag}^+$  ions, thereby making the  $\psi_0$ -potential more negative. Bromide and chloride ions act similarly but less effectively. The principal potential-determining ion for proteins is  $\text{H}^+$  (and hence  $\text{OH}^-$ ); those for aluminum hydroxide are  $\text{OH}^-$  (and hence  $\text{H}^+$ ) and,  $\text{Al}^{3+}$  as well as  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$ , which form mixed hydroxides with  $\text{Al}^{3+}$ .
